Final Safety Evaluation Report Related to Certification of the AP1000 Standard Plant Design
Docket No. 52-006

NUREG-1793
Supplement 2

Division of New Reactor Licensing
Office of Nuclear Reactor Regulation
U.S. Nuclear Regulatory Commission
Washington, DC 20555-0001

ABSTRACT

This report supplements the final safety evaluation report (FSER) for the AP1000 standard plant design. The FSER was issued by the U.S. Nuclear Regulatory Commission (NRC) as NUREG-1793 in September 2004, and NUREG-1793 Supplement 1 in December 2005, to document the NRC staff's technical review of the AP1000 design. The application for the AP1000 design was submitted on June 28, 2002, by Westinghouse Electric Corporation (Westinghouse) in accordance with Subpart B, "Standard Design Certifications," of Title 10 of the *Code of Federal Regulations* (10 CFR) Part 52, and Appendix 0, "Standardization of Design: Staff Review of Standard Designs." This supplement documents the NRC staff's review of Westinghouse's changes to the AP1000 design documentation in the design control document (DCD) since the issuance of Supplement 1 of the FSER. On the basis of the evaluation described in the AP1000 FSER (NUREG-1793, NUREG-1793 Supplement 1) and this report, the NRC staff concludes that the changes to the DCD (up to and including Revision 19 to the AP1000 DCD) are acceptable and that Westinghouse's application for design certification meets the requirements of Subpart B to 10 CFR Part 52 that are applicable and technically relevant to the AP1000 standard plant design.

CONTENTS

1. INTRODUCTION AND GENERAL DISCUSSION

1.1 Introduction

Supplement 2 to NUREG-1793, "Final Safety Evaluation Report Related to the Certification of the AP1000 Standard Design," addresses a revision to the AP1000 design control document (DCD) to reflect design changes submitted by Westinghouse Electric Company (the applicant) after the U.S. Nuclear Regulatory Commission (NRC) certified the design in Appendix D, "Design Certification Rule for the AP1000 Design," to Title 10 of the *Code of Federal Regulations* (10 CFR) Part 52, "Licenses, certifications, and approvals for nuclear power plants." The current review involves an amendment to the AP1000 design certification (DC), as documented in proposed changes to the AP1000 DCD through Revision 19.

Background

The certified AP1000 design, addressed in Appendix D to 10 CFR Part 52, has a nuclear steam supply system (NSSS) power rating of 3,415 megawatts thermal (MWt), with an electrical output of at least 1,000 megawatts electric (MWe). Prior to approval of the DC amendment, Revision 15 of the AP1000 DCD documented the approved design; NUREG-1793, issued September 2004, and Supplement 1, issued December 2005, documented the NRC staff's approval of this design.

From March 2006 through May 2007 (the preapplication period), NuStart and the applicant provided the NRC with technical reports (TRs) for preapplication review in an effort to: (1) close specific, generically applicable COL information items in the AP1000 certified standard design; (2) identify standard design changes resulting from the AP1000 detailed design efforts; and (3) provide specific standard design information in areas or for topics where the AP1000 DCD was focused on the design process and acceptance criteria. Appendix H, "Technical Reports," to this report includes a list of these TRs. The TRs include proposed revisions to the DCD and supporting information providing the basis for acceptability of the changes.

The application submitted on May 26, 2007, which transmitted Revision 16 to the DCD, was also supplemented by letters dated October 26, November 2, and December 12, 2007, and January 11 and January 14, 2008. The staff notified the applicant, in a letter dated January 18, 2008, that it accepted the May 26, 2007, application, as supplemented, for docketing. The January 18, 2008, letter included a *Federal Register* Notice (FRN) that provided public notification that the NRC had accepted the May 26, 2007, application, as supplemented, for docketing and that a future *Federal Register* Notice would provide an opportunity to comment on the proposed rulemaking.

In a letter dated September 22, 2008, the applicant submitted Revision 17 to the AP1000 DCD. The staff's review also included other design changes identified by the applicant following submittal of Revision 17, associated with Interim Staff Guidance (ISG) DC/COL-ISG-11, "Interim Staff Guidance Finalizing Licensing-basis Information," as detailed in Section 1.15, herein. On December 1, 2010, the applicant submitted Revision 18 to the DCD. Revision 18 incorporated the ISG design changes as well as the DCD changes to resolve confirmatory items from the Advanced Final Safety Evaluation (AFSE). Revision 19, submitted on June 13, 2011, includes additional DCD changes resulting from the staff's review of Revision 18. Revision 19 is a complete DCD and includes the relevant information from the certified design (Revision 15) that was not modified by subsequent revisions, and the net result of the changes from Revision 16 to 17 to 18 to 19.

Since this is a supplement to the previous safety evaluation report (SER), the staff's review of the application was based on the proposed changes included in Revisions 16 through 19 of the DCD. Material from Revision 15 and earlier is evaluated in the original NUREG-1793 or Supplement 1. This SER supplement is applicable to Revision 19 of the DCD, which is the revision intended for certification in the final rule. Individual SER sections may refer to specific revisions other than Revision 19 depending on the context; however, if information was added in Revisions 16, 17 or 18 and was not further modified, it is part of Revision 19.

1.1.1 Metrication

This report conforms to the Commission's policy statement on metrication published in the FR on June 19, 1996. Therefore, measures are expressed as metric units, followed by English units in parentheses. An example of a typical conversion would be as follows: The unit of air volume flow is measured in standard cubic meters per second (m^3/s) at 101 kilopascal (kPa) and 20 °Celsius (C) (standard cubic feet per minute (ft^3/min) at 14.7 pounds-force per square inch absolute (psia) and 68 °Fahrenheit (F).

1.1.2 Proprietary Information

This report references Westinghouse reports. Some of these reports and communications include information that the applicant requested be exempt from public disclosure, as provided by 10 CFR 2.390, "Public inspections, exemptions, requests for withholding." For each such report, the applicant provided a nonproprietary version, similar in content except for the omission of the proprietary information. The staff based its findings on the proprietary versions of these documents, which are those primarily referenced throughout this report. Table 1.6-1 of Chapter 1, Tier 2, of the DCD lists all of the proprietary reports referenced that are viewed as part of the licensing basis for the AP1000 design.

Within certain chapters of this report, the staff needed to present proprietary information for completeness. In these chapters, the proprietary information was subsequently redacted in order to make this report publicly available but references are provided to the proprietary version of the chapter for those individuals permitted to review the proprietary information.

1.1.3 COL Applicants Referencing the AP1000 Design

Future applicants referencing the AP1000 standard design for specific facilities will retain architect-engineers, constructors, and consultants, as needed. As part of its review of an application for a combined license (COL) referencing the AP1000 design, the staff will evaluate, for each plant-specific application, the technical competence of the COL applicant and its contractors to manage, design, construct, and operate a nuclear power plant. COL applicants will also be subject to the requirements of 10 CFR Part 52, Subpart C, "Combined Licenses," and any requirements resulting from the staff's review of this standard design. Throughout the DCD, the applicant identified matters to be addressed by plant-specific applicants as "combined license information." This report generally refers to such matters as "COL action items" throughout (see also Section 1.9 below).

1.1.4 Additional Information

Parts of the DCD include summary tables (e.g., Introduction Table 1-1, Tables 1.6-1, 1.8-2, Appendix 1A of Chapter 1 of Tier 2) and drawings (e.g., figures in Section 1.2, Tier 2) that reflect proposed changes in the DCD to conform to changes in other chapters. Determinations about acceptability of those changes depend on conclusions to be documented in other chapters of the final safety evaluation report (FSER).

This FSER includes appendices to assist the reader. Appendix A provides a preapplication chronology of the principal actions, and submittals related to the processing of the AP1000 application; and Appendix B provides the post-application chronology. Appendix C of this report includes a list of references for the FSER; Appendix D lists the definitions of the acronyms and abbreviations; Appendix E lists the principal technical reviewers who evaluated the amendment to the AP1000 design; Appendix F provides an index of the applicant's technical reports (TRs); and Appendix G provides an index of the applicant's responses to requests for additional information (RAIs). Appendix H of this report includes a copy of the letters received from the Advisory Committee on Reactor Safeguards providing the results of its review of the safety evaluation chapters.

The NRC licensing project managers assigned to the AP1000 DC amendment review are Perry Buckberg and David H. Jaffe (Lead Project Managers), William Gleaves, Sikhindra Mitra, Phyllis Clark, Patrick Donnelly, Brian Anderson, and Terri Spicher. They may be reached by calling (301) 415-7000 or by writing to the U.S. Nuclear Regulatory Commission, Office of New Reactors, Washington, DC 20555-0001.

1.2 General Design Description

The DCD through Revision 19 includes a complete description of the AP1000.

1.3 Comparison with Similar Facility Designs

The AP1000 standard design includes many features that are not found in the designs of currently operating reactors. For example, a variety of engineering and operational improvements provides additional safety margins and addresses Commission policy statements regarding severe accidents, safety goals, and standardization. The most significant improvement to the design is the use of safety systems for accident prevention and mitigation that rely on passive means, such as gravity, natural circulation, condensation and evaporation, and stored energy. DCD Tier 2, Table 1.3-1, "AP1000 Plant Comparison with Similar Facilities," provides a detailed comparison of the principal design features of the AP1000 standard design with the certified AP600 design and a typical two-loop plant.

1.4 Summary of Principal Review Matters

The matters under review as part of the DC amendment process were mainly determined by the application. The DCD associated with the DC amendment identified changes, subject to review, by marginal lines. The remaining DCD text was from Revision 15 to the DCD and represented the unchanged elements of the DC of record referenced in Appendix D to 10 CFR Part 52. The staff did not repeat the review of the unchanged elements of Revision 15 to the DCD, in accordance with 10 CFR 52.63, "Finality of standard design certifications."

Examples of significant design changes include the following:

- extension of seismic spectra to soil conditions
- revisions to buildings for enhanced protection (such as for aircraft impact)
- protection system instrumentation update
- revisions to the electrical system (additional auxiliary transformer; change in direct current (dc) voltage)
- turbine manufacturer change
- sump screen design and analysis
- control room ventilation system
- increased assembly capacity in the spent fuel pool (SFP) (change in rack design)
- updated load handling systems
- additional waste-water monitor tanks
- integrated head package (IHP) revision
- revision to loss-of-coolant accident (LOCA) methods
- reactor internal changes (flow skirt addition)
- pressurizer shape change
- reactor coolant pump design
- addition of containment vacuum relief system
- completion of human factors engineering commitments
- revision to closure logic for component cooling system isolation
- reactor vessel structural support

The subjects in Supplement 2 to NUREG-1793 are organized in the same manner as NUREG-1793, which generally conforms to the organization of NUREG-0800, "Standard Review Plan for the Review of Safety Analysis Reports for Nuclear Power Plants." The only exception is Chapter 23, which documents the review of changes submitted late in the review process of design changes not prompted by NRC review activities. The absence in Supplement 2 to NUREG-1793 of a section that appeared in NUREG-1793 indicates that the staff did not repeat the review of this material as part of the DC amendment process because there were no DCD changes that affected its content.

1.5 Requests for Additional Information

RAIs are questions asked of the applicant by the staff concerning the application. The NRC sent the questions to the applicant by e-mail, and the applicant responded in letters to the NRC.

The nomenclature for RAIs concerning TRs took one of the following two forms:

- TRXX-YY, where XX was the TR number and YY was the RAI sequence number.

- TRXX-ABREV-YY, where ABREV was the abbreviation of the NRC review organization that initiated the question.

In early 2008, the staff began its review of the application using NUREG-0800. It then added the RAI designation RAI-SRPZ.ZZ-ABREV-YY, where Z.ZZ was the NUREG-0800 section number.

1.6 Open Items

In many cases, the applicant's responses to the RAIs resulted in the RAIs being closed in that the information that was provided was sufficient to resolve the issue. In those cases where the responses to the RAIs did not resolve the issue, the staff created an "Open Item [OI]" using the same conventions as used for RAIs with the prefix OI replacing the prefix RAI. The staff then issued a "Safety Evaluation with Open Items" for chapters of this report.

1.7 Confirmatory Items

Following issuance of the safety evaluation with open items, the applicant responded to the open items and all open items were resolved. Where information to resolve the open item would be in Revision 18 to the DCD (or a future activity by the applicant or the staff), the staff created a "Confirmatory Item" using the same conventions as used for open items with the prefix CI replacing the prefix OI. The staff then issued a safety evaluation with confirmatory items, also referred to as an AFSE for each chapter. Upon receipt of Revision 18 to the DCD, the staff confirmed that the information required to resolve the confirmatory items was in Revision 18 to the DCD or, where necessary, in Revision 19. The staff is issuing the final SER as Supplement 2 to NUREG-1793 which removes discussion about the resolved confirmatory items.

1.8 Index of Exemptions

There are no exemptions associated with the DC amendment; the exemptions that were part of the initial certification remain in effect.

1.9 COL Information Items

COL applicants and licensees referencing the certified AP1000 standard design must satisfy the requirements and commitments identified in the DCD. The AP1000 DCD identifies certain general commitments as "combined license information items." The COL information items are tabulated in Table 1.8-2 of the DCD, Tier 2. These COL information items relate to programs, procedures, and issues that are outside the scope of the certified design review. These COL information items do not establish requirements; rather, they identify an acceptable set of information to be included in a plant-specific safety analysis report. An applicant for a COL must address each of these information items in its application. An applicant may deviate from or omit these information items, provided that the deviation or omission is identified and justified in the plant-specific safety analysis report. As noted earlier, several of the DCD changes proposed in this amendment are for the purpose of responding, within the DCD, to COL information items from the original certification, so that no further action by a COL applicant would be necessary. In its evaluations, the staff may refer to these as COL action items, as was done in the original NUREG-1793. The DCD refers to these items as COL information items.

1.10 Technical Reports

The applicant submitted TRs for more than a year before providing the DC amendment application. The main purpose of the TRs was to provide the basis for proposed changes to the AP1000 DCD, and most TRs included marked-up DCD pages to show where these proposed changes would occur. TR-134, "AP1000 DCD Impacts to Support COLA Standardization," APP-GW-GLR-134, through Revision 5, followed the submittal of Revision 16 to the AP1000 DCD. The purpose of TR-134 was to show the cumulative changes to the DCD, following Revision 16, from all sources, including the submittal of and changes to TRs (and similar documents referred to as "impact reports") and responses to RAIs.

1.11 Criteria of 10 CFR Part 52, Section 52.63(a)(1)

In 2007, the Commission was involved in rulemaking in 10 CFR Part 52. The rulemaking included a new 10 CFR 52.63, which would provide criteria for a rulemaking to amend a DC. The rule in 10 CFR 52.63(a)(1) states in part:

> …the Commission may not modify, rescind, or impose new requirements on the certification information, whether on its own motion, or in response to a petition from any person, unless the Commission determines in a rulemaking that the change:
>
> (i) Is necessary either to bring the certification information or the referencing plants into compliance with the Commission's regulations applicable and in effect at the time the certification was issued;
>
> (ii) Is necessary to provide adequate protection of the public health and safety or the common defense and security;
>
> (iii) Reduces unnecessary regulatory burden and maintains protection to public health and safety and the common defense and security;
>
> (iv) Provides the detailed design information to be verified under those inspections, tests, analyses, and acceptance criteria (ITAAC) which are directed at certification information (i.e., design acceptance criteria);
>
> (v) Is necessary to correct material errors in the certification information;

(vi) Substantially increases overall safety, reliability, or security of facility design, construction, or operation, and the direct and indirect costs of implementation of the rule change are justified in view of this increased safety, reliability, or security; or

(vii) Contributes to increased standardization of the certification information.

These criteria, items (i) through (vii) above, were adopted as part of the final rule for 10 CFR Part 52, on August 28, 2007.

In revising the DCD, the applicant proposed numerous changes to the AP1000 design, including, but not limited to, minor component design details, replacement of a design feature with another having similar performance (e.g., turbine manufacturer, power for the auxiliary boiler), and changes allowing additional capability for operational flexibility (e.g., liquid waste holdup tanks, unit reserve transformer). The applicant included in its application a detailed list of each DCD content change and the basis under 10 CFR 52.63(a)(1) that supported including that change in the amendment. The staff considered these bases and formed its own judgment on applicability of the criteria to the changes under review. More than one criterion may be satisfied for any particular change; it is only necessary that one criterion be met to support inclusion in the amendment in accordance with 10 CFR 52.63. In a few instances, the staff concluded that none of the criteria were met and thus rejected inclusion of those changes. For those changes remaining in the scope of the amendment, the NRC concluded that at least one of the criteria in 10 CFR 52.63(a) is met and therefore did not constitute a violation of the finality provisions in that section.

The proposed rule includes a list of the changes to the DCD that the staff considers to be the most significant, the location in this SER where the change is evaluated and the principal criterion in 10 CFR 52.63(a)(1) that was cited as the basis for the change. Due to the significance of these particular changes, the NRC addressed the criteria of 10 CFR 52.63(a)(1) in detail in the proposed rule notice. Most of these changes cited criterion (vii) “contributes to increased standardization of the certification information.” The NRC further stated that increased standardization is realized through changes that are included in the amendment and incorporated by reference and, therefore, do not need to be handled as departures by each of the COL applicants. Other changes that provide more detailed information within the DCD (as for instance where a COL information item was resolved) also contribute to increased standardization.

For other changes evaluated in the SER, the finality criteria are addressed in varying degrees of detail in the notice and in this report.

1.12 DCD Editorial Changes and Changes for Consistency

The applicant has proposed numerous changes to the DCD that can be categorized as editorial changes or changes for consistency as follows:

- Editorial changes correct a spelling, punctuation, or similar error and result in text that has the same essential meaning; these changes are not subject to a safety evaluation.

- Changes for consistency must be made to the text in one or more instances to achieve uniformity. These changes require a safety evaluation, which is located in the SER where the subject is normally addressed via NUREG-0800 (e.g., a change to the type of reactor coolant pump motor is evaluated in Chapter 5 of this report; however, for consistency, a change to the description of the motor is needed elsewhere in the DCD, where the type of motor is described).

The revision change roadmap in the front of Revisions 16 through 19 shows the specific pages in the DCD where such changes were made.

Editorial changes to the DCD do not require a safety evaluation because they do not result in a change to any regulatory requirement. In accordance with 10 CFR 52.63(a)(1)(vii), these proposed changes are acceptable, since they contribute to standardization by making these changes on an individual basis unnecessary for subsequent COL applicants. Changes that generated additional changes that were needed for consistency are acceptable for reasons described in this safety evaluation in sections where these subject matters are normally addressed via NUREG-0800. Internal consistency in the DCD is needed so that it is an accurate document, and thus the conforming changes are acceptable.

1.13 Editorial Format Changes Related to COL Applicant and COL Information Items

In a letter dated June 6, 2007, the applicant submitted TR-130, "Editorial Format Changes Related to Combined License Applicant and Combined License Information Items," APP-GW-GLR-130, Revision 0. The revision change roadmap located in the front of Revision 16 shows the specific pages in the DCD where such changes were made. TR-130 proposed two classes of changes to the DCD:

- Editorial Format Changes Related to Combined License Applicant. In sections of the DCD that refer to a COL applicant's or COL holder's commitments (other than "Combined License Information" sections), the reference to a COL applicant or COL holder is deleted and replaced by a reference to the DCD section where the commitment is discussed. Certain sections in DCD Chapters 2 and 14 have not been changed, in this regard, as described in TR-130. The staff has reviewed these proposed DCD changes described in TR-130 and concludes that no changes to COL applicant or COL holder commitments result from the proposed changes, since the statement of the COL information items remains unchanged. Since the proposed changes add useful information, by referencing the DCD section that discusses the commitments, the overall result is an improvement in the usability of the DCD.

- Editorial Format Changes Related to Combined License Information Items. It has been the applicant's practice, when closing COL information items, to simply note that the item is "completed" when the commitment has been satisfied. In TR-130, the applicant has proposed adding information to the statement of the COL information items indicating how the commitment was completed (e.g., by identifying a Westinghouse document) and what tasks, if any, remain to be accomplished by the COL applicant or holder. Similar information would also be added to DCD, Tier 2, Table 1.8-2, "Summary of AP1000 Standard Plant Combined License Information Items." The staff has reviewed these proposed DCD changes described in TR-130 and concludes that no changes to COL applicant or COL holder commitments result from the proposed changes. Useful information is added to show how commitments were satisfied and what, if anything, is still needed to satisfy the remaining commitments. Since the proposed changes add useful information, the overall result is an improvement in the usability of the DCD.

In accordance with 10 CFR 52.63(a)(1)(vii), these proposed changes are acceptable, since they contributed to standardization by making these changes unnecessary for subsequent COL applicants.

1.14 Severe Accident Mitigation Design Alternatives

In 10 CFR 51.55(b), "Environmental report—construction permit, early site permit, or combined license stage," the NRC requires each applicant for an amendment to a DC to submit a separate document entitled, "Applicant's Supplemental Environmental Report—Amendment to Standard Design Certification." The environmental report must address whether the design change that is the subject of the proposed amendment either causes a severe accident mitigation design alternative (SAMDA) previously rejected in an environmental assessment to become cost-beneficial, or results in the identification of new SAMDAs that may be reasonably incorporated into the DC. In a letter dated September 21, 2007, the applicant submitted TR-135, "AP1000 Design Change Proposal Review for PRA and Severe Accident Impact," APP-PRA-GER-001, Revision 0. In TR-135, the applicant documented the review of all design-change proposals approved since the DC and evaluated their potential impact on the AP1000 probabilistic risk assessment (PRA). The staff has reviewed TR-135 and supplemental letters dated October 26 and November 9, 2010, and concludes that these design changes have no significant impact on the results of the AP1000 PRA. Chapter 19 presents the staff's review of changes to the PRA. Consequently, the AP1000 SAMDA analyses remain valid: none of the previously evaluated SAMDAs is cost-beneficial. No new SAMDAs have been identified.

Based upon the above, the staff concludes that the applicant has complied with the requirements of 10 CFR 51.55(b) with regard to the application to amend the DC for the AP1000.

1.15 Changes to Regulatory Guides and Criteria

The applicant has submitted the following two TRs that, together, describe changes in the AP1000 DCD related to conformance to regulatory guides (RGs), Three Mile Island (TMI) issues, unresolved safety issues and generic safety issues, and advanced light-water reactor (LWR) certification issues since Revision 15:

- TR-129, "Changes to Conformance with Regulatory Guidance and Criteria," APP-GW-GLN-129, issued June 2007

- TR-141, "Regulatory Guide Conformance Changes," APP-GW-GLN-141, issued October 2007

Conformance to RGs, TMI issues, unresolved safety issues and generic safety issues, and advanced LWR certification issues are addressed in DCD, Tier 2, Sections 1.9.1 (and Appendix 1A), 1.9.3, 1.9.4 and 1.9.5, respectively.

TR-129 also proposes to add COL Information Item 1.9-1 to DCD, Tier 2, Table 1.8-2, “Summary of AP1000 Standard Plant Combined License Information Items,” and a new DCD, Tier 2, Section 1.9.1.5, “Combined License Information,” as follows:

> The Combined License applicant will address conformance with regulatory guides that are not applicable to the certified design or not addressed by the activities required by COL information items.

The list of RGs proposed by the applicant, as shown in Table 1.15-1, is the subject of proposed COL Information Item 1.9-1. COL applicants may supplement the list of RGs in Table 1.15-1 as needed. In addition, as part of an RAI, the staff may request COL applicants to address one or more additional RGs; otherwise, the staff finds the proposed COL information item to be acceptable, in accordance with 10 CFR 52.63(a)(1)(vii), in that it contributes to standardization by making it unnecessary for individual COL applicants to request the associated changes.

DCD, Tier 2, Table 1.9-1, “Regulatory Guides/DCD Section Cross-References,” and Appendix 1A discuss details regarding conformance to RGs, including the changes proposed by TR-129 and TR-141 and as a result of other design changes. NUREG-1793, Chapter 1, did not present an evaluation of the applicant’s conformance to RGs with regard to the AP1000 and, similarly, no evaluation is presented herein regarding changes to these positions in this tabular form. Conformance to RGs is evaluated in the specific sections of the SER where the DCD material concerning the RG is discussed. For example, RG 1.82, Revision 3, “Water Sources for Long-Term Recirculation Cooling Following a Loss-of-Coolant Accident” is discussed in DCD Section 6.2.2 and evaluated in Section 6.2.1.8 of this report.

Table 1.15-2 includes a list of changes to regulatory criteria (TMI issues, unresolved safety issues and generic safety issues, and advanced LWR certification issues) where the changes proposed in TR-129 and TR-141 are editorial, are required for consistency with proposed changes elsewhere in the DCD, or provide additional useful information. These proposed changes have no impact on safety-related structures, systems, components (SSCs), or other design aspects and are acceptable, in accordance with 10 CFR 52.63(a)(1)(vii), in that they contribute to standardization by making it unnecessary for individual COL applicants to request the associated changes.

Finally, Table 1.15-3 includes changes to regulatory criteria that are addressed elsewhere in this SER and indicates the location in this report. Also, the location of the staff’s evaluation as documented in the SER is indicated in Table 1.15-3.

1.16 Design Changes Proposed in Accordance with Interim Staff Guidance (ISG)-11

DC/COL-ISG-11 describes the staff position regarding the control of licensing-basis information during and following the initial review of applications for DCs. It describes the categories of design changes that applicants should not defer until after the issuance of the DC rule. These criteria are presented in Chapter 23 of this report.

Chapter 23 addresses new design changes, proposed in accordance with DC/COL-ISG-11 that were then included in Revision 18 of the AP1000 DCD. The design changes that are evaluated in Chapter 23 do not constitute all of the changes that the applicant included in DCD, Revision 18. Rather, the design changes evaluated in Chapter 23 are in addition to those that the applicant has submitted to the NRC as a part of responses to RAIs or SER open items.

Organizationally, Chapter 23 is different from other SER chapters in that these design changes consider all aspects of a design together (i.e., electrical, instrumentation and control (I&C), piping, etc.) in one section rather than including various aspects of a design in separate chapters. Those who use this SER should also refer to Chapter 23 in that the analyses included therein supplement the analyses found elsewhere in this report.

1.17 Tier 2* Information

Information designated as Tier 2* (Tier 2 Information Requiring NRC Approval for Change) is identified in the DCD by brackets, italics, and a footnote noting that prior NRC approval is needed for any departure from that information. It is also summarized in Table 1-1 of the DCD. The rule text in Appendix D to 10 CFR Part 52 lists the topic areas with Tier 2* information. During the review of the amendment request, some changes to the material designated as Tier 2* occurred, as summarized below.

In DCD Chapter 3, “Design of Structures, Components, Equipment and Systems,” Sections 3.8 and Appendix 3H, as originally certified, considerable information about critical sections of the structures was designated as Tier 2*. This included load combinations, specific analytical results (loads and moments), and resultant structural reinforcement thicknesses. The staff determined that having Tier 2* designation on analytical results (with several significant digits) was unduly restrictive. As a result, the DCD tables with Tier 2* information were revised to retain the designation on loads and reinforcements (with some tolerance), but removed the results from the scope of Tier 2*. The rule text did not change for this reason.

In addition, the staff determined that other structural information about aspects of the design, such as the shield building and containment penetrations, should be designated as Tier 2*. Multiple locations in Section 3.8 and Appendix 3H are now so marked (and listed in Table 1-1 of the DCD Introduction). In addition, a referenced technical report (GLR-602) that includes proprietary information about the shield building also has Tier 2* information (see Table 1.6-1 of the DCD). Conforming changes to the final rule language will be made as needed to include the type of information in the sections of the rule that identify Tier 2* information. The Tier 2* designation for these structural details would expire at first full power.

The staff requested that the applicant add Tier 2* designation to the specification of the reactor coolant pump (RCP) characteristics, a new Tier 2* item that does not expire. This information appears in DCD Chapter 5, “Reactor Coolant System and Connected Systems,” and it was added to Table 1-1 of the Introduction. A new item was included in the proposed rule to reflect this change.

In Revision 15 of the AP1000 DCD (Sections 3.8.2.2 and 5.2.1.1), the specific Edition and Addenda of the American Society of Mechanical Engineers (ASME) Boiler and Pressure Vessel Code, Section III were designated as Tier 2* information. At the time of the initial DC, the staff accepted the 1998 Edition up to and including the 2000 Addenda of the ASME Code, Section III (except for piping design, which uses the 1989 Edition including the 1989 Addenda) as Tier 2* to ensure that the ASME Code, Section III piping seismic design rules that the staff did not fully accept would not be used for completing the AP1000 piping design without first obtaining NRC approval. The NRC issued a final rule amending 10 CFR 50.55a, “Codes and standards,” (64 FR 51370 dated September 22, 1999) that included a condition in 10 CFR 50.55a(b)(1)(III), “Seismic design of piping,” prohibiting the use of these piping seismic design rules that first appeared in the 1994 Addenda of the ASME Code, Section III. This limitation remained in effect and applicable up to and including the 2004 Edition (referenced in 10 CFR 50.55a). As a result of the NRC establishing the limitation in 10 CFR 50.55a(b)(1)(III) prohibiting those portions of the ASME Code, Section III related to revised seismic design rules, the need to designate the specific Edition and Addenda of the ASME Code, Section III as Tier 2* became redundant and unnecessary. However, the NRC is requiring that certain DCD provisions, related to piping design that was already marked as Tier 2*, remain with that designation.

For design of components as discussed in DCD Section 5.2.1.1, the staff concluded that the Tier 2* designation was not necessary for the specific ASME Code Edition and Addenda, as listed in Item VIII.B.6.c (2) of Appendix D to 10 CFR Part 52. Subsequent to the certification, 10 CFR 50.55a was modified to include provisions in paragraphs (c)(3), (d)(2) and (e)(2), for reactor coolant pressure boundary (RCPB), Quality Group B components, and Quality Group C components, respectively. These paragraphs provide the controls on use of later Edition/Addenda to the ASME Code, Section III through the conditions NRC established on use of paragraph NCA-1140 of the ASME Code. As a result, these rule requirements would adequately control the ability of a licensee to use a later Edition of the ASME Code and Addenda, such that the Tier 2* designation is not necessary for components. Thus, the item in VIII.B.6.c (2) for the ASME Code was proposed to be modified in the proposed rule to be more limited in scope. In addition, Item VIII.B.6.c (2) now also refers to ASME Code cases; Table 5.2-3 of the DCD lists the applicable Code cases and which ones are Tier 2*.

The NRC is retaining the Tier 2* designation for the ASME Code Edition applicable to containment design in VIII.B.6.c (14). The designation of the Edition and Addenda of the ASME Code, Section III, for completing the construction of the AP1000 steel containment is Tier 2.

The ACRS review highlighted the significance of certain assumptions about debris in containment to the adequacy of long-term core cooling, and a concern that the values not be revised with substantial additional testing and analysis. As a means of emphasizing this, the applicant proposed to designate the key information as Tier 2*, to require prior NRC approval, in a letter dated February 23, 2011. This change is included in Revision 19. The NRC agrees that this is a prudent change and will modify the final rule language to reflect this addition, as a Tier 2* item without expiration at fuel load.

The staff requested that the applicant revise the Tier 2* expiration for human factors engineering in DCD Chapter 18, “Human Factors Engineering,” from no expiration to expiration at initial power operation. The rule item thus was proposed to be moved from paragraph VIII.B.6(b) to VIII.B.6(c) in the proposed rule.

The changes in Tier 2* information described above have been incorporated in Revision 19 to the DCD.

Table 1.15-2. Changes to Regulatory Criteria (Changes are Editorial, Required, or Provide Additional Useful Information)

Item	Issue	Acceptability
1	Revise Footnote f. to Table 1.9-2	Editorial format changes related to Combined License applicant
2	Revise the response to 1.9.3, (2)(i), Simulator Capability (NUREG-0933, Item I.A.4.2)	Same as Item 1
3	Revise the response to 1.9.3, (2)(ii), Plant Procedures (NUREG-0933, Item I.C.9)	Same as Item 1
4	Revise the response to 1.9.3, (2)(xxv), Emergency Response Facilities (NUREG-0737, Item III.A.1.2)	Same as Item 1
5	Revise the response to 1.9.3, (3)(vii), Management Plan (NUREG-0933, Item II.J.3.1)	Same as Item 1
6	Revise the response to 1.9.4.2.3, II.K.1(10), Review and Modify Procedures for Removing Safety-related Systems from Service	Same as Item 1
7	Revise the final paragraph of the response to A-31, Residual Heat Removal Requirements	Same as Item 1
8	Revise the response to 1.9.4.2.3, Issue 79, Unanalyzed Reactor Vessel Thermal Stress During Natural Convection Cooldown	Same as Item 1
9	Revise the final paragraph of the response to 1.9.4.2.3, Issue 113, Dynamic Qualification Testing of Large-Bore Hydraulic Snubbers	Same as Item 1
10	Revise the ninth bullet under Task 3 of the response to 1.9.4.2.3, Issue 135, Integrated Steam Generator Issues	Same as Item 1
11	Revise the sixth bullet of the response to 1.9.5.1.5, Station Blackout	Same as Item 1
12	Revise the response to 1.9.5.1.15, In-Service Testing of Pumps and Valves	Same as Item 1
13	Revise the response to 1.9.5.2.6, Tornado Design Basis	Same as Item 1
14	Revise the response to 1.9.5.3.7, Simplification of Off-Site Emergency Planning	Same as Item 1
15	Revise Section 1.9.6, References	Same as Item 1

Table 1.15-3. Changes to Regulatory Criteria (Addressed Elsewhere in this SER)

Items	Issues	Addressed in SER
1	Revise reference to QME testing standard in Issue 87	Section 3.9.6
2	Revise the response to 1.9.4.2.3, Issue 103, Design for Probable Maximum Precipitation	Sections 2.4.3 and 2.4.4
3	Revise 1.9.4.2.3, Issue 191, Assessment of Debris Accumulation on PWR Sump Performance	Section 6.2.1.8
4	Revise 1.9.4.2.4, HF4.4, Guidelines for Upgrading Other Procedures	Section 13.5
5	Revise the ninth bullet of the response to 1.9.5.1.5, Station Blackout	Section 8.3.1.2
6	Revise the response to 1.9.5.2.14, Site-Specific Probabilistic Risk Assessments (PRAs)	Section 19.1.5

2. SITE ENVELOPE

2.2 Nearby Industrial, Transportation, and Military Facilities

2.2.1 Introduction

AP1000 design control document (DCD) Section 2.2.1 states that the combined license (COL) applicants referencing the AP1000 certified design will provide site-specific information related to the identification of hazards within the site vicinity, including an evaluation of potential accidents due to nearby industrial, transportation, and military facilities.

2.2.2 Evaluation

The U.S. Nuclear Regulatory Commission (NRC) staff has prepared safety evaluation report (SER) Section 2.2 in accordance with the review procedures described in the March 2007 revision of NUREG-0800, "Standard Review Plan [SRP] for the Review of Safety Analysis Reports for Nuclear Power Plants," Section 2.2.1-2.2.2, "Identification of Potential Hazards in Site Vicinity," and Section 2.2.3, "Evaluation of Potential Accidents," using information presented in the revised AP1000 DCD. Since the AP1000 design specific standard chemicals were not evaluated for explosion hazard, the staff has requested in request for additional information (RAI)-SRP2.2-RSAC-01, that the applicant provide required information pertaining to hazards of explosive chemicals stored onsite. The applicant responded with proposed changes to the AP1000 DCD. The staff has reviewed the applicant's response and the proposed changes to the AP1000 DCD.

2.2.3 Description of Proposed Change

The applicant identified the proposed changes to DCD Section 2.2 based on RAI-SRP2.2-RSAC-01, Revision 1. These changes included the description and evaluation of the AP1000 certified design-specific (standard) chemicals stored onsite for the explosion hazard. The applicant presented, for each explosive chemical, the minimum safe distance from the nearest structures, systems, and components (SSCs) that would not result in an overpressure in excess of 6.9 kilopascals (kPa) (1 pounds per square inch (psi)) from potential explosions and flammable vapor clouds (delayed ignition). The list of chemicals along with calculated minimum safe distances are presented in the proposed AP1000 DCD Table 2.2-1.

2.2.4 Applicable Regulations and Associated Acceptance Criteria

The relevant requirements of the NRC's regulations for these areas of review, and the associated acceptance criteria, are given in Sections 2.2.1, 2.2.2, and 2.2.3 of NUREG-0800, and are summarized below. Review interfaces with other NUREG-0800 sections can be found in Sections 2.2.1, 2.2.2, and 2.2.3.

1. Title 10 of the *Code of Federal Regulations* (10 CFR) 52.47(a)(1), "Contents of applications; technical information," which requires a design certification (DC) applicant to provide site parameters postulated for the design. However, DC applications do not provide site characteristics because this information is site-specific and is not standard design-specific and, therefore, is addressed by the COL applicant. There are no

postulated site parameters for a DC related to Sections 2.2.1, 2.2.2, and 2.2.3 of NUREG-0800.

2. This regulatory basis is provided for information only since it applies to a COL applicant's final safety analysis report (FSAR) Sections 2.2.1 and 2.2.2. 10 CFR 100.20(b), "Factors to be considered when evaluating sites," which requires that the nature and proximity of man-made hazards (e.g., airports, dams, transportation routes, military and chemical facilities) be evaluated to establish site parameters for use in determining whether plant design can accommodate commonly occurring hazards, and whether the risk of other hazards is very low (applies to DCD Sections 2.2.1 and 2.2.2 only).

3. This regulatory basis is provided for information only since it applies to a COL applicant's FSAR Sections 2.2.1, 2.2.2, and 2.2.3. 10 CFR 52.79(a)(1)(iv), Contents of applications; technical information in final safety analysis report," as it relates to the factors to be considered in the evaluation of sites, which require the location and description of industrial, military, or transportation facilities and routes, and of 10 CFR 52.79(a)(1)(vi), as it relates to the compliance with 10 CFR Part 100, "Reactor site criteria," (applies to DCD Sections 2.2.1, 2.2.2 and 2.2.3).

Acceptance criteria are provided in NUREG-0800 to meet the above requirements:

1. This acceptance criterion for Section 2.2.1-2.2.2 of NUREG-0800 is provided for information only since it applies to a COL applicant's FSAR Section 2.2.1. Data in the safety analysis report (SAR) should adequately describe the locations and distances from the plant of nearby industrial, military, and transportation facilities and that such data are in agreement with data obtained from other sources, when available (applies to DCD Section 2.2.1 only).

2. This acceptance criterion for Section 2.2.1-2.2.2 of NUREG-0800 is provided for information only since it applies to a COL applicant's FSAR Section 2.2.2. Descriptions of the nature and extent of activities conducted at the site and in its vicinity, including the products and materials likely to be processed, stored, used, or transported, are adequate to permit identification of the possible hazards cited in Section III of Sections 2.2.1 and 2.2.2 of NUREG-0800 (applies to DCD Section 2.2.2 only).

3. This acceptance criterion for Section 2.2.1-2.2.2 of NUREG-0800 is provided for information only since it applies to a COL applicant's FSAR Section 2.2.2. Sufficient statistical data with respect to hazardous materials are provided to establish a basis for evaluating the potential hazards to the plant or plants considered at the site (applies to DCD Section 2.2.2 only).

4. This acceptance criterion for Section 2.2.3 of NUREG-0800 is provided for information only since it applies to a COL applicant's FSAR Section 2.2.3. Event Probability: The identification of design basis events (DBEs) resulting from the presence of hazardous materials or activities in the vicinity of the plant or plants of specified type is acceptable if all postulated types of accidents are included for which the expected rate of occurrence of potential exposures resulting in radiological dose in excess of the 10 CFR 50.34(a)(1), "Design objectives for equipment to control releases of radioactive material in effluents—nuclear power reactors," limits as it relates to the requirements of 10 CFR Part 100 is estimated to exceed the staff's objective of an order of magnitude of 10^{-7} per year (applies to DCD Section 2.2.3 only).

5. This acceptance criterion for Section 2.2.3 of NUREG-0800 is provided for information only since it applies to a COL applicant's FSAR Section 2.2.3. DBEs: The effects of DBEs have been adequately considered, in accordance with 10 CFR 100.20(b), if analyses of the effects of those accidents on the safety-related features of the plant or plants of specified type have been performed and measures have been taken (e.g., hardening, fire protection) to mitigate the consequences of such events (applies to DCD Section 2.2.3 only).

2.2.5 Evaluation

The staff reviewed the applicant's response to RAI-SRP2.2-RSAC-01, which included the proposed revision to AP1000 DCD, Section 2.2 pertaining to the description and evaluation of potential explosion hazards of explosive standard AP1000 design-specific chemicals stored onsite. The applicant evaluated the accidents involving potential explosions from the explosive chemicals stored onsite. Minimum safe distance not to exceed 1 psi peak incident overpressure to nearest critical plant structure is determined and presented in Table 2.2-1. The applicant concluded in this section that peak incident overpressure of 1 psi is not exceeded at the nearest SSC. The staff performed independent confirmatory analyses with conservative assumptions and using regulatory guide (RG) 1.91, "Evaluations of Explosions Postulated to Occur on Transportation Routes Near Nuclear Power Plants," Revision 1 methodology and found that the results are comparable to those determined by the applicant. Therefore, the staff concludes that the applicant's methodology is reasonable, and the results and conclusions are acceptable. In a subsequent revision to the AP1000 DCD, the applicant included these changes in the DCD text.

2.2.6 Conclusions

The staff reviewed the applicant's response to RAI-SRP2.2-RSAC-01 and proposed revision to AP1000 DCD, Section 2.2. The results of the staff's technical evaluation of the information related to the evaluation of potential explosion hazard of explosive chemicals stored onsite are comparable to the results presented by the applicant in the revised AP1000 DCD. Therefore, the staff concludes that the applicant's analyses and conclusions are acceptable.

As set forth above, the applicant has identified potential explosion hazards of standard AP1000 design-specific chemicals stored onsite, and has appropriately determined those that should be considered in DBEs, and has demonstrated that the AP1000 design is adequately protected against potential design-basis events resulting from explosive chemicals stored onsite. The staff has reviewed the proposed information that included in the AP1000 DCD and, for the reasons specified above, concludes that the applicant has established that the AP1000 design meets the requirements of 10 CFR 52.47(a)(1) and also complies with 10 CFR 52.79(a)(1)(iv).

2.3 Meteorology

2.3.1 Regional Climatology

The revised AP1000 DCD changed some of the air temperature site parameters listed in DCD Tier 1, Table 5.0-1, and DCD Tier 2, Table 2-1. Table 2.3.1-1 of this SER presents these changes. Revision 17 changes are benchmarked against Revision 15, because Revision 15 is the version of the AP1000 DCD previously approved by the staff.

Table 2.3.1-1 Revisions to Air Temperature Site Parameter Values

TIER LEVEL	SITE PARAMETER	DCD REVISION 15	DCD REVISION 17
Tiers 1 and 2	maximum safety dry bulb with coincident wet bulb	115 °Fahrenheit (F)/80 °F (46.1 °Celsius (C)/26.7 °C)	115 °F/86.1 °F (46.1 °C/30.1 °C)
	maximum safety wet bulb (noncoincident)	81 °F (27.2 °C)	86.1 °F (30.1 °C)
Tier 2	maximum normal dry bulb with coincident wet bulb	100 °F/77 °F (37.8 °C/25.0 °C)	101 °F/80.1 °F (38.3 °C/26.7 °C)
	maximum normal wet bulb (noncoincident)	80 °F (26.7 °C)	80.1 °F (26.7 °C)

There were no changes in: (1) the minimum safety air temperature site parameter value (-40 °C (-40 °F)) presented in DCD Tier 1, Table 5.0-1; and (2) the minimum normal air temperature site parameter value (-23.3 °C (-10 °F)) presented in both DCD Tier 1, Table 5.0-1, and DCD Tier 2, Table 2-1.

Revision 17 also made the following changes to the footnotes in DCD Tier 2, Table 2-1:

- Footnote (b) was expanded to clarify that: (1) the maximum normal values are 1-percent seasonal exceedance temperatures (June through September in the northern hemisphere), which are approximately equivalent to the annual 0.4-percent exceedance temperatures; and (2) the minimum normal value is the 99-percent seasonal exceedance temperature (December through February in the northern hemisphere), which is approximately equivalent to the annual 99.6-percent exceedance temperature.

- Footnote (g) was added to state that the containment pressure response analysis is based on a conservative set of dry-bulb and wet-bulb temperatures that envelop any conditions where the dry-bulb temperature is 46.1 °C (115 °F) or less and the wet-bulb temperature is less than or equal to 30.1 °C (86.1 °F).

These revisions relied on the following source documents:

- APP-GW-GLN-108, "AP1000 Site Interface Temperature Limits," Revision 2, September 2007

- APP-GW-GLE-036, "Impact of a Revision to the Current Wet Bulb Temperature Identified in Table 5.0-1 (Tier 1), and Table 2-1 (Sheet 1 of 3) of the DCD (Revision 16)," Revision 0, June 27, 2008

2.3.1.1 Evaluation

The staff has prepared SER Section 2.3.1 in accordance with the review procedures described in NUREG-0800 Section 2.3.1, using information presented in DCD Revision 17, APP-GW-GLN-108, APP-GW-GLE-036, and the applicant's responses to RAIs on APP-GW-GLN-108 and APP-GW-GLE-036. Where appropriate, the applicant has incorporated its RAI responses in Revision 17 of the DCD. Since the staff has reviewed the DCD Revision 17 and DCD Revision 17 includes the incorporation of the RAI responses, the staff considers the RAIs related to the DCD to be closed.

2.3.1.1.1 General Description

10 CFR 52.47(a)(1) requires in part that the standard DC application include the site parameters postulated for the design, and 10 CFR 52.79(d)(2) requires a COL application (FSAR) referencing a standard design to demonstrate that the site characteristics fall within the site parameters specified in the DC. AP1000 DCD Tier 1, Table 5.0-1, and DCD Tier 2, Table 2-1, present the list of AP1000 site parameters. If the FSAR does not demonstrate that the site characteristics fall within the site parameters specified in the DC, the COL application must include a request for an exemption or departure, as appropriate, that complies with the requirements of the referenced DC rule and 10 CFR 52.93, "Exemptions and variances."

SER Section 2.3.1 addresses the climatic site parameters (i.e., air temperature, wind speed, precipitation (snow and ice)) used as design bases for the AP1000. The list of Tier 1 site parameters includes maximum and minimum safety air temperature values, which are based on historical data and exceed peaks of less than 2 hours; the list of Tier 2 site parameters includes the same maximum and minimum safety air temperature values as well as maximum and minimum normal air temperature values, which are 1-percent seasonal exceedance values.

2.3.1.1.2 Description of Proposed Change

SER Table 2.3.1-1 lists the changes in air temperature site parameter values from DCD Revision 15 to DCD Revision 17. SER Table 2.3.1-1 shows that all the revised air temperature site parameter values are greater than before: the maximum safety coincident wet bulb increased 3.4 °C (6.1 °F) (from 26.7 °C (80 °F) to 30.1 °C (86.1 °F)), the maximum safety noncoincident wet bulb increased 2.8 °C (5.1 °F) (from 27.2 °C (81 °F) to 30.1 °C (86.1 °F)), the maximum normal dry bulb increased 0.5 °C (1 °F) (from 37.8 °C (100 °F) to 38.3 °C (101 °F)), the maximum normal coincident wet bulb increased 1.7 °C (3.1 °F) (from 25.0 °C (77 °F) to 26.7 °C (80.1 °F)), and the maximum normal noncoincident wet bulb increased 0.05 °C (0.1 °F) (from 26.7 °C (80 °F) to 26.7 °C (80.1 °F)).

The applicant used APP-GW-GLN-108 as its source document for the DCD Revision 16 changes in maximum safety noncoincident wet bulb (from 27.2 °C (81 °F) to 29.7 °C (85.5 °F)), maximum normal coincident wet bulb (from 25.0 °C (77 °F) to 26.7 °C (80.1 °F)), and maximum normal noncoincident wet bulb (from 26.7 °C (80 °F) to 26.7 °C (80.1 °F)). This document states that these modifications to air temperature site parameters better accommodate a broader range of conditions to encompass the potential sites for AP1000 plants. It also provides details on the effects of these changes to air temperature site parameters on a number of SSCs, such as the passive containment cooling system, the normal residual heat removal system, the spent fuel pool cooling system, the service water system, the component cooling water system, and the central chilled water system.

The applicant used APP-GW-GLE-036 as its source document for the subsequent changes in maximum safety coincident wet bulb (from 26.7 °C (80 °F) to 30.1 °C (86.1 °F)), maximum safety noncoincident wet bulb (from 29.7 °C (85.5 °F) to 30.1 °C (86.1 °F)), and maximum normal dry bulb (from 37.8 °C (100 °F) to 38.3 °C (101 °F)). This document states that these changes encompass more sites in the eastern United States, such as Levy County and Turkey Point. It also provides details on the effects of these changes to air temperature site parameters on the SSCs listed above.

2.3.1.1.3 Applicable Regulations and Associated Acceptance Criteria

Acceptance criteria regarding regional climatology site parameters, such as air temperature, are based on meeting the relevant requirements of General Design Criterion (GDC) 2, “Design Bases for Protection Against Natural Phenomena,” in Appendix A, “General Design Criteria for Nuclear Power Plants,” to 10 CFR Part 50, “Domestic licensing of production and utilization facilities.” GDC 2 states, in part, that SSCs important to safety must be designed to withstand the effects of natural phenomena without losing the ability to perform their safety functions.

GDC 2 also states that the design bases for these SSCs shall reflect, in part, appropriate consideration of the most severe of the natural phenomena that have been historically reported for the site and surrounding area, with sufficient margin for the limited accuracy, quantity, and period of time in which the historical data have been accumulated.

NUREG-0800 Section 2.3.1 states that the DC application should include ambient temperature and humidity statistics for use in establishing heat loads for the design of normal plant heat sink systems; post-accident containment heat removal systems; and plant heating, ventilation, and air conditioning systems. NUREG-0800 Section 2.3.1 also states that the climatic conditions identified as site parameters for DC applications should be representative of a reasonable number of sites that may be considered within a COL application and that a basis should be provided for each of the site parameters.

2.3.1.1.4 Evaluation

This SER section is limited to reviewing the appropriateness of the values chosen as air temperature site parameters; other SER sections (e.g., 5.4.7, 6.2.2, 9.1.3, 9.2.1, 9.2.2, and 9.2.7) review the effects of these changes to air temperature site parameters on SSCs.

To determine if the applicant’s revised air temperature site parameters are representative of a reasonable number of potential COL sites, the staff reviewed dry-bulb and wet-bulb data from the Weather Data Viewer database of the American Society of Heating, Refrigerating and Air-Conditioning Engineers (ASHRAE). This database, which is discussed in Chapter 28 of the 2005 “ASHRAE Handbook—Fundamentals,” includes climatic design information for approximately 700 weather stations in the continental United States. The ASHRAE database includes statistics for each weather station, such as extreme wet-bulb, 0.4-percent annual exceedance wet-bulb, and 0.4-percent annual exceedance dry-bulb temperatures.

The ASHRAE extreme wet-bulb data represent hourly data (e.g., the highest of the values measured once each hour), whereas the AP1000 maximum safety coincident and noncoincident wet-bulb site parameter values of 30.1 °C (86.1 °F) exclude peaks of less than 2 hours. Consequently, the staff examined the ASHRAE database to identify those weather stations that had extreme wet-bulb data exceeding 30.6 °C (87.1 °F), assuming such occurrences would be equivalent to a 2-hour peak exceeding 30.1 °C (86.1 °F). The staff found that approximately 15 percent (97 out of 660) of the weather stations located throughout the continental United States had an extreme wet-bulb value exceeding 30.6 °C (87.1 °F). Because only a small number (i.e., 15 percent) of weather stations had an extreme wet-bulb value that exceeded 30.6 °C (87.1 °F), the staff concludes that the AP1000 maximum safety coincident and noncoincident wet-bulb air temperature site parameter values of 30.1 °C (86.1 °F) can be expected to bound a reasonable number of sites that have been or may be considered for a COL application.

The staff also examined the ASHRAE database to identify the number of weather stations that exceeded a 0.4-percent annual exceedance wet-bulb value of 26.7 °C (80.1 °F). The AP1000 maximum normal coincident and noncoincident wet-bulb site parameter values of 26.7 °C (80.1 °F) are 1-percent seasonal exceedance values, which are likely to be about the same as a 0.4-percent annual exceedance wet-bulb value of 26.7 °C (80.1 °F). The staff found that approximately 11 percent (75 out of 660) of the weather stations had a 0.4-percent wet-bulb value exceeding 26.7 °C (80.1 °F). Because only a small number (i.e., 11 percent) of weather stations had a 0.4-percent wet-bulb value that exceeded 26.7 °C (80.1 °F), the staff concludes that the AP1000 maximum normal coincident and noncoincident wet-bulb air temperature site parameter values of 26.7 °C (80.1 °F) can be expected to bound a reasonable number of sites that have been or may be considered for a COL application.

The staff also examined the ASHRAE database to identify the number of weather stations where the 0.4-percent annual exceedance dry-bulb value exceeded 38.3 °C (101 °F). The AP1000 maximum normal dry-bulb site parameter value of 38.3 °C (101 °F) is a 1-percent seasonal exceedance value that is likely to be about the same as a 0.4-percent annual exceedance dry-bulb value of 38.3 °C (101 °F). The staff found that approximately 5 percent (38 out of 700) of the weather stations had a 0.4-percent dry-bulb value exceeding 38.3 °C (101 °F). Because only a small number (i.e., 5 percent) of weather stations had a 0.4-percent dry-bulb value that exceeded 38.3 °C (101 °F), the staff concludes that the AP1000 maximum normal dry-bulb air temperature site parameter of 38.3 °C (101 °F) which is likely to bound a reasonable number of sites that have been or may be considered for a COL application.

2.3.1.1.5 Technical Conclusions

The applicant has selected a revised set of air temperature site parameters referenced above for plant design inputs, and the staff agrees that these revised site parameters can be expected to be representative of a reasonable number of sites that have been or may be considered for a COL application. This will ensure that GDC 2 is met, in that SSCs important to safety will be designed to withstand the effects of natural phenomena (e.g., extreme air temperatures) without losing the ability to perform their safety functions and will reduce the number of requests for exemptions or departures in future COL applications, which could occur if the FSAR cannot demonstrate that the design of the facility falls within the characteristics of the site.

AP1000 COL Information Item 2.3-1 states that COL applicants referencing the AP1000 design will address site-specific information related to regional climatology. The COL applicant will also need to demonstrate that the characteristics of the selected site fall within the site parameters specified in the design approval, pursuant to 10 CFR 52.79(c)(1). For a selected site with any of the air temperature site characteristics in excess of the corresponding AP1000 site parameters, the COL applicant will need to address how the SSCs important to safety will be able to withstand the effects of the natural phenomena without losing the ability to perform their safety functions in accordance with GDC 2.

In determining site characteristic values for comparison with the AP1000 maximum safety site parameter values, a COL applicant should select the higher of either: (1) the most severe value that has been historically reported for the site and surrounding area; or (2) the 100-year return period value. Regulations in 10 CFR 52.79(a)(1)(iii) state, in part, that the COL FSAR shall include the meteorological characteristics of the proposed site with appropriate consideration of the most severe of the natural phenomena that have been historically reported for the site and surrounding area and with sufficient margin for the limited accuracy, quantity, and time in which the historical data have been accumulated. To comply with 10 CFR 52.79(a)(1)(iii), the maximum safety ambient temperature site-specific characteristic values identified by the COL applicant should be based on the higher of either: (1) the historic maximum values recorded in the site vicinity; or (2) the 100-year return period values. Temperatures based on a 100-year return period are considered to provide sufficient margin for the limited accuracy, quantity, and period of time in which the historical data have been accumulated, as required by the regulation.

APP-GW-GLE-036 states that the revisions to the maximum safety coincident and noncoincident wet-bulb temperatures were implemented to encompass more sites in the eastern United States, such as Levy and Turkey Point. APP-GW-GLE-036 further states that Progress Energy chose the revised wet-bulb temperature values to support the COL application for the Levy site, to avoid any departures from the AP1000 design. The staff’s acceptance of the revised AP1000 maximum safety coincident and noncoincident wet-bulb temperature values as being expected to bound a reasonable number of sites does not imply that the staff finds that these revised values bound the corresponding site characteristic values for any given COL site, such as the Levy site. The staff will assess the maximum safety coincident and noncoincident wet-bulb temperature site characteristic values as part of its review of a COL application.

2.3.1.2 Conclusion

The staff has reviewed the information presented by the applicant and concludes that the changes in air temperature site parameters are acceptable, because they meet the requirements of GDC 2 in Appendix A to 10 CFR Part 50 and 10 CFR 52.63(a)(1), “Finality of standard design certifications,” as well as the associated acceptance criteria specified in NUREG-0800 Section 2.3.1.

2.3.4 Short-Term (Accident) Atmospheric Relative Concentration

Revision 17 to the AP1000 DCD made changes to some of the control room (CR) atmospheric dispersion factors (also known as atmospheric relative concentration or χ/Q values) presented in DCD Revision 15. The staff benchmarked the Revision 17 changes against Revision 15, which is the previously staff-approved version of the AP1000 DCD. The applicant made the following changes:

- The applicant revised the CR χ/Q values presented in DCD Tier 1, Table 5.0-1, and DCD Tier 2, Tables 2-1 and 15A-6, for plant vent or passive containment cooling system (PCS) air diffuser and ground-level containment releases to the CR heating, ventilation, and air conditioning (HVAC) intake and annex building door. Table 2.3.4-1 of this SER lists these revisions.

- The applicant added CR χ/Q values for condenser air removal stack releases to the HVAC intake and annex building door to DCD Tier 1, Table 5.0-1, and DCD Tier 2, Tables 2-1 and 15A-6. SER Table 2.3.4-1 presents a list of these revisions.

- The applicant revised some of the CR source and receptor data provided in DCD Tier 2, Table 15A-7, for determining CR atmospheric dispersion factors. SER Table 2.3.4-2 lists these revisions.

The following served as source documents for these revisions:

- APP-GW-GLE-001 Revision 0, March 7, 2008, “Impact of Annex Building Expansion and Condenser Air Removal Stack Location on the Control Room Atmospheric Dispersion Factors”

- APP-GW-GLN-122 Revision 0, July 2007, “Offsite and Control Room Dose Changes”

2.3.4.1 Evaluation

The staff prepared SER Section 2.3.4 in accordance with the review procedures described in NUREG-0800 Section 2.3.4, using information presented in Revision 17 of the AP1000 DCD, APP-GW-GLE-001, APP-GW-GLN-122, and the applicant’s responses to RAIs on APP-GW-GLE-001 and APP-GW-GLN-122. Where appropriate, the applicant has incorporated its RAI responses in Revision 17 of the DCD. Since the staff has reviewed the DCD Revision 17 and DCD Revision 17 includes the incorporation of the RAI responses, the staff considers the RAIs related to the DCD to be closed.

2.3.4.1.1 General Description

Section 2.3.4 addresses, among other items, the χ/Q estimates at the CR for postulated design-basis accidental radioactive airborne releases. In lieu of site-specific meteorological data, the applicant provided a set of hypothetical, short-term CR χ/Q values to evaluate the AP1000 design. The set of AP1000 site parameters listed in DCD Tier 1, Table 5.0-1, and DCD Tier 2, Table 2-1, includes these CR χ/Q values. DCD Tier 2, Section 2.3.4, states that the applicant derived the short-term χ/Q site parameters from a study performed to determine the short-term χ/Q values that would envelop most current plant sites. The CR radiological consequence analyses presented in DCD Tier 2, Sections 6.4 and 15.6.5, use the resulting CR short-term χ/Q values.

2.3.4.1.2 Description of Proposed Changes

(1) Changes in Plant Vent or PCS Air Diffuser and Ground-Level Containment Release χ/Q Values

SER Table 2.3.4-1 lists the applicant’s changes to the CR χ/Q values from DCD Revision 15 to DCD Revision 17 for plant vent or PCS air diffuser and ground-level containment releases to the HVAC intake and annex building door. SER Table 2.3.4-1 shows that all plant vent or PCS air diffuser and ground-level containment release CR χ/Q values increased in DCD Revision 17. The extent of this increase ranged from 36 percent to over 400 percent.

The CR habitability analyses used the HVAC intake χ/Q values for: (a) evaluating the time period preceding the isolation of the main CR and actuation of the emergency habitability system; (b) evaluating the time period after 72 hours when the compressed air supply in the emergency habitability system would be exhausted and outside air would be drawn into the main CR; and (c) determining CR doses when the nonsafety ventilation system is assumed to remain operable such that the emergency habitability system is not actuated. The analyses used the annex building door χ/Q values when the emergency habitability system is in operation and the only pathway for contaminated air entering the CR is assumed to be the result of ingress or egress.

The applicant's source document for these revisions in atmospheric dispersion factors is APP-GW-GLN-122. Revision 0 to this document described three changes implemented in the AP1000 DCD, Revision 16 that reduced some of the calculated radiological doses off site and in the main CR for design-basis accidents. These three changes were: (a) directing the main CR emergency habitability system discharge airflow into the entry vestibule to provide a continuous vestibule purge; (b) increasing the decay time in Technical Specification 3.9.7, "Decay Time, Refueling Operations," from 24 hours to 48 hours to provide increased radioactive decay of short-lived fission products before irradiated fuel assemblies are handled; and (c) revising the calculation of radioactivity released for the postulated loss-of-coolant accident (LOCA) to take credit for aerosol impaction removal in the containment leakage pathway. The staff approved the first two changes but did not approve the last change; nonetheless, the first two changes allowed the CR atmospheric dispersion site parameter values shown in SER Table 2.3.4-1 to be increased to accommodate sites with higher χ/Q values than those originally specified in the AP1000 DCD, Revision 15. Larger χ/Q values are associated with less dilution capability, resulting in higher radiological doses. When comparing a site parameter χ/Q value and a site characteristic χ/Q value, the site is acceptable for the design if the site characteristic χ/Q value is smaller than the site parameter χ/Q value. Such a comparison shows that the site has better dispersion characteristics than those required by the reactor design.

(2) New Condenser Air Removal Stack Release χ/Q Values

SER Table 2.3.4-1 lists the new condenser air removal stack release χ/Q values presented in the AP1000 DCD, Revision 17. DCD Revision 15 did not present CR χ/Q values for this release pathway.

The applicant's source document for these new χ/Q values is APP-GW-GLE-001. This report addresses concerns associated with a correction made to the location of the condenser air removal stack, as shown in DCD Tier 2, Table 15A-7 and Figure 15A-1. The corrected location decreased the distance between the condenser air removal stack and the annex building access door. Footnote 5 in Revision 15 of DCD Tier 1, Table 5.0-1, and DCD Tier 2, Table 2-1, stated that the listed χ/Q values for the power-operated relief valve (PORV) and safety valve releases bound the dispersion factors for releases from the condenser air removal stack. With the revised location of the condenser air removal stack, the applicant was concerned that this statement may no longer be valid. Consequently, in APP-GW-GLE-001, the applicant: (a) modified Footnote 5 to eliminate the assertion that the listed χ/Q values for the PORV and safety valve releases bound the dispersion factors for releases from the condenser air removal stack; (b) added atmospheric dispersion factors specifically for the condenser air removal stack release point; and (c) added Footnote 7 to DCD Tier 1, Table 5.0-1, and DCD Tier 2, Tables 2-1 and 15A-6, which states that the condenser air removal stack release point was included for information only as a potential activity release point and none of the design-basis accident radiological consequence analyses model releases from this release point.

APP-GW-GLE-001 states that because the straight-line distances are similar, the applicant chose the same atmospheric dispersion factors for the condenser air removal stack releases to the HVAC intake as those currently defined values used for the release-receptor pair of the fuel-handling area to the HVAC intake. Similarly, APP-GW-GLE-001 states that, because the straight-line distances are similar, the applicant chose the same atmospheric dispersion factors for the condenser air removal stack releases to the annex building entrance as those currently defined values used for the release-receptor pair of PORV and safety values to the HVAC intake.

(3) Revised Control Room Source and Receptor Data

SER Table 2.3.4-2 lists the changes in CR source and receptor data between the AP1000 DCD, Revision 15 and the DCD, Revision 17. SER Table 2.3.4-2 shows that the horizontal straight-line distances from all release points (except for the condenser air removal stack) to the HVAC intake and annex building access receptors increased.

The applicant used APP-GW-GLE-001 as the source document for these source and receptor changes. This report addresses the impact of a relocation of the annex building entrance and HVAC intake on the CR source and receptor data to be used in determining site-specific CR χ/Q values. With an exception for the condenser air removal stack, the relocation of these two CR receptor locations increased the distances between the previously identified release points and these receptors. A correction made to the location of the condenser air removal stack, as discussed above, decreased the distances between the condenser air removal stack release pathway and the HVAC intake and annex building access receptors.

2.3.4.1.3 Applicable Regulations and Associated Acceptance Criteria

Acceptance criteria regarding the CR χ/Q site parameter values are based on meeting the relevant requirements of GDC 19, “Control Room,” in Appendix A of 10 CFR Part 50, which states, in part, that a CR shall be provided from which actions can be taken to maintain the nuclear power unit in a safe condition under accident conditions, including a LOCA. Atmospheric dispersion factors are an important component of the CR radiological habitability analyses used to demonstrate that the CR operator dose criterion in GDC 19 is met.

NUREG-0800 Section 2.3.4 states that the DC application should include CR atmospheric dispersion factors for the appropriate time periods in the list of site parameters. The DC application should also include figures and tables showing the design features that the COL applicant will use to generate CR χ/Q values (e.g., intake heights, release heights, building cross-sectional areas, and distance to receptors). NUREG-0800 Section 2.3.4 also states that the postulated site parameters should be representative of a reasonable number of sites that may be considered within a COL application and a basis should be provided for each of the site parameters. RG 1.194, “Atmospheric Relative Concentrations for Control Room Radiological Habitability Assessments at Nuclear Power Plants,” presents criteria for characterizing atmospheric dispersion conditions for evaluating the consequences of radiological releases to the CR. RG 1.194 states that the ARCON96 atmospheric dispersion model (Revision 1 to NUREG/CR-6331, “Atmospheric Relative Concentrations in Building Wakes”) is an acceptable methodology for assessing CR χ/Q values for use in CR design-basis accident radiological analyses, subject to the provisions in RG 1.194.

2.3.4.1.4 Evaluation

This SER section is limited to reviewing the appropriateness of the values chosen as atmospheric dispersion site parameters; other SER sections (e.g., Sections 6.4 and 15.3) review the effects of the implemented χ/Q revisions on the design-basis dose calculations.

To confirm that the revised set of plant vent or PCS air diffuser and ground-level containment release CR χ/Q site parameters and the new set of condenser air removal stack release CR χ/Q site parameters presented in Revision 17 to the DCD are representative of a reasonable number of sites that have been or may be considered for a COL application, the staff generated site-specific χ/Q values for the four docketed early site permit (ESP) applications (North Anna, Clinton, Grand Gulf, and Vogtle) using the ARCON96 computer code with: (1) the revised source and receptor information presented in DCD Tier 2, Table 15A-7 (assuming the AP1000 plant north was aligned to true north at each site), and (2) the site-specific hourly meteorology data sets provided in support of each ESP application. The staff found that the AP1000 CR χ/Q site parameter values were bounding in all cases. Consequently, the staff finds that the applicant has provided CR atmospheric dispersion site parameter values that bound several sites that may be considered within a COL application and are, therefore, acceptable. The CR atmospheric dispersion site parameters will help to ensure that the CR operator dose criterion in GDC 19 is met. APP-GW-GLE-001 revised the CR χ/Q source and receptor data presented in DCD Tier 2, Table 15A-7, based on a correction made to the location of the condenser air removal stack and relocation of the annex building entrance and CR air inlet. In all cases (except for the condenser air removal stack), the distances between the sources and receptors increased. Since χ/Q values generally decrease as downwind travel distances increase, APP-GW-GLE-001 was conservative in that it did not change the CR atmospheric dispersion factors presented in DCD Tier 1, Table 5.0-1, and DCD Tier 2, Tables 2-1 and 15A-6, to reflect the increases in downwind distances. The applicant based the revisions in χ/Q values presented in SER Table 2.3.4-1 on the changes implemented in response to the findings of APP-GW-GLN-122 as discussed previously. Based on the information above the staff finds this acceptable.

Table 2.3.4-1. Revisions to CR Atmospheric Dispersion Factor (χ/Q) Site Parameter Values (s/m^3)

SITE PARAMETER	DCD REVISION 15	DCD REVISION 17	% INCREASE
Plant Vent or PCS Air Diffuser Release to the HVAC Intake			
0–2 hours	2.2×10^{-3}	3.0×10^{-3}	136%
2–8 hours	1.4×10^{-3}	2.5×10^{-3}	179%
8–24 hours	6.0×10^{-4}	1.0×10^{-3}	167%
1–4 days	4.5×10^{-4}	8.0×10^{-4}	178%
4–30 days	3.6×10^{-4}	6.0×10^{-4}	167%
Plant Vent or PCS Air Diffuser Release to the Annex Building Door			
0–2 hours	6.6×10^{-4}	1.0×10^{-3}	152%
2–8 hours	4.8×10^{-4}	7.5×10^{-4}	156%
8–24 hours	2.1×10^{-4}	3.5×10^{-4}	167%
1–4 days	1.5×10^{-4}	2.8×10^{-4}	187%
4–30 days	1.3×10^{-4}	2.5×10^{-4}	192%
Ground-Level Containment Release to the HVAC Intake			
0–2 hours	2.2×10^{-3}	6.0×10^{-3}	273%
2–8 hours	1.4×10^{-3}	3.6×10^{-3}	257%
8–24 hours	6.0×10^{-4}	1.4×10^{-3}	233%
1–4 days	4.5×10^{-4}	1.8×10^{-3}	400%
4–30 days	3.6×10^{-4}	1.5×10^{-3}	417%
Ground-Level Containment Release to the Annex Building Door			
0–2 hours	6.6×10^{-4}	1.0×10^{-3}	152%
2–8 hours	4.8×10^{-4}	7.5×10^{-4}	156%
8–24 hours	2.1×10^{-4}	3.5×10^{-4}	167%
1–4 days	1.5×10^{-4}	2.8×10^{-4}	187%
4–30 days	1.3×10^{-4}	2.5×10^{-4}	192%

Table 2.3.4-1. Revisions to CR Atmospheric Dispersion Factor (χ/Q) Site Parameter Values (s/m^3)

SITE PARAMETER	DCD REVISION 15	DCD REVISION 17	% INCREASE
Condenser Air Removal Stack Release to the HVAC Intake 0–2 hours 2–8 hours 8–24 hours 1–4 days 4–30 days	None Provided	 6.0×10^{-3} 4.0×10^{-3} 2.0×10^{-3} 1.5×10^{-3} 1.0×10^{-3}	--
Condenser Air Removal Stack Release to the Annex Building Door 0–2 hours 2–8 hours 8–24 hours 1–4 days 4–30 days	None Provided	 2.0×10^{-2} 1.8×10^{-2} 7.0×10^{-3} 5.0×10^{-3} 4.5×10^{-3}	--

Table 2.3.4-2. Revisions to CR Atmospheric Dispersion Factor (χ/Q) Site Parameter Values (s/m^3)

RELEASE POINT	RELEASE ELEVATION		HORIZONTAL STRAIGHT-LINE DISTANCE TO RECEPTOR			
			HVAC INTAKE (ELEVATION 19.9 METERS (m))		ANNEX BUILDING ACCESS (ELEVATION 1.5 METERS (m))	
	REVISION 15	REVISION 17	REVISION 15	REVISION 17	REVISION 15	REVISION 17
Plant Vent	55.7 m	No Change	39.6 m	44.9 m	76.8 m	115.6 m
PCS Air Diffuser	71.3 m	69.8 m	32.3 m	36.0 m	68.9 m	104.6 m
Fuel Building Blowout Panel	17.4 m	No Change	50.0 m	61.9 m	89.7 m	130.3 m
Fuel Building Rail Bay Door	1.5 m	No Change	52.4 m	66.6 m	92.1 m	132.1 m
Steam Vent	17.1 m	No Change	18.3 m	18.8 m	48.8 m	79.7 m
PORV/Safety Valves	19.2 m	No Change	19.8 m	20.4 m	44.1 m	77.8 m
Condenser Air Removal Stack	7.6 m	38.4 m	63.0 m	60.4 m	59.9 m	17.8 m
Containment Shell	Same as receptor elevation (19.9 m or 1.5 m)	No Change	11.0 m	12.8 m	47.2 m	83.0 m

2.3.4.1.5 Technical Conclusions

The applicant has selected a revised set of short-term (accident) CR atmospheric dispersion site parameters referenced above for plant design inputs. The staff agrees that these revised CR χ/Q values can be expected to be representative of a reasonable number of sites that have been or may be considered for a COL application. AP1000 COL Information Item 2.3-4 states, in part, that a COL applicant referencing the AP1000 design will address the site-specific CR χ/Q values. For a site selected that exceeds the bounding CR χ/Q values, COL Information Item 2.3-4 further states that the COL applicant will address how the radiological consequences associated with the controlling design-basis accident continue to meet the CR operator dose limits given in GDC 19 using site-specific χ/Q values. The staff concludes that successful completion of COL Information Item 2.3-4 will demonstrate that the short-term (accident) atmospheric dispersion factors for the CR will be acceptable.

2.3.4.2 Conclusion

The staff has reviewed the information presented by the applicant and concludes that the changes in short-term (accident) CR site parameters are acceptable because they meet the requirements of GDC 19 and 10 CFR 52.63(a)(1) and the associated acceptance criteria specified in NUREG-0800 Section 2.3.4.

2.4 Hydrologic Engineering

2.4.1 Hydrological Description

The AP1000 is a standard design with a plant configuration that assumes a normal water level at 0.6 meters (m) (2 feet (ft)) below the grade, and a flood level at the design plant grade of 30.5 m (100 ft). The actual grade level will be a few inches lower to prevent surface water ingress through the doorways. This provision recognizes that the Utility Requirements Document (URD) states that the maximum flood (or tsunami) level site envelope parameter is 0.3 m (1 ft) below grade. Although the AP1000 design flood level of 30.5 m (100 ft) does not meet the URD flood level criterion explicitly, this deviation is considered inconsequential to safety.

The maximum flood level mentioned above is based on a site parameter referred to as the probable maximum flood (PMF). The PMF is the flood that may be expected from the most severe combination of critical meteorological and hydrologic conditions that are reasonably possible in a particular drainage area and is generated by a separate parameter called the probable maximum precipitation (PMP). The PMP is the greatest depth (amount) of precipitation, for a given storm duration, that is theoretically possible for a particular area and geographic location. PMP values are typically found in the National Weather Service hydro-meteorological reports (HMRs).

The applicant proposed a change to the PMP parameter value from 0.0137 centimeters/second (cm/s) (19.4 inches per hour (in/h)) to 0.0146 cm/s (20.7 in/h) in the AP1000 DCD, Revision 17.

2.4.2 Regulatory Basis

The staff considered the following regulatory requirements in reviewing the applicant's submittal:

- 10 CFR 100.20(c)(3), as it relates to the PMF

- 10 CFR 52.47(a)(1), as it relates to the site parameters postulated for the design

- 10 CFR 52.79(a)(1)(iii), as it relates to the hydrologic characteristics of the proposed site with appropriate consideration of the most severe of the natural phenomena that have been historically reported for the site and surrounding area and with sufficient margin for the limited accuracy, quantity, and period of time in which the historical data have been accumulated

- GDC 2, which states in part that SSCs important to safety shall be designed to withstand the effects of natural phenomena such as earthquakes, tornadoes, hurricanes, floods, tsunami, and seiches without the loss of capability to perform their safety functions

2.4.3 Summary of Technical Information

In Revision 0 of APP-GW-GLE-012, "Probable Maximum Precipitation Value Increase," the applicant proposed to change the PMP value from 0.0137 cm/s (19.4 in/h) to 0.0146 cm/s (20.7 in/h). This value is found in Tier 1, Table 5.0-1, "Site Parameters," on page 5.0-2, and in Tier 2, Table 2-1 (Sheet 3 of 4), "Site Parameters," on page 2-21 of the AP1000 DCD, Revision 17.

2.4.4 Evaluation

The applicant has determined a new PMP value of 0.0146 cm/s (20.7 in/h) based on an interpretation of Figure 24 in HMR-52 from the National Weather Service. The staff, while not agreeing with this interpretation of Figure 24 found in HMR-52, does agree with the applicant's statements made in the associated AP1000 DCD impact document and has no objection to this change in the PMP value for the AP1000 DCD. The staff held a phone conference call with the applicant on August 21, 2008, to discuss technical issues related to the change. As a follow-up to that phone call, the staff issued RAI-SRP2.4-RHEB-01. The RAI included three surface water and three ground water questions. The first surface water question was associated with Table 3.3-5, Tier 1, inspections, tests, analyses, and acceptance criteria (ITAAC) Design Commitment 2.b related to the tolerance value of ±1.07 m (±3.5 ft) between the design plant grade and the site grade. In a letter dated September 15, 2008, the applicant responded to RAI-SRP2.4-RHEB-01. Specifically, the applicant, in its response to this question, stated that the tolerance of 1.07 m (3.5 ft) between design plant grade and site grade in DCD Tier 1, Table 3.3-5, is based on seismic and soil-structure interaction (SSI) considerations for the auxiliary, shield, and containment buildings. Furthermore, this tolerance is not related to hydrology or surface water considerations. The applicant further stated that it is not appropriate to use this tolerance to establish the relationship between the design plant grade and the PMF. Based on this clarification, the staff finds the response acceptable and considers this question resolved.

The second surface water question asked the applicant to specify where on the site the ITAAC Design Commitment 2.b should be met and to which buildings the commitment should be applied. In the September 15, 2008, letter, the applicant stated that the zone of influence of soil characteristics on the structural response of an embedded structure is generally considered to extend horizontally away from the structure the same distance as the depth of the embedment.

For the AP1000, this distance is approximately 12.2 m (40 ft) from the auxiliary and shield buildings. Additionally, the applicant stated that other evaluations and analyses address the effects of buildings founded at grade adjacent to the nuclear island on the seismic interaction. The applicant also stated that ITAAC Commitment 2.b in DCD Tier 1, Section 3.3, does not apply to site surface water flooding. Based on this information, the staff considers the applicant's response to be acceptable, and the issue is resolved.

The third surface water question asked the applicant to describe the expected vertical distance and tolerance between: (1) the design plant grade; (2) the to-be-built site grade; and (3) the maximum surface water elevation associated with a flood (see Table 5.0-1, DCD Tier 1) and to identify to which building these distances and tolerances apply. In the September 15, 2008, letter, the applicant stated that Table 5.0-1 includes the COL information specifying the compliance of the site PMF level with the plant site design parameters. This table defines the distance between the design plant grade of elevation 30.5 m (100 ft) and the maximum surface water elevation. The applicant also stated that ITAAC Commitment 2.b in DCD Tier 1, Section 3.3, does not define the distance between the design plant grade of elevation 30.5 m (100 ft) and the maximum surface water elevation. The staff finds this response acceptable and considers this issue resolved.

The first ground water question in RAI-SRP2.4RHEB-01 asked the applicant to clarify its definition of normal ground water elevation in Tier 2 of the DCD. In the September 15, 2008, letter, the applicant stated that Table 5.0-1 of DCD Tier 1 defines the maximum ground level as plant elevation 98 ft and the maximum flood level as plant elevation 30.5 m (100 ft.) The applicant also stated that the reference to normal ground water is applicable at all times except when there is surface water flooding. The staff found this response to be unacceptable because the applicant did not specify the maximum ground water level, but instead allowed an exception to the ground water level under certain conditions. This issue was Open Item OI-SRP2.4RHEB-01-01. In its response to RAI-SRP2.4RHEB-01, the applicant retracted the statement referencing normal ground water levels except under conditions of surfacing water flooding and made clear there are no exceptions to the normal ground water elevation. With this exception removed, this response is acceptable to the staff, and Open Item OI-SRP2.4RHEB-01-01 is resolved.

The second ground water question in RAI-SRP2.4RHEB-01 asked the applicant to specify to which buildings in Table 5.0-1, DCD Tier 1 the maximum ground water level elevations should be applied. The applicant replied that the DCD Tier 1, Table 5.0-1, specification of maximum flood level at plant elevation 30.5 m (100 ft) (design-grade elevation) is specifically applicable to the safety-related nuclear island. Furthermore, the buildings adjacent to the nuclear island are founded at grade and use the same reference elevation designation as the auxiliary building and the containment building. The applicant also stated that differences in actual elevation between the nuclear island and the adjacent buildings conform to standard construction tolerances and are independent of site grade variation.

The applicant further stated that the site grading, including local slope to encourage run off away from the doorways of the buildings included in the certified design, is site-specific. Based on the information, the staff finds this response acceptable, and the issue is resolved.

The third ground water question in RAI-SRP2.4RHEB-01 asked the applicant to specify the maximum allowed water table elevation and the maximum time this elevation can be sustained without an increase in safety risk. The applicant responded stating that the normal water table elevation is expected to be exceeded only during surface water flooding events. In addition, while surface water flooding may impede access to the AP1000, the AP1000 is designed to cope with impeded access for a period of 7 days. The staff found this response unacceptable because the applicant failed to specify the maximum allowed water table and the time this elevation can be sustained without an increase in safety risk. This issue was Open Item OI-SRP2.4RHEB-01-02. In response to RAI-SRP2.4RHEB-01, the applicant retracted the statement referencing normal ground water levels except under conditions of surface water flooding and made clear there are no exceptions to the normal ground water elevation. With the removal of this exception, this response is acceptable to the staff and Open Item OI-SRP2.4RHEB-01-02 is resolved.

2.4.5 Conclusion

The applicant has presented information relative to the PMP value found in AP1000 DCD Tier 1, Table 5.0-1, and in DCD Tier 2, Table 2-1 (Sheet 3 of 4). The staff reviewed the information provided and considers all RAIs and open items to be resolved. Additionally, the staff concludes that this portion of the application meets the requirements of GDC 2, 10 CFR Part 52, “Licenses, certifications, and approvals for nuclear power plants,” and 10 CFR Part 100, relating to hydrologic characteristics.

2.5 Geological, Seismological, and Geotechnical Engineering

In Section 2.5, “Geology, Seismology, and Geotechnical Engineering,” of Revision 17 of the AP1000 DCD, Tier 2, the applicant described geologic, seismic, and geotechnical engineering properties required for a COL applicant referencing this standard design. DCD Section 2.5.1, “Basic Geologic and Seismic Information,” presents geologic and seismic characteristics of the site and region that COL applicants referencing the AP1000 DCD need to address. DCD Section 2.5.2, “Vibratory Ground Motion,” identifies the vibratory ground motion assessment, including the safe-shutdown earthquake (SSE) and design response for the COL applicant to follow. DCD Section 2.5.3, “Surface Faulting Combined License Information,” describes the requirements for the COL applicant to address regarding the potential for surface tectonic and nontectonic deformation. DCD Sections 2.5.4, “Stability and Uniformity of Subsurface Materials and Foundations,” and 2.5.5, “Combined License Information for Stability and Uniformity of Slopes,” describe the foundation and subsurface material stability criteria to be met by COL applicants. DCD Section 2.5.6, “Combined License Information for Embankments and Dams,” discusses requirements for stability of embankments and dams near the COL site.

The six main sections of this part of the SER (i.e., Section 2.5) parallel the six main sections included in the applicant’s DCD. Except for the sections where the applicant made no changes from Revision 15 of the AP1000 DCD, the SER sections are divided into six sections: (1) the “Introduction” section, which briefly describes the contents of each main DCD section; (2) the “Technical Information in the Application” section, which describes the technical content of the DCD; (3) the “Regulatory Basis” section, which summarizes the regulations and NRC regulatory guides used by the staff to review the DCD; (4) the “Evaluation” section, which describes the staff’s evaluation of what the applicant did, including requests for RAIs and open items, and confirmatory analyses performed by the staff, if applicable; (5) the “Post Combined License Activities” section, which identifies related post-COL activities; and (6) the “Conclusions” section, which provides the staff’s conclusions and documents whether the applicant provided sufficient and adequate information to meet all relevant regulatory requirements.

The staff also reviewed the AP1000 DCD Tier 1 information that is related to DCD Tier 2, Section 2.5, and incorporated the Tier 1 information review into the appropriate sections of the Tier 2 DCD review discussed in this SER section. The SER focuses on the changes the applicant made in Revision 17 of the AP1000 DCD as compared to the previously certified revision of the DCD.

2.5.1 Basic Geologic and Seismic Information

The applicant made no changes or additions to DCD Section 2.5.1 from Revision 15 of the AP1000 DCD. Therefore, the staff did not reevaluate any of the previously certified information included in this section.

2.5.2 Vibratory Ground Motion

2.5.2.1 Introduction

DCD Section 2.5.2 states that the AP1000 certified seismic design response spectra (CSDRS) were developed using the response spectra of RG 1.60, “Design Response Spectra for Seismic Design of Nuclear Power Plants,” as the base. The applicant then modified the base spectra to include additional high-frequency amplification at a control point at 25 Hertz (Hz) with equal peak ground acceleration (PGA) in the horizontal and the vertical directions, as presented in Figures 3.7.1-1 and 3.7.1-2 in the DCD. The applicant also stated that for a site, at which the nuclear island is founded on hard rock, the design response spectra specified in Appendix 3I to the DCD and Figures 3I.1-1 and 3I.1-2 can be used in place of the CSDRS.

2.5.2.2 Technical Information in the Application

2.5.2.2.1 Combined License Seismic and Tectonic Characteristics Information

AP1000 DCD, Section 2.5.2.1, “Combined License Seismic and Tectonic Characteristics Information,” states that the site-specific ground motion response spectra (GMRS) would be defined at the ground surface in the free-field and compared to the CSDRS. For sites with soil layers that will be completely excavated to expose competent material (in situ material with a shear wave velocity of 305 m/s (1000 feet per second (fps)) or higher), the applicant stated that the GMRS will be specified on an outcrop or a hypothetical outcrop that would exist after excavation. The applicant further clarified that the motions at the hypothetical outcrop are developed as a free-surface motion, not as an in-column motion with no soil above the outcrop.

In addition, the applicant described seven requirements in AP1000 DCD Section 2.5.2.1 for the COL applicant to address in order to demonstrate that a selected site was suitable for the AP1000 standard design. The applicant updated the following five requirements in Revision 17 of the DCD:

- For a site at which the nuclear island is founded on hard rock with a shear wave velocity greater than 2,438 m/s (8,000 fps), the site-specific GMRS can be defined at the foundation level and may be shown to be less than or equal to the CSDRS.

- For a site at which the nuclear island is directly founded on hard rock, the site-specific PGA and spectra should be developed for the top of competent rock and shown to be less than or equal to those values given in DCD Figures 3I.1-1 and 3I.1-2 at the foundation level and over the entire frequency range.

- Layers of the soil beneath the foundation are approximately horizontal, sloping less than 20 degrees, and the minimum estimate of the low-strain shear wave velocity of the soil underneath the nuclear island foundation is greater than or equal to 305 m/s (1,000 fps).

- For sites at which the nuclear island is founded on soil, the median estimate of the strain-compatible soil shear modulus and hysteretic damping is compared to the values used in the AP1000 generic analyses shown in DCD Table 3.7.1-4 and Figure 3.7.1-17. Properties of soil layers within a depth of 36.6 m (120 ft) below finished grade are compared to those in the generic soil site analyses (soft soil (SS), soft-to-medium (SM) soil, and upper bound soft-to-medium (UBSM) soil). The shear wave velocity should also increase with depth, and the average low-strain shear wave velocity should not be less than 80 percent of the average shear wave velocity at a higher elevation.

- A site-specific evaluation, as described in DCD Section 2.5.2.3, may be performed in lieu of the other requirements.

DCD Tier 1, Table 5.0-1, specifies the site parameter for the SSE as follows:

> SSE free-field peak ground acceleration of 0.30 g with modified regulatory guide 1.60 response spectra (See Figures 5.0-1 and 5.0-2). Seismic input is defined at finished grade except for sites where the nuclear island is founded on hard rock. If the site-specific spectra exceed the response spectra in Figures 5.0-1 and 5.0-2 at any frequency, or if soil conditions are outside the range evaluated for AP1000 design certification, a site-specific evaluation can be performed. This evaluation will consist of a site-specific dynamic analysis and generation of in-structure response spectra at key locations to be compared with the floor response spectra of the certified design at 5-percent damping. The site is acceptable if the floor response spectra from the site-specific evaluation do not exceed the AP1000 spectra for each of the locations or the exceedances are justified.
>
> The hard rock high frequency (HRHF) ground motion response spectra (GMRS) are shown in Figure 5.0-3 and Figure 5.0-4 defined at the foundation level for 5 percent damping. The HRHF GMRS provides an alternative set of spectra for evaluation of the site-specific GMRS. A site is acceptable if its site-specific GMRS falls within the AP1000 HRHF GMRS.

Revision 17 of the DCD added Figures 5.0-1 and 5.0-2 in Tier 1, Section 5.0, accordingly.

DCD Tier 1, Table 5.0-1, also states that there should be no potential for fault motion in the site area.

2.5.2.2.2 Site-Specific Seismic Evaluation

In DCD Tier 2, Section 2.5.2.3, “Site-Specific Seismic Evaluation,” the applicant revised the requirements to clarify that, if the site-specific spectra at foundation level exceed the response spectra in Figures 3.7.1-1 and 3.7.1-2 at any frequency, or if soil conditions were outside the range evaluated for AP1000 DC, a site-specific evaluation can be performed. For sites at which the response spectra exceed the CSDRS, or at which the soil parameters are outside those specified in the DCD, the applicant concluded that either a two-dimensional (2-D) or three-dimensional (3-D) site-specific analysis can be used to demonstrate site suitability.

Two-Dimensional Analyses

The applicant stated that for those features that were not within the site parameters, a site-specific SSI analysis may be performed following the guidance in Appendix 3G to the AP1000 DCD. The applicant stated that the results of such an analysis would need to be compared with the results of the 2-D SASSI analyses described in Appendix 3G and should demonstrate that local features are within the bounds established in the DCD. If the 2-D results are not clearly enveloped at significant frequencies of response, the applicant concluded that a 3-D analysis might be required.

Three-Dimensional Analyses

The applicant described the 3-D analyses that may be required if the 2-D results are inconclusive. The 3-D analyses would consist of a site-specific dynamic analysis and generation of in-structure response spectra at six key locations. Upon completion of the analysis, the COL applicant will need to compare the results with the floor response spectra of the certified design at 5-percent damping. The applicant specified that the CSDRS should be used to develop the floor response spectra, and they should be applied at the foundation level for the hard rock site and at finished grade for a soil site. The applicant concluded that the site would be acceptable if the floor response spectra from the site-specific evaluation did not exceed the AP1000 spectra for each of the following locations: containment internal structures at elevation of reactor vessel support, containment operating floor, auxiliary building at northeast corner elevation of 35.5 m (116.5 ft), shield building at fuel building roof, shield building roof, and the steel containment vessel at polar crane support.

2.5.2.3 Regulatory Basis

The staff relied on the following applicable regulatory requirements and guidance in reviewing the applicant’s discussion of vibratory ground motion:

10 CFR 52.47, with respect to requiring COL applicant to provide site parameters postulated for the design and an analysis and evaluation of the design in terms of those site parameters

- 10 CFR Part 50, Appendix A, GDC 2, as it relates to consideration of the most severe of the natural phenomena that have been historically reported for the site and surrounding area, with sufficient margin for the limited accuracy, quantity and period of time in which the historical data have been accumulated

- 10 CFR 100.23, ”Geologic and seismic siting criteria,” with respect to obtaining geologic and seismic information necessary to determine site suitability and ascertain that any new information derived from site-specific investigations would not impact the GMRS derived by a probabilistic seismic hazard analysis

- RG 1.132, “Site Investigations for Foundations of Nuclear Power Plants”

- RG 1.206, “Combined License Applications for Nuclear Power Plants”

- RG 1.208, “A Performance-Based Approach to Define Site-Specific Earthquake Ground Motion”

2.5.2.4 Evaluation

The applicant stated in Section 2.5.2 that "the AP1000 is also evaluated for a safe shutdown earthquake defined by a peak ground acceleration of 0.30 g and the design response spectra specified in Appendix 3I and Figures 3I.1-1 and 3I.1-2. These design response spectra are applicable to certain east coast rock sites." After examining DCD Figures 3I.1-1 and 3I.1-2, the staff asked the applicant, in RAI-SRP2.5-RGS1-01, to clarify what kind of response spectra the figures presented: GMRS or CSDRS, and to explain why the figures showed a PGA of 0.25 g.

In response to the RAI, the applicant revised the DCD text to clarify that Figures 3I.1-1 and 3I.1-2 showed HRHF response spectra resulting from the applicant's evaluations of hard rock sites, as described in Appendix 3I to the DCD. The applicant clarified that HRHF is not the design spectra, but it is the response spectra that can be used to evaluate the hard rock sites when the site-specific GMRS exceed the CSDRS shown in DCD Figures 3.7.1-1 and 3.7.1-2. The applicant stated that if the site-specific spectra are enveloped by the HRHF, it is non-damaging, and that AP1000 CSDRS control the AP1000 design. The details of the staff's evaluation of the applicant's process to determine the HRHF spectra are described in SER Section 3.7.1.

The applicant also revised Section 2.5.2 of the AP1000 DCD in response to this RAI to state that the AP1000 was designed for an earthquake with a PGA of 0.30 g, referring to the AP1000 CSDRS. In its response, the applicant explained that the PGA of 0.25 g addressed in RAI-SRP2.5-RGS1-01 is not that of the CSDRS, but it is the PGA of the HRHF spectra described above. The staff considers this response adequate as it clarifies the differences between the AP1000 CSDRS and the HRHF shown in DCD Figures 3I.1-1 and 3I.1-2 and the differences between the PGA values of the CSRDS and the HRHF spectra. Since the applicant revised the DCD to clarify the roles of CSDRS and HFRS, the staff considers RAI-SRP2.5-RGS1-01 resolved.

2.5.2.4.1 Combined License Seismic and Tectonics Characteristics Information

The staff considered the guidance in NUREG-0800 while reviewing the use of backfill soil to support the seismic Category I structures. In RAI-SRP2.5-RGS1-02, the staff asked the applicant to clarify how the GMRS would be calculated when backfill soil was involved. In response to this RAI, the applicant revised the DCD to clarify that no soil or backfill layers may exist above the outcrop when determining a site-specific GMRS. The staff reviewed this update in Revision 17 of the AP1000 DCD and noted that the revised DCD clearly describes how the site-specific GRMS should be determined. Since the revised DCD text clearly states that GMRS calculations will not include an overlying soil column, the staff concludes that the applicant's revised DCD satisfies the regulatory requirements; thereby, the staff considers RAI-SRP2.5-RGS1-02 resolved.

The staff found that, in general, requiring the COL applicant to demonstrate that the proposed site satisfies the seven requirements as described in the DCD meets NUREG-0800 guidelines; however, some issues needed to be clarified. In RAI-SRP2.5-RGS1-03, the staff asked the applicant to address the following issues of concern:

- Define "thin soil layer" and "soft soil layer" referred to in Requirement 4.

- Replace the phrase "median estimate" with the phrase "minimum estimate" in Requirement 5.

- Provide acceptance criteria and a basis to show the comparison to be acceptable in Requirement 6.

In response to this RAI, the applicant revised DCD Section 2.5.2.1 by eliminating the sentence containing "thin soil layer" and "soft soil layer" and replacing "median estimate" with "minimum estimate." The applicant also referred to detailed information regarding acceptance criteria for foundation soil in Section 3.7.1.4 of the DCD. After review of these revisions to the DCD, as well as the acceptance criteria for foundation soils found in Section 3.7.1.4 of the DCD, the staff concludes that this information is insufficient to resolve the issues identified in RAI-SRP2.5-RGS1-03 because the information does not satisfy the sixth screening requirement. The staff tracked this as Open Item OI-SRP2.5-RGS1-03.

To resolve the issues identified in Open Item OI-SRP2.5-RGS1-03, the applicant submitted a revised response dated November 9, 2009. In its response, the applicant proposed a revision to the DCD that would make the site acceptance criteria and the six screening criteria described in AP1000 DCD Tier 1 Section 2.5 consistent with those used in site response analyses, seismic system analyses, and SSI analyses. The most important site parameter is the shear wave velocity of the generic site soil profiles. The proposed DCD revision requires the shear wave velocities of the three generic soil profiles (SS, SM soil, and UBSM soil) to be within the lower and upper bounds of the shear wave velocities of the individual layers constituting the site-specific soil profiles. The lower bound and upper bound shear wave velocities correspond to Gmax/1.5 and 1.5*Gmax, respectively, where Gmax is the low-strain maximum shear modulus. The minimum shear wave velocity; however, will still be greater than or equal to 305 m/s (1000 fps). Since the applicant adequately addressed the concerns of the staff by making the site acceptance criteria consistent with the rest of the DCD, and committed to revise the DCD. In a subsequent revision to the AP1000 DCD, the applicant included these changes in the DCD text.

In Section 2.5.2.1 of the DCD, the applicant stated that, when site-specific parameters were not enveloped by the AP1000 standard design, a COL applicant might perform site-specific SSI analyses based on 2-D SASSI models and compare the results with those documented in Appendix 3G to DCD Chapter 3 to determine the adequacy of the standard design for the site. However, in Section 2.5.2.3 of DCD Revision 15, the applicant stated that site-specific SSI analyses should be performed using the 3-D SASSI models described in Appendix 3G. The staff asked the applicant, in RAI-SRP2.5-RGS1-04, to clarify the inconsistency and explain why the AP1000 DCD does not require the COL applicant to perform 3-D SSI analysis for a site at which 3-D effects cannot be ignored (such as a site with sloping excavation). In response to this RAI, the applicant moved the entire paragraph relating to the COL applicant's performance of site-specific SSI analysis from this section to DCD Section 2.5.2.3 and changed the section title from "Sites with Geoscience Parameters outside the Certified Design" to "Site Specific Evaluation." The applicant also explained that a COL applicant would perform a site-specific SSI analysis based on actual site conditions, and if a 2-D analysis was adequate the 3-D analysis would be unnecessary, as discussed in response to RAI-TR85-SEB1-07 and RAI-TR03-015. Furthermore, the applicant added Sections 2.5.2.3.1, "2-D Analyses," and 2.5.2.3.2, "3-D Analyses," to Revision 17 of the DCD. The staff considered these revisions of the AP1000 DCD and finds that, although the revised DCD added two separate sections to define when a 2-D or 3-D analysis would be required, it did not fully address the concerns of the staff described in RAI-SRP2.5-RGS1-04, RAI-TR85-SEB1-07 and in RAI-TR03-015, about the adequacy of a 2-D SSI analysis for an AP1000 structure where loads are not evenly applied on its foundation. The staff was concerned that the site-specific analysis should consider a 3-D effect for site conditions outside the certified design. This issue was tracked as Open Item OI-SRP2.5-RGS1-04.

In a letter dated December 9, 2009, the applicant addressed the staff's concerns described in Open Item OI-SRP2.5-RGS1-04. In its response, the applicant agreed to modify the DCD by adding a requirement that site-specific analysis should consider 3-D effects for cases where site parameters fall outside the certified design and loads are not evenly applied throughout the AP1000 foundation. The staff reviewed the response and concluded that the proposed revision of the AP1000 DCD provides adequate criteria for a site where the site parameters do not meet the certified design. Performing site-specific analyses with consideration of 3-D effects will ensure the stability of structures and foundations. In a subsequent revision to the AP1000 DCD, the applicant included these changes in AP1000 DCD, Tier 2 Section 2.5.2.3, and the issue is closed.

The staff reviewed APP-GW-GLE-004, Revision 0, "Soil and Seismic Parameter Change," with respect to shear wave velocity conditions and the statement made regarding minimum shear wave velocity. In RAI-SRP2.5-RGS1-15, Question 3, Issue 4, the staff asked the applicant to provide the criterion for the case of a soil layer with low-strain shear wave velocities of less than 762 m/s (2,500 fps). In Issue 5 of Question 3 of the same RAI, the staff also asked the applicant to revise the statement made regarding minimum shear wave velocity from "greater than or equal to 1000 fps based on low-strain, best estimate soil properties over the footprint of the nuclear island at its excavation depth" to "greater than or equal to 305 m/s (1000 fps) based on low-strain, minimum soil properties at its excavation depth."

In its response to RAI-SRP2.5-RGS1-15, the applicant first explained that Revision 15 of the AP1000 DCD originally included the criterion for the low-strain shear wave velocity of less than 762 m/s (2,500 fps), but the criterion was removed as indicated in APP-GW-GLE-004. The applicant explained that the tight limits of ±10 percent stated in the previous revision of the DCD were found to be unrealistic based on shear wave velocity variability. The applicant concluded that soil sites would require site-specific evaluation rather than following some special case. With respect to Issue 5, the applicant responded by stating that it would revise DCD Tier 1, Table 5.0-1, and DCD Tier 2, Table 2-1, to reflect the criterion for the minimum shear wave velocity.

The staff reviewed the applicant's responses, and determined that elimination of the criterion for soil layers with seismic velocities less than 762 m/s (2,500 fps) is justifiable, as it is replaced by a more conservative approach, which requires a site-specific evaluation when shear wave velocities are less than 762 m/s (2500 fps). Hence, the staff considers Issue 4 of Question 3 in RAI-SRP2.5-RGS1-15 resolved.

The staff also confirmed the changes made in Revision 17 to the Tier 1 and Tier 2 tables to address the issue raised in RAI-SRP2.5-RGS1-15, Question 3, Issue 5 regarding the minimum shear wave velocity. Based on the fact that the applicant revised the criterion for the low-strain shear wave velocity in DCD Tier 1, Table 5.0-1, and DCD Tier 2, Table 2-1, the staff considers Issue 5 of Question 3 in RAI-SRP2.5-RGS1-15 resolved.

The staff also reviewed the applicant's description of the SSE. In Issue 6 of Question 3 of RAI-SRP2.5-RGS1-15, the staff asked the applicant to address the following five concerns related to the SSE: (1) designate the free-field ground motion "CSDRS" instead of "SSE"; (2) review the definition of "outside the range evaluated for the AP1000 design certification" because possible shear-wave velocity inversions were not discussed, but may significantly affect the results of site response and SSI analyses; (3) clarify whether HRHF GRMS were defined at foundation level or in the free field; (4) amend the statement regarding acceptability of site-specific GRMS falling within the AP1000 HRHF to reflect acceptability "over the entire frequency range"; and (5) update DCD Tier 1, Table 5.0-1, and DCD Tier 2, Table 2-1, to be in agreement with changes made to Section 2s.5. In addition, in RAI-SRP2.5-RGS1-21, Question 3, the staff asked the applicant to further clarify the term HRHF GMRS and the differences between the AP1000 HRHF GMRS and the AP1000 CDRS.

The applicant addressed each item separately in its response. With respect to the staff's first concern, the applicant referred the staff to its response to RAI-SRP2.5-RGS1-02, and stated that "The ground motion response spectra have been revised to the certified seismic design response spectra (CSDRS) instead of the SSE." Since the revised DCD now uses the proper terminology, the staff considers this issue resolved. The applicant addressed the second item in staff's question by referring to its response to RAI-SRP2.5-RGS1-04, and stated that the revised DCD text now states the following: "The shear wave velocity should generally increase with depth. The average low strain shear wave velocity in any layer should not be less than 80 percent of the average shear wave velocity in any layer at higher elevation." Since the applicant clarified the phrase "outside the range evaluated for the AP1000 design certification" as 80 percent of the velocities of the overlying layers, the staff considers this issue resolved. In response to the third concern identified by the staff, the applicant proposed a revision to the DCD and referred the staff to the proposed revisions described in the applicant's responses to RAI-SRP2.5-RGS1-02 and RAI-SRP2.5-RGS1-03. The staff's evaluations of these responses are discussed above. The applicant addressed the fourth staff concern by making a simple revision to include the phrase "over the entire frequency range." Hence, the staff considers this issue resolved. The applicant addressed the fifth item by revising the tables in question and committing to incorporate the revised tables in Revision 17 of the DCD. After reviewing Revision 17 of the AP1000 DCD, the staff determined that the tables in question were revised, but not exactly as specified in the applicant's response to RAI-SRP2.5-RGS1-15. The applicant presented the revision for the site parameter SSE in DCD Tier 1, Table 5.0-1, but not in DCD Tier 2, Table 2-1. Therefore, the staff considered RAI-SRP2.5-RGS1-15 unresolved and tracked this as Open Item OI-SRP2.5-RGS1-15.

To address the staff's concerns described in Open Item OI-SRP2.5-RGS1-15, the applicant submitted a revised response on October 20, 2009, and proposed DCD revisions that are consistent with the commitments made by the applicant in its responses to RAI-SRP2.5-RGS1-02, RAI-SRP2.5-RGS1-03, RAI-SRP2.5-RGS1-04 and RAI-SRP2.5-RGS1-15. In a subsequent revision to the DCD, the applicant incorporated the DCD changes in Tier 1 Table 5.0-1, Tier 2 Table 2-1, and Tier 2 Sections 3.7.1 and 3.7.1.1.

In response to RAI-SRP2.5-RGS1-21, Question 3 the applicant stated that it will replace the term "HRHF GMRS" with "HRHF envelope response spectra" in its next DCD revision. In regard to the issues related to the differences between HRHF and the AP1000 CSDRS, the applicant clarified that the HRHF response spectra are not a second set of CSDRS. The HRHF serves the purpose of determining the acceptability of the site-specific response spectra when there is exceedance in the high-frequency component of the AP1000 CSDRS for a hard rock site. Following further discussions with the staff, the applicant agreed to add sentences to the

Tier 1 table describing when the HRHF frequency could be applied for a site. The added text would state, "Evaluation of a site for application of the HRHF envelope response spectra includes consideration of the limitation on shear wave velocity identified for use of the HRHF envelope response spectra. This limitation is defined by a shear wave velocity at the bottom of the basemat equal to or higher than 7,500 fps, while maintaining a shear wave velocity equal to or above 8,000 fps at the lower depths."

Since specific shear wave velocities were defined for the soil profile that was used in development of the HRHF envelope response spectra, the applicant stated that it will address the limitation on shear wave velocity in its next DCD revision. The applicant also proposed a DCD revision to reflect the necessary changes. Based on review of the response, the staff finds that: (1) The use of "HRHF envelope response spectra" instead of "HRHF GMRS" will eliminate the confusion between design response spectra and GMRS, because the HRHF response spectra are design basis for hard rock site, while the GMRS is obtained from site-specific seismic response analysis; (2) The applicant stated that the HRHF envelope response spectra are not a second set of design spectra but specifically for hard rock sites with higher seismic response spectra in high frequencies. The applicant also specified the shear wave velocity condition for the hard rock sites where the HRHF envelope response spectra may apply; and (3) the proposed DCD revision will ensure that all necessary changes will be documented in the AP1000 DCD. The staff, therefore, concludes that the response to Question 3 of RAI-SRP2.5-RGS1-21 is adequate. The applicant incorporated conforming changes in a subsequent revision to AP1000 DCD Tier 1, Section 5.0, Tables 5.0-1, 5.0-3 and 5.0-4; Tier 2, Table 2-1; Sections 2.5.2, 3I.1, and 3I.2; and Figures 3I.1-1 and 3I.1-2. Therefore, this issue is resolved.

2.5.2.4.2 Sites with Geoscience Parameters outside the Certified Design

In Section 2.5.2.3, the applicant stated that, if soil conditions are outside the range evaluated for the AP1000 DC, a site-specific evaluation can be performed. The staff asked the applicant, in RAI-SRP2.5-RGS1-05, to provide acceptance criteria regarding soil properties. In RAI-SRP2.5-RGS1-06, the staff asked the applicant to state the requirements for a site-specific soil degradation model that is one of the basic inputs to the SSI analysis in the AP1000 DCD. In response to these questions, the applicant indicated that: (1) it would add the requirement for a site-specific soil degradation model in a later revision of the DCD; and (2) Section 3.7.1.4 of the DCD provides tables and figures illustrating soil properties that were used for the design of the nuclear island. The applicant stated that COL applicants referencing the AP1000 DCD would generate site-specific soil profile plots and compare them with the design presented in Section 3.7.1.4. The applicant also stated that it revised DCD Table 3.7.1.4 to reflect the strain compatible properties. The staff considers RAI-SRP2.5-RGS1-06 resolved as the applicant implemented the staff's recommendation and revised the DCD to explicitly state that site-specific soil degradation models are a part of the site-specific soil conditions. Since the applicant stated in its response to RAI-SRP2.5-RGS1-05 that Section 3.7.1.4 of the DCD provides tables and plots that can be used by a COL applicant to compare the site soil profile to determine if the soil conditions are outside the range evaluated for the AP1000 DC, the staff concludes that the applicant's response provided an adequate description of how a COL applicant would assess whether the soil conditions at a site are outside the range defined by the DCD and considers question RAI-SRP2.5-RGS1-05 resolved. Based on the RAI responses from the applicant and review of Section 3.7.1.4, the staff concludes that the applicant provided adequate information to resolve RAI-SRP2.5-RGS1-05 and RAI-SRP2.5-RGS1-06.

The staff considered the incorporation of APP-GW-CLE-004 into DCD Section 2.5.2.3. In RAI-SRP2.5-RGS1-16, the staff asked the applicant to define the term "geoscience parameters" used in the subtitle of Section 2.5.2.3, "Sites with Geoscience Parameters Outside the Certified Design." In addition, the staff also asked the applicant to clarify the discrepancy between DCD Section 2.5.2.3 and DCD Section 3.7.1.1. DCD Section 2.5.2.3 states that a site-specific evaluation can be performed if the site-specific spectra at foundation level exceed the response spectra at any frequency or if the soil conditions are outside the range evaluated in Section 2.5.2.3. DCD Section 3.7.1.1 states that design response spectra are applied at the foundation level in the free field at hard rock sites and at finished grade in the free field at firm rock and soil sites. The staff also asked the applicant to clarify the statement that the site design response spectra at the foundation level in the free-field were used to develop the floor response spectra, which is inconsistent with DCD Section 3.7.1.1 for soil sites.

In its response, the applicant stated that DCD Section 2.5.2.3 was re-written based on the staff's question RAI-SRP2.5-RGS1-04 and referred the staff to its response to RAI-SRP2.5-RGS1-04. In that response, the applicant stated that it revised the title of Section 2.5.2.3 from "Sites with Geoscience Parameters Outside the Certified Design" to "Site Specific Seismic Evaluation." With this revision, the staff considers the first issue closed since the applicant revised the title and eliminated the questioned phrase. The applicant also clarified the apparent discrepancy between DCD Section 2.5.2.3 and Section 3.7.1.1 by revising its response to RAI-SRP2.5-RGS1-04. The applicant revised the DCD to state that "If the site-specific spectra at foundation level at a hard rock site or at grade for other sites exceed the certified seismic design response spectra in Figures 3.7.1-1 and 3.7.1-2 at any frequency, or if soil conditions are outside the range evaluated for AP1000 design certification, a site-specific evaluation can be performed." With this revision, the staff concludes that the apparent discrepancy has been eliminated and the issue resolved. The applicant also modified the DCD to clarify the statement outlined above by the staff's question. The revised DCD clarified this third issue. The DCD text now reads "The certified design response spectra in the free-field given in Figures 3.7.1-1 and 3.7.1-2 were used to develop the floor response spectra." With this revision, the staff considers the third issue in the staff's question above resolved.

2.5.2.5 Post Combined License Activities

The staff will identify post-COL activities on a site-by-site basis as part of the review of a COL application referencing the AP1000 DCD.

2.5.2.6 Conclusions

Based on the review of Revision 17 of the AP1000 DCD Tier 2, Section 2.5.2; Tier 1, Table 5.0-1 (and Tier 2, Table 2-1); and APP-GW-GLE-004, the staff finds that the applicant adequately detailed how to determine site-specific GMRS, specified criteria for a site to be suitable for the AP1000 standard design, and provided detailed guidance on performing site-specific seismic evaluation for sites that do not meet the scope of the seven siting requirements described in the DCD. The applicant also provided a set of site parameters related to the geological and seismological basis for the AP1000 standard design, such as requirements on SSE and associated site response spectra, fault displacement potential, and the subsurface material lateral variability requirement. The staff concludes that the geological and seismological related site parameters and requirements presented in the DCD are acceptable and meet the regulatory requirements of 10 CFR 100.23, GDC 2, and 10 CFR 52.47(a)(1).

The applicant submitted changes to the DCD that provide the seismic design and supporting analysis for a range of soil conditions representative of expected applicants for a COL referencing the AP1000 design. These changes provide increased standardization for this aspect of the design. In addition, these changes reduce the need for COL applicants to seek departures from the current AP1000 design, since many sites do not conform to the currently-approved hard rock sites. Therefore, the change increases standardization and meets the finality criterion for changes in 10 CFR 52.63(a)(1)(vii).

2.5.3 Surface Faulting

The applicant changed the site parameter provided in Tier 1, Table 5.0-1 and Tier 2, Table 2-1, for "Fault Displacement Potential" from "None" in Revision 15 to "Negligible" in Revision 17 of AP1000 DCD. The staff, in Question 1 of the RAI-SRP2.5-RGS1-21, asked the applicant to clarify the definition of "negligible." In its response to this question, the applicant first explained that the reason of making this change is because of the difficulty for a COL applicant to demonstrate that the fault displacement potential for a site is absolutely "None." Following further discussions with the staff, the applicant subsequently proposed to change this site parameter to "No potential fault displacement considered beneath the seismic Category I and seismic Category II structures and immediate surrounding area. The immediate surrounding area includes the effective soil supporting media associated with the seismic Category I and seismic Category II structures." The staff considers that no fault displacement potential beneath these structures is a reasonable design basis for representing most existing nuclear power plant sites, as well as the ESP and COL application site. DCD Section 2.5.3 describes the information on surface faulting that the COL applicant needs to provide to satisfy the requirement for no surface faulting by completing geological, seismological, and geophysical investigations. Therefore, the staff concludes that this design site parameter is acceptable because it is consistent with the guidance in RG 1.206, and can reasonably ensure that the regulatory requirements of 10 CFR 100.23 will be met. Accordingly, the issue of clearly defining the site parameter for fault displacement potential in Question 1 of the RAI-SRP2.5-RGS1-21 is resolved. The applicant incorporated conforming changes in a revised subsequent revision to AP1000 DCD Tier 1, Table 5.0-1 and Tier 2, Table 2-1.

2.5.4 Stability and Uniformity of Subsurface Materials and Foundations

2.5.4.1 Introduction

Section 2.5.4, "Stability and Uniformity of Subsurface Materials and Foundations," of the AP1000 DCD presents the requirements related to stability of subsurface materials and foundations for COL applicants referencing the AP1000 standard design. The site-specific information includes excavation, bearing capacity, settlement, and liquefaction potential.

2.5.4.2 Technical Information in the Application

2.5.4.2.1 Excavation

Section 2.5.4.1 of the AP1000 DCD provides the requirements for site excavation. In this section, the applicant stated that, for the nuclear island structures below grade, a COL applicant may use either a sloping excavation or a vertical face. The applicant further stated that, if a COL applicant uses a sloping excavation, an evaluation of the 3-D effects on the site response and site-specific SSI analyses must be performed using a combination of either 2-D or 3-D SASSI models that reflect the sloping excavations. In the event that a vertical face is used, the

COL applicant would need to cover the face with a waterproof membrane, as described in DCD Section 3.4.1.1.1.1, or use soil nailing and mechanically stabilized earth (MSE) walls as the outside form for the exterior walls below grade of the nuclear island.

DCD Section 2.5.4.1.1 describes the detailed requirements for using a soil nailing method as an alternative to stabilize vertical faces of undisturbed soil or rock below grade for nuclear island structures. The applicant stated that the soil nailing method produced a vertical surface down to the bottom of the excavation and was used as the outside form for the exterior walls below grade of the nuclear island. The applicant also provided details on soil-retaining wall installation in this section.

DCD Section 2.5.4.1.2 describes the MSE as a flexible retaining wall using strip, grid, or sheet type of tensile reinforcements so that the wall behaves as a retaining wall. The applicant stated that the tensile strength of the reinforcements provides internal stability and the walls could be used in areas where retaining wall soils have been removed or elevation needs to be raised.

DCD Section 2.5.4.1.3 describes the mud mat, including both the upper and lower mats, which will be placed ahead of the placement of reinforcements for the foundation mat structural concrete. The applicant stated that both the lower mud mats would have a compressive strength of 17,236 kPa (2,500 psi) and be a minimum of 15.24 cm (6 in) thick. Finally, DCD Section 3.4.1.1.1.1 describes waterproofing system alternatives.

2.5.4.2.2 Bearing Capacity

DCD Section 2.5.4.2, “Bearing Capacity,” specifies that the maximum bearing reaction is less than 1,676 kPa (35,000 pounds per square foot (psf)) under all combined loads, including the SSE, based on the analyses described in Appendix 3G to the AP1000 DCD and occurs at the western edge of the shield building. The DCD applicant noted that the COL applicant would need to verify whether the site-specific allowable soil-bearing capacities for static and dynamic loads would exceed this demand with a factor of safety appropriate for the design load combination, including SSE loads.

In DCD Tier 1, Table 5.0-1, and Tier 2, Table 2-1, the applicant listed the site parameters of average allowable bearing capacity. These tables stated the average allowable static soil bearing capacity as greater than or equal to the average bearing demand of 8,900 psf over the footprint of the nuclear island at its excavation depth. It also defined the maximum allowable dynamic bearing capacity for normal plus SSE loads as greater than or equal to the maximum bearing demand of 35,000 psf at the edge of the nuclear island at its excavation depth, or by performing site-specific analyses to demonstrate a factor of safety appropriate for normal plus SSE loads.

2.5.4.2.3 Settlement

DCD Section 2.5.4.3, “Settlement,” requires the COL applicant to address both short-term (elastic) and long-term (heave and consolidation) settlement for soil sites for the history of loads imposed on the foundation consistent with the construction sequence. The applicant noted that the time-history of settlements should include construction activities and construction of the superstructure. The applicant also stated that the AP1000 design does not rely on SSCs located outside the nuclear island footprint for safety-related functions.

In Revision 17 of the AP1000 DCD, the applicant added Table 2.5-1 which provides guidance to the COL applicant on predictions of absolute and differential settlement that are acceptable without additional evaluation.

2.5.4.2.4 Liquefaction

In DCD Section 2.5.4.4, the DCD applicant stated that the COL applicant will demonstrate that, for soil sites, the potential for liquefaction is negligible for both the soil underneath the nuclear island foundation and at the side embedment engaged in passive resistance adjacent to the nuclear island. DCD Tier 1, Table 5.0-1, as well as Tier 2, Table 2-1, state that liquefaction potential is negligible at the site.

2.5.4.2.5 Subsurface Uniformity

Section 2.5.4.5 of the DCD states that, although the design and analysis of the AP1000 was based on soil or rock conditions with uniform properties within horizontal layers, provisions and design margins to accommodate many nonuniform sites were also included. The applicant described, in detail, the types of site investigation that would be sufficient for a “uniform” site or a “nonuniform” site. The applicant indicated that the acceptability of a nonuniform site would be based on an individual site evaluation. The applicant concluded that, for uniform sites whose site parameters fall within the site profiles evaluated as part of the DC, no further action will be needed. However, for nonuniform sites, or other sites whose parameters do not fall within the site profiles, a site-specific evaluation will need to be performed. For nonuniform sites, Sections 2.5.1 and 2.5.4.6.1 of the DCD outline the geological investigations for the extended investigation effort to determine whether the site is acceptable for construction of an AP1000 reactor. In Revision 17 of the DCD, the applicant deleted Sections 2.5.4.5.1 and 2.5.4.5.2 and labeled them as “Not Used.”

2.5.4.2.5.1 Site Foundation Material Evaluation Criteria

DCD Section 2.5.4.5.3 states that the COL applicant will demonstrate that the variation of subgrade modulus across the nuclear island footprint will be within the range considered for design of the nuclear island basemat. The DCD also stated that the COL applicant will consider the subsurface conditions within the nuclear island footprint and 12.2 m (40 ft) beyond, and to a depth of 36.6 m (120 ft) below finished grade within the nuclear island footprint. The applicant also noted that a uniform site would be acceptable for the AP1000 design, without additional site-specific analyses, based on the analyses and evaluations performed to support the DC. The applicant also outlined two criteria for site uniformity.

2.5.4.2.5.2 Site-Specific Subsurface Uniformity Design Basis

DCD Section 2.5.4.5.3.1 states that nonuniform soil conditions may require the evaluation of the AP1000 seismic response, as described in DCD Section 2.5.2.3.

For the rigid basemat evaluation, the applicant stated that if the site variability can be identified without significant variations in the horizontal direction, a 2-D analysis can be used. However, the applicant also stated that sites with variability in the horizontal direction indicate the need for a 3-D analysis. The applicant further stated that the bearing pressure from the site-specific analysis needs to be less than or equal to 120 percent of that for a similar site with uniform soil properties.

For a flexible basemat evaluation, the applicant stated that soils may be represented by soil springs or by a finite element model, depending on the variability identified at the site. The applicant also pointed out that, for a site to be acceptable, the bearing pressures from the site-specific analyses will need to be less than the design bearing strength of each portion of the basemat under both static and dynamic loads.

In DCD Tier 1, Table 5.0-1, the applicant addressed the site parameters for lateral variations by stating that the soils supporting the nuclear island should not have extreme variations in subgrade stiffness. The applicant described the documentation of variations as follows:

- Soils supporting the nuclear island are uniform in accordance with RG 1.132 if the geologic and stratigraphic features at depths less than 36.6 m (120 ft) below grade can be correlated from one boring or sounding location to the next with relatively smooth variations in thicknesses or properties of the geologic units; or

- Site-specific assessment of subsurface conditions demonstrates that the bearing pressures below the footprint of the nuclear island do not exceed 120 percent of those from the generic analyses of the nuclear island at a uniform site; or

- Site-specific analysis of the nuclear island basemat demonstrates that the site-specific demand is within the capacity of the basemat.

The applicant further stated that, as an example of sites that are considered uniform, the variation of shear wave velocity in the material below the foundation to a depth of 36.6 m (120 ft) below finished grade within the nuclear island footprint and 12.2 m (40 ft) beyond the boundaries of the nuclear island footprint meets the criteria in the case outlined below.

Case 1: For a layer with a low-strain shear wave velocity greater than or equal to 2,500 fps, the layer should have approximately uniform thickness, should have a dip not greater than 20 degrees, and should have less than 20-percent variation in the shear wave velocity from the average velocity in any layer.

DCD Tier 1, Table 5.0-1, also states that the shear wave velocity should be greater than or equal to 305 m/s (1,000 ft/s) based on minimum low-strain soil properties over the footprint of the nuclear island at its excavation depth.

2.5.4.2.6 Combined License Information

In response to RAI-TR-85-SEB1-36 (Revision 4 dated October 22, 2010), the applicant proposed to revise Section 2.5.4.6.11 to state that the COL applicant will provide data on short-term (elastic) and long-term (heave and consolidation) settlement for soil sites for the history of loads imposed on the nuclear island foundation and adjacent buildings consistent with the construction sequence. The response also specifies that special construction requirements will be described, if required, to accommodate settlement predicted to exceed the design settlement limits.

In response to RAI-TR-85-SEB1-17 (Revision 5 dated July 15, 2010), the applicant proposed to revise Section 2.5.4.6.11 to state that Section 3.8.5.4.2 includes analyses of settlement during construction completed to support the DC and the required limitations on construction sequence for some sites. The limitations on construction sequence impose limits on the placement of concrete for the shield building and the auxiliary building prior to completion of both buildings at elevation 25.15 m (82.5 ft).

In response to RAI-TR-85-SEB1-35 (Revision 3 dated, June 30, 2010), the applicant proposed to add Section 2.5.4.6.12, “Waterproofing System” to the DCD. This section states that the COL applicant shall provide a waterproofing system used for the foundation mat (mudmat) and below grade exterior walls exposed to flood and groundwater under seismic Category I structures. It specifies that the waterproofing membrane should be placed immediately beneath the upper mudmat and on top of the lower mudmat. This section also refers the detailed performance requirements for the waterproofing system to Section 3.4.1.1.1.1.

All COL information items are summarized in AP1000 DCD Tier 2, Table 1.8-2, “Summary of AP1000 Standard Plant Combined License Information Items.”

2.5.4.3 Regulatory Basis

The applicable regulatory requirements and guidance for reviewing the applicant’s discussion of stability of subsurface materials and foundations are as follows:

- 10 CFR Part 50, Appendix A, GDC 2, as it relates to consideration of the most severe of the natural phenomena that have been historically reported for the site and surrounding area, with sufficient margin for the limited accuracy, quantity, and period of time in which the historical data have been accumulated.

- 10 CFR Part 50, Appendix S, “Earthquake Engineering Criteria for Nuclear Power Plants,” as it applies to the ability of the design of nuclear power plant SSCs important to safety to withstand the effects of earthquakes.

- 10 CFR 100.23, which provides the nature of the investigations required to obtain the geologic and seismic data necessary to determine site suitability and identify geologic and seismic factors required to be taken into account in the siting and design of nuclear power plants.

- RG 1.132

- RG 1.138, “Laboratory Investigations of Soils for Engineering Analysis and Design of Nuclear Power Plants”

- RG 1.206

2.5.4.4 Evaluation

2.5.4.4.1 Excavation

In DCD Section 2.5.4.1, the applicant stated that if a sloping excavation was used for a site, then the 3-D effect on the SSI analysis should be considered. In RAI-SRP2.5-RGS1-07, the staff asked the applicant to add this statement to the DCD as a requirement for COL applicants. In response to this RAI, the applicant added a requirement for the COL applicant to evaluate the 3-D effects by performing a site-specific SSI analysis using either 2-D or 3-D SASSI models, or both, for sloping excavations. The staff reviewed DCD Revision 17 and confirmed that the applicant had included this updated information. Accordingly, the staff considers the revised DCD to be sufficient to resolve RAI-SRP2.5-RGS1-07, which requested that the applicant include the requirement to evaluate the 3-D effects through site-specific SSI analyses in the DCD.

Since the staff found that at least one COL applicant used precast facing panels to retain the side soil, RAI-SRP2.5-RGS1-08 asked the applicant to clarify whether it would revise the DCD regarding other methods that can be used to retain the vertical excavation face. In response to this RAI, as well as to RAI-TR85-SEB1-040, the applicant stated that it substantially revised Section 2.5.4.1 to address the option of using an MSE wall with precast concrete facing panels to retain the side soil. The staff reviewed the revisions to the DCD, particularly the option to use an MSE wall, and concludes that the additional options to retain side soil are sufficient to resolve the geotechnical engineering aspects of RAI-SRP2.5-RGS1-08. Therefore, the staff considers this RAI resolved.

2.5.4.4.2 Bearing Capacity

Based on its review of Section 2.5.4.2, the staff raised the following concerns in RAI-SRP2.5-RGS1-09:

- Since bearing capacity is highly site-specific, replace the “bearing capacity” value calculated from seismic analyses with the “bearing demand” value based on the maximum foundation contact pressure.

- Justify why Revision 16 states that the maximum allowable dynamic bearing capacity (bearing demand) is greater than or equal to 1,676 kPa (35,000 psf), which is far less than 5,746 kPa (120,000 psf), as listed in the prior revision of DCD Tier 1, Table 5.0-1, and DCD Tier 2, Table 2-1.

- Define the “factor of safety” for the bearing capacity evaluation.

In response to this RAI, the applicant replaced the term “bearing capacity” with “bearing demand” in DCD Tier 1, Table 5.0-1, and DCD Tier 2, Table 2-1, and changed average allowable static soil bearing capacity from 421 kPa (8,600 psf) to 426 kPa (8,900 psf) to reflect the enhanced shield building design. Revision 17 of the DCD includes these changes, and the staff considers Issue 1 of RAI-SRP2.5-RGS1-09 resolved.

In response to Issue 2 above, the applicant referred the staff to its response to RAI-TR85-SEB1-03 for an explanation as to why Revision 16 of the AP1000 DCD listed the bearing capacity value of 1,676 kPa (35,000 psf). In responding to the RAI, the applicant stated that this difference resulted from: (1) Different seismic loads being applied to the foundation dynamic response analysis. The prior revision used a seismic load for hard rock certified design, while the current version used a design that envelops all rock and soil cases; and (2) the prior revision used the results from a more conservative equivalent static analyses, while the current version used the result from a nonlinear dynamic analyses. The dynamic nonlinear analyses showed a much lower bearing reaction (1,331 kPa (27,008 psf) for hard rock) than those from the equivalent static design analyses for the basemat. Using the commercial computer software 2-D ANSYS, the applicant completed nonlinear analyses, which yielded higher bearing pressures (1,652 kPa (34,500 psf)) for a SM soil case than those for the hard rock case. Based on the new analysis results, the applicant chose the soil bearing reaction of 1,676 kPa (35,000 psf) to cover both soil and rock sites. The applicant further indicated that the bearing pressures from the ANSYS analyses were conservative because the effect of the side soil was neglected. Since the applicant re-analyzed the bearing capacity calculations using a more realistic non-linear soil model, the staff considers this reduction in bearing capacity value as acceptable since the non-linear model would result in more realistic estimates than the previous equivalent static analyses the applicant conducted. Hence, the staff considers Issue 2 resolved.

Regarding the factor of safety used for the bearing capacity evaluation, the applicant stated that the factor of safety should be site-specific and, therefore, COL applicants will be responsible for defining an appropriate factor of safety for their sites. Since this issue will be addressed by each COL applicant, the staff considers Issue 3 in RAI-SRP2.5-RGS1-09 resolved.

After reviewing the applicant's response, including the revision of the DCD, the explanation of the allowable bearing capacity, and the site-specific nature of the factor of safety, the staff concludes that the applicant provided adequate information to address all three areas of concern identified in RAI-SRP 2.5-RGS1-09. However, since RAI-SRP2.5-RGS1-09 also relates to another RAI related to structural engineering (RAI-TR85-SEB1-03), the staff will not consider the RAI resolved until the applicant adequately addresses the structural engineering concerns. This issue was tracked as Open Item OI-SRP2.5-RGS1-09.

To close Open Item OI-SRP2.5-RGS1-09, the applicant provided a response to RAI-TR85-SEB1-03, dated September 18, 2007. In the response, the applicant provided detailed explanations of the soil model used in the 3-D ANSYS finite element model and how it determined the maximum dynamic bearing pressure. In a later response dated October 20, 2009, the applicant also provided a new maximum bearing demand value that is based on a 3-D SASSI analyses. As a result of these new analyses, a more realistic and conservative limit of maximum bearing seismic demand will now be used as a site parameter in the DCD. Based on the review of the applicant's responses to RAI-TR85-SEB1-03 and Open Item OI-SRP2.5-RGS1-09, the staff concludes that the analysis model used in the dynamic bearing pressure determination is adequate and that the design parameter specified in the DCD is reasonable. Because the applicant adequately addressed all issues identified in RAI-TR85-SEB1-03, Open Item OI-SRP2.5-RGS1-09, and RAI-TR85-SEB1-03, and also because the staff confirmed that the applicant revised related site parameters in AP1000 DCD, Open Item OI-SRP2.5-RGS1-09 is closed.

While reviewing this section, the staff also considered the information provided in APP-GW-GLE-004 and DCD Tier 1, Table 5.0-1. The staff asked the applicant, in Questions 1 and 2 of RAI-SRP2.5-RGS1-15, to clarify the use of the terms, "average allowable static soil bearing capacity," and "average allowable dynamic soil bearing capacity," and justify the use of the phrase "greater than or equal to" for the calculated soil bearing demand values. In its response, the applicant cited the proposed changes to DCD Tier 1, Table 5.0-1, and DCD Tier 2, Table 2-1, made in response to RAI-SRP2.5-RGS1-09, which include the definitions of average allowable static and dynamic bearing capacity. In response to the second question, the applicant stated that site-specific allowable bearing capacity must be "greater than or equal to" the AP1000 calculated demand values. Since the staff had already determined that the revisions to the two tables were acceptable in RAI-SRP2.5-RGS1-09, the staff concludes that Question 1 of RAI-SRP2.5-RGS1-15 is resolved. Furthermore, the staff considered the statement of requiring the site-specific allowable bearing capacity to be greater than or equal to the calculated demand values and concludes that this statement sufficiently addresses the geotechnical engineering concerns of the second question of RAI-SRP2.5-RGS1-15. Accordingly, the staff considers Questions 1 and 2 of RAI-SRP2.5-RGS1-15 to be resolved.

In RAI-SRP2.5-RGS1-21, Question 2, the staff also requested the applicant redefine the site parameter for dynamic bearing capacity, which is labeled as “Maximum Allowable Dynamic Bearing Capacity for Normal Plus Safe Shutdown Earthquake (SSE)” used in AP1000 DCD, Revision 17, Tier 1, Table 5.0-1 and Tier 2, Table 2-1. The staff considered this label to not clearly define the requirement that a site must have the minimum capacity to meet the maximum dynamic bearing demand. Therefore, in Question 2 of RAI-SRP2.5-RGS1-21, the staff asked the applicant to justify the use of “Maximum Allowable” for dynamic bearing capacity parameter. In response to this RAI, the applicant stated that the modifier “maximum allowable” was not necessary and proposed to eliminate it from the referenced tables. Based on this proposed change the staff considers Question 2 of RAI-SRP2.5-RGS1-21 resolved. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

2.5.4.4.3 Settlement

In response to RAI-TR85-SEB1-36 (Revision 4 dated October 22, 2010), regarding the settlement criteria, the applicant proposed the following revisions to the AP1000 DCD:

1. Adding “Limits Of Acceptable Settlement Without Additional Evaluation” site parameter in Tier 1, Table 5.0-1, which specifies the design settlement limits.

2. Adding detailed settlement criteria in DCD Section 2.5.4.3 to specify that the predicted settlements will cover the periods before and through the construction phase, and for the subsequent plant operating period or otherwise justified. The COL applicant needs to provide detailed evaluation and construction sequence plan if the predicted settlements exceed the limits of design settlements. For a soil site, settlements would be measured and compared to the predicted settlement values during construction and plant operation, and any exceedances would require additional investigation.

3. Procedures for additional settlement evaluation were provided, the word “suggested” being removed from the characterization of the alternatives. The procedures include evaluating the impact of the elevated estimated settlement values on the critical components of the AP1000 structures; submitting a construction sequence to control the predicted settlement behavior; providing a uniform excavation and engineered backfill to manage static building rotation and differential settlement between the nuclear island and adjacent structures; and implementing an active settlement monitoring system throughout the entire construction sequence and plant operation (a long-term plan). The proposed DCD revision also specifies primary elements in the settlement monitoring system, and requires that the settlement data to be maintained during construction and post-construction, as needed, depending on the field measurement results.

The staff reviewed the settlement requirements for the AP1000 reactor, as specified in Tier 1, Table 5.0-1 and Tier 2, Section 2.5.4.3 and Table 2.5-1 of the AP1000 DCD, and the assertion that because of the locations of all safety-related structures on the nuclear island, the differential settlement requirements are defined for adjacent structures. The staff also reviewed the proposed methods for additional evaluation if the predicted settlements exceed the design limits at a COL site, and the requirement for implementing an active settlement monitoring system throughout the entire construction sequence, including plant operation (long-term plan), for a soil site. The staff concludes that the applicant adequately described settlement criteria and provided clear requirements and detailed evaluation procedure for COL applicants referencing the AP1000 DCD to follow. Therefore, the settlement requirements described in the DCD are sufficient and acceptable. However, the applicant proposed to revise the settlement requirements in Tier 2, Section 2.5.4.3, “Settlement,” and to add the settlement site parameter to Tier 1, Table 5.0-1, as stated in its response to RAI-TR-85-SEB1-36. In a subsequent revision to the AP1000 DCD, the applicant made appropriate changes to the DCD text, which resolves this issue.

2.5.4.4.4 Liquefaction

During the review of DCD Section 2.5.4.4, the staff noted that DCD Tier 1, Table 5.0-1 and DCD Tier 2, Table 2-1 in Revision 15, stated the liquefaction potential at the plant site as “NONE.” In Revision 16 of DCD Section 2.5.4.4, the applicant changed ‘NONE’ to “NEGLIGIBLE.” In separate questions, RAI-SRP2.5-RGS1-11 and Question 1 in RAI-SRP2.5-RGS-21, the staff asked the applicant to define how and where the potential for liquefaction was negligible at a site. In response to these RAIs, the applicant revised Section 2.5.4.4 to define that, for a soil site, the COL applicant should demonstrate that the potential for liquefaction was negligible for both the soil underneath the nuclear island foundation and the soil of the side embedment engaged in passive resistance adjacent to the nuclear island. The applicant restated in DCD Revision 17 that for the AP1000 liquefaction beneath the certified design. The applicant further stated:

> The AP1000 design has not been evaluated for a site where there is a liquefaction potential of the soil below the nuclear island. A COL applicant must describe the soil and rock structure beneath the nuclear island in their application. DCD Subsection 2.5.4.6 describes the geotechnical information that should be provided by the COL applicant. Liquefaction potential for the site is evaluated for the site specific SSE ground motion (specific site GMRS). A COL applicant will satisfy the requirement for no liquefaction by providing information concerning the properties and stability of supporting soils and rock consistent with the guidance of regulatory guide 1.206.

Regarding the word change from “None” to “Negligible,” the applicant explained that the reason for making this change is because of the difficulty for a COL applicant to demonstrate the liquefaction potential at a site as absolutely “None.” The applicant, however, recognized that the AP1000 design has not been evaluated for a site where there is a liquefaction potential of the soil below the nuclear island. Following further discussions with the staff, the applicant subsequently proposed to change this site parameter to “No liquefaction considered beneath the seismic Category I and seismic Category II structures and immediate surrounding area. The immediate surrounding area includes the effective soil supporting media associated with the seismic Category I and seismic Category II structures.” The staff considers that no potential liquefaction beneath these structures at a site is a reasonable design basis for representing most of the existing nuclear power plant sites, as well as ESP and COL application sites. DCD Section 2.5.4.6 describes the information concerning the properties and stability of supporting soils and rock that the COL applicant needs to provide in order to evaluate the liquefaction potential beneath the nuclear island and to satisfy the requirement of no liquefaction potential. Therefore, the staff concludes that this design site parameter is acceptable because it is consistent with the guidance of RG 1.206, and can reasonably ensure the regulatory requirements of 10 CFR 100.23 are met.

Based on the applicant’s responses and the staff’s confirmation that Revision 17 of the AP1000 DCD includes these revisions, the staff concludes that the applicant clarified the liquefaction potential requirement and sufficiently addressed the concerns of the RAIs. Accordingly, the staff considers RAI-SRP2.5-RGS1-11 and Question 1 of RAI-SRP2.5-RGS-21 resolved provided the proposed changes are incorporated in the revised DCD Tier 1 Table 5.0-1 and Tier 2, Table 2-1. In a subsequent revision to the AP1000 DCD, the applicant made appropriate changes to the DCD text, which resolves this issue.

2.5.4.4.5 Subsurface Uniformity

At the end of Section 2.5.4.5, Revision 15 of the DCD presented a survey of 22 commercial nuclear power plant sites in the United States that focused on site parameters that affect the seismic response. All but one of the 22 sites were uniform sites. In RAI-SRP2.5-RGS1-12, the staff questioned the purpose of this survey and the reasons for its inclusion in the AP1000 DCD. As a response to this RAI, the applicant removed the paragraph referencing the survey, having decided that it was no longer applicable. Since the questionable paragraph has been removed, the staff considers RAI-SRP2.5-RGS1-12 to be resolved.

Regarding the site investigation criteria, in RAI-SRP2.5-RGS1-13, the staff asked the applicant to explain why it addressed issues related to settlement caused by static loads but did not consider the criteria needed to evaluate site response and dynamic SSI issues. In response to this RAI, the applicant revised the DCD to remove Sections 2.5.4.5.1 and 2.5.4.5.2, stating that the site investigation criteria should not be part of the DCD, but should be part of the COL applicant’s submittal. Since the content in question was removed from the DCD, the staff considers this RAI resolved.

In RAI-SRP2.5-RGS1-14, the staff asked the applicant to clarify and provide the basis for evaluation criteria for the site uniformity discussed in APP-GW-GLE-004. The applicant responded by referring to the evaluation criteria given in DCD Section 2.5.4.5, as revised in the technical report. The applicant stated that the AP1000 would be acceptable at uniform sites without further evaluation based on the definition of uniform given in RG 1.132. The applicant justified the acceptability of relatively smooth variations by citing design analyses of the basemat described in DCD Section 3.8.5, which considered the basemat to be supported by uniform soil springs. Furthermore, the applicant indicated that the AP1000 design included a 20-percent margin above the results of uniform soil springs to accommodate the smooth variations that may occur at a uniform site. Finally, the applicant stated that, although additional evaluation would be required for nonuniform sites, the level of detail would depend on the nonuniformity identified in the site investigations.

The staff considered this response, particularly the 20-percent margin above uniformity of soil springs, as well as the applicant’s adoption of the definition of “uniform” as described in RG 1.132, and concluded that the applicant adequately addressed the concern of variations in uniformity of the site identified in the RAI. Therefore, the staff considers RAI-SRP2.5-RGS1-14 resolved.

In Question 3 of RAI-SRP2.5-RGS1-15, the staff asked the applicant to: (1) clarify the definition of uniform soils in Criterion 1 and address the incorporation of specific criteria on shear wave and compressional wave velocity profiles needed to ensure the adequacy of SSI calculations; (2) clarify how the variability in bearing pressure relates to the corresponding variability of the soil stiffness and shear wave velocity and describe the basis of Criterion 2; and (3) provide the basis for using the phrase “within the NI [nuclear island] footprint” in describing Criterion 3, since the zone of influence under the foundation level would extend beyond the boundary of the nuclear island foundation mat.

The applicant responded to the first issue of Question 3 by stating that, while the uniformity conditions of RG 1.132 were subjective, for sites where uniformity was not clear, the site will be evaluated as nonuniform. The applicant provided more discussion on shear wave velocity profiles in DCD Section 2.5.2. With respect to the second issue, the applicant stated that the AP1000 design included a 20-percent margin above the results of the uniform soil springs analyses to accommodate relatively smooth variation in soil springs at uniform sites. The applicant further stated that the member forces and required reinforcement were conservatively assumed to increase in the same percentage as bearing pressure. With respect to the third issue of Question 3, the applicant reiterated information from Paragraph 3 of DCD Section 2.5.4.5.3 stating that it will add the phrase "and 40 feet [12.2 m] beyond the boundaries of the nuclear island footprint" to both DCD Tier 1, Table 5.0-1, and DCD Tier 2, Table 2-1.

The staff reviewed the applicant's response and confirmed that the applicant updated DCD Tier 1, Table 5.0-1, and DCD Tier 2, Table 2-1, in Revision 17 of the DCD with the additions described in the RAI response. The staff concludes that the applicant provided sufficient information to address the concerns of site uniformity, uniform soil springs analyses, and the zone of influence at the nuclear island foundation mat. Accordingly, the staff considers Issues 1 through 3 of Question 3 of RAI-SRP2.5-RGS1-15 resolved.

In RAI-SRP2.5-RGS1-17, the staff asked the applicant to explain the applicability of the survey of nuclear power plant conditions in the United States and how the survey results can be used to justify the site uniformity of a prospective site. In response to this RAI, the applicant pointed out that it had deleted the paragraph regarding the survey of nuclear plant conditions in response to RAI-SRP2.5-RGS1-12. Since RAI-SRP2.5-RGS1-12 is already considered resolved, the staff concludes that RAI-SRP2.5-RGS1-17 is also resolved.

In RAI-SRP2.5-RGS1-18, the staff asked the applicant to incorporate in DCD Section 2.5.4.5.1, the potential effects of a lack of uniformity outside the nuclear island footprint in SSI responses. In response to this RAI, the applicant referred to its response to RAI-SRP2.5-RGS1-13, in which the applicant stated that it planned to delete DCD Sections 2.5.4.5.1 and 2.5.4.5.2. Since RAI-SRP2.5-RGS1-13 is resolved, the staff concludes that RAI-SRP2.5-RGS1-18 is also resolved.

In RAI-SRP2.5-RGS1-19, the staff asked the applicant to clarify why it did not discuss faulting criteria. The applicant responded that, although faulting was not discussed as a separate criterion, faulting may result in different soil properties on each side of a fault and that, therefore, the difference in properties would be evaluated against the criteria for lateral variability. The staff reviewed this response and finds that an assessment of lateral variability of soils will be an acceptable substitute to faulting criteria because it will address the offset of the fault in the site area. Therefore, the staff concludes that RAI-SRP2.5-RGS1-19 is resolved.

Finally, in RAI-SRP2.5-RGS1-20, the staff asked the applicant to justify the exclusion of site uniformity evaluation criteria for the case of a soil layer with a low-strain shear wave velocity less than 762 m/s (2,500 fps). In its response, the applicant referred to RAI-SRP2.5-RGS1-15 Question 3, Issue 4, which stated that soil sites would require a site-specific evaluation because of the unrealistically tight limit of ±10 percent. The staff resolved this question in its review of the applicant's response to RAI-SRP2.5-RGS1-15. Therefore, the staff concludes that RAI-SRP2.5-RGS1-20 is resolved.

2.5.4.4.6 Combined License Information

In AP1000 DCD Tier 2 DCD Section 2.5.4.6, the applicant summarizes all COL information items related to geotechnical engineering aspects of a site, with brief descriptions and pointers to related DCD sections, that COL applicants referencing the AP1000 design must address. The COL information items are also listed in AP1000 DCD Tier 2, Table 1.8-2. The staff reviewed this section and concluded that it is necessary to summarize all COL information items to ensure that COL applicants adequately address those items in the COL application to meet the design requirements; therefore, this section is acceptable. However, since the applicant proposed to revise Section 2.5.4.6.11, "Settlement of Nuclear Island," to add Section 2.5.4.6.12, "Waterproofing System," to DCD Tier 2, Section 2.5.4.6; and to add COL Information Item 2.5-17 to DCD Tier 2, Table 1.8-2, as stated in its response to RAI-TR-85-SEB1-17, RAI-TR-85-SEB1-35 and RAI-TR-85-SEB1-36. In a subsequent revision to the AP1000 DCD, the applicant made appropriate changes to the DCD text, which resolves this issue.

2.5.4.5 Post Combined License Activities

The staff will identify post-COL activities on a site-by-site basis as part of its review of a COL application referencing the AP1000 DCD.

2.5.4.6 Conclusions

Based on its review of Revision 17 of AP1000 DCD Section 2.5.4; DCD Tier 1, Table 5.0-1, and Tier 2, Table 2-1; and APP-GW-GLE-004, as well as the applicant's responses to RAIs and open items, the staff finds the following:

- The applicant described the requirements for site excavation and backfill used for safety-related structure foundations, as well as the requirement for soil retaining structures for COL applicants that reference the AP1000 standard design. The staff finds this acceptable.

- The applicant presented the technical basis for establishing proper static and dynamic foundation bearing capacity requirements, which consider the design static and dynamic loadings, including SSE seismic loading. The staff finds this acceptable.

- Based on the previous review and evaluation performed by the staff, as well as the proposed revisions to DCD Revision 17, the specification regarding foundation settlement adequately addressed the settlement requirement for the AP1000 nuclear island foundation and adjacent structures, and procedures for COL applicants to follow if predicted settlement exceeds the design limits. The staff finds this acceptable.

- The information provided by the applicant in the DCD on subsurface uniformity is reasonable, and the site investigation and site foundation material evaluation criteria are acceptable because they acknowledge that site parameter information is required to satisfy the design and regulation. The staff finds this acceptable

In summary, the staff finds that the changes to AP1000 DCD Tier 1, Table 5.0-1, and DCD Tier 2, Section 2.5.4, adequately describe the site-specific geotechnical and geophysical information and investigations that a COL applicant referencing the AP1000 DCD must provide to determine the properties and stability of all soils and rock that may affect the safety of nuclear power plant facilities, under both static and dynamic conditions, including the vibratory ground motions associated with the SSE. The staff concludes that the geological, seismological, and geotechnical engineering-related site parameters presented in Tier 1, Table 5.0-1, as well as in Tier 2, Table 2-1, are acceptable, because they meet the requirements of GDC 2, 10 CFR 52.47(a)(1), and 10 CFR 52.47(a)(2)(iv).

The applicant submitted changes to the DCD that provide the seismic design and supporting analysis for a range of soil conditions representative of expected applicants for a COL referencing the AP1000 design. These changes provide increased standardization for this aspect of the design. In addition, these changes reduce the need for COL applicants to seek departures from the current AP1000 design, since many sites do not conform to the currently-approved hard rock sites. Therefore, the change increases standardization and meets the finality criterion for changes in 10 CFR 52.63(a)(1)(vii).

2.5.5 Combined License Information for Stability and Uniformity of Slopes

The applicant made no additions or changes to DCD Section 2.5.5 from the certified design of Revision 15 of the DCD; therefore, the staff did not reevaluate any of the previously certified information in this section.

2.5.6 Combined License Information for Embankments and Dams

The applicant made no additions or changes to DCD Section 2.5.6 from the certified design of Revision 15 of the DCD; therefore, the staff did not reevaluate any of the previously certified information in this section.

3. DESIGN OF STRUCTURES, COMPONENTS, EQUIPMENT, AND SYSTEMS

Westinghouse Electric Company, LLC (Westinghouse or the applicant) has submitted information in support of its design certification (DC) amendment application that it considers "proprietary" within the meaning of the definition provided in Title 10 of the Code of Federal Regulations (10 CFR) 2.390(b)(5), "Public inspections, exemptions, requests for withholding." The applicant has requested that this information be withheld from public disclosure and the Nuclear Regulatory Commission (NRC) staff agrees that the submitted information sought to be withheld includes proprietary commercial information and should be withheld from public disclosure. This chapter of the NRC staff's evaluation includes proprietary information that has been redacted in order to make the evaluation available to the public. The redacted information will appear as a blank space surrounded by "square brackets" as follows:

[ ]

The complete text of this chapter, including proprietary information, can be found at Agencywide Documents Access and Management System (ADAMS) Accession Numbers ML112091879. This document can be accessed by those who have specific authorization to access the applicant's proprietary information.

3.2 Classification of Structures, Systems, and Components

3.2.1 Seismic Classification

Revisions 16 and 17 of the AP1000 Design Control Document (DCD) include a number of changes to Section 3.2.1, Tables 3.2-2 and 3.2-3 as well as related Chapter 17 changes for quality assurance (QA) requirements. The change to Section 3.2.1 is limited to a clarification regarding reference to 10 CFR 50.34, "Contents of applications; technical information," rather than 10 CFR Part 100, "Reactor site criteria." The change to Table 3.2-2 consists of the inclusion of notes to clarify the non-seismic (NS) classification of certain structures described in other DCD sections. The changes to the Table 3.2-3 primarily involve the addition of components and their seismic classifications.

3.2.1.1 Evaluation

The staff reviewed Revisions 16 and 17 of the DCD according to the guidance in NUREG-0800, "Standard Review Plan [SRP] for the Review of Safety Analysis Reports for Nuclear Power Plants," Section 3.2.1, "Seismic Classification," which references Regulatory Guide (RG) 1.29, , "Seismic Design Classification," Revision 4; RG 1.143, , "Design Guidance for Radioactive Waste Management Systems, Structures, and Components Installed in Light-Water-Cooled Nuclear Power Plants," Revision 2; RG 1.151, "Instrument Sensing Lines," Revision 1; and RG 1.189, "Fire Protection for Nuclear Power Plants," Revision 2, for seismic classification of various structures, systems, and components (SSCs). As identified in 10 CFR 52.47, "Contents of applications; technical information," the application is based on regulatory guide revisions that were in effect 6 months before the docket date of the initial application. An NRC audit of design specifications performed October 13-17, 2008, for risk-significant components was also considered relative to seismic classification. The staff reviewed related technical reports (TRs) and also reviewed the nonsite-specific SSCs included in DCD Section 3.2.1 to determine if the scope was essentially complete.

The staff determined that the Section 3.2.1 change referencing 10 CFR 50.34 rather than 10 CFR Part 100 was acceptable, since 10 CFR 50.34 is referenced in the definition of the term safety-related in addition to 10 CFR Part 100. Both regulations provide similar acceptance criteria for offsite doses. The other DCD changes were primarily intended to resolve staff questions on the regulatory treatment of nonsafety systems (RTNSS). The staff determined that the clarifying notes to Table 3.2-2 were acceptable on the basis that structures designated as NS have augmented seismic requirements described in other DCD sections.

The staff's review of the DCD classification changes for RTNSS determined that, in general, the specific changes identified in the amendment are acceptable, but during the review of Revision 16, the staff identified several potential errors and omissions in a number of technical areas that needed clarification in the DCD. The staff reviewed Revision 17 to determine if the issues identified during the Revision 16 review could be closed. The staff's review evaluated the DCD changes to determine if it was appropriate to resolve these errors and omissions and these are discussed below under each topic. The technical review and resulting requests for additional information (RAIs) are not considered to represent new NRC requirements, but are intended to clarify statements in the DCD and address omissions in the application that have not been reviewed in the DC.

Augmented Seismic Requirements for RTNSS SSCs (RAI-SRP3.2.1-EMB2-01)

To comply with 10 CFR Part 50, "Domestic licensing of production and utilization facilities," Appendix A, "General Design Criteria for Nuclear Power Plants," General Design Criteria (GDC) 2,, "Design Basis for Protection Against Natural Phenomena," SSCs important to safety are to be designed to withstand earthquakes. RTNSS SSCs that are important to safety but not specifically considered safety-related need not be classified as seismic Category I, but do require additional seismic design considerations under the RTNSS process to enable them to withstand earthquakes and meet GDC 1. The extent to which non-safety-related SSCs are seismically qualified is defined by the RTNSS process.

In DCD Revisions 16 and 17, a number of changes were made to the classification of SSCs including classification Table 3.2-3; and the changes in Revision 17 include previously omitted SSCs important to safety, such as the ancillary diesel generators and portions of the fire protection system (FPS).

The inclusion of the ancillary diesel generators reflects a Revision 16 RAI response defining additional seismic requirements for this RTNSS equipment to be located within buildings designed to Uniform Building Code (UBC) seismic requirements with additional requirements designated in some cases. DCD Section 8.3.1.1.3 identifies that the ancillary diesel generators and the fuel tanks are located in the portion of the Annex Building that is a seismic Category II structure. This location is acceptable because the supplemental seismic treatment does meet minimum requirements defined in the staff requirements memorandum (SRM) dated June 23, 1997, concerning SECY-96-128, "Policy and Key Technical Issues Pertaining to the Westinghouse AP600 Standardized Passive Reactor Design," for equipment needed post-72 hour to be located such that there are no spatial interactions with any other nonseismic SSCs. On the basis of the SRM, no dynamic qualification of active equipment is necessary for SSCs needed for post-72 hour actions and staff considers equipment location in a seismic Category II building with seismic Category II anchorage to be acceptable. The RAI response also indicated that the seismic classification of SSCs is considered to be complete, but if design finalization identifies changes, the design change process should identify changes that would impact the detailed application of the classification to systems and components.

Although the standpipe portions of the FPS that are inside the reactor containment and auxiliary building are designated in DCD Table 3.2-3 as NS, comments in the table stipulate a seismic analysis consistent with American Society of Mechanical Engineers (ASME) Code Section III Class 3 systems. The staff finds this to be acceptable, since this meets the criteria for seismic analysis identified in NUREG-0800 Section 9.5.1 and RG 1.189 for portions of FPSs.

It was still not clear what additional seismic requirements may apply to certain Class D systems and components. DCD Section 3.2.2.6 states that, in regard to Class D, the systems and components are not designed for seismic loads. For example, other than anchorage, the seismic requirements for the ancillary diesel generators and other equipment to ensure their functionality following a seismic event is not defined. The staff’s guidance in a memorandum dated July 18, 1994, pertaining to AP600, identified a proposed review approach for equipment designated as important by the RTNSS process. Although a dynamic qualification test may not be necessary for this equipment, the SRM identified an approach where a dynamic analysis or qualification of electrical and mechanical equipment by experience may be used on a case-by-case basis. Staff is concerned that seismic anchorage alone does not ensure functionality of electrical and mechanical equipment following a safe-shutdown earthquake (SSE), unless it is supported by an analysis or experience. This concern was identified during the Revision 16 review as Open Item OI-SRP3.2.1-EMB2-01.

In an attempt to resolve this Revision 16 open item, the staff performed an onsite review to examine detailed design documents that could define the additional information for staff to reach a reasonable safety conclusion. The results of the onsite review are documented in the NRC report dated March 17, 2009. The applicant responded to Open Item OI-SRP3.2.1-EMB2-01 by referencing SECY-96-128 and NUREG-1793, “Final Safety Evaluation Report [FSER] Related to Certification of the AP1000 Standard Design,” Section 22.5.6, but DCD Section 3.2.1 was not updated to identify the basis cited in the response. The applicant believes that the guidance in the SRM dated July 18, 1994, is not applicable to the AP1000 DC review and the seismic design requirements imposed on components, identified as important by the RTNSS process, as identified in the AP1000 DCD in Table 3.2-3 and Westinghouse Commercial Atomic Power (WCAP)-15985, “AP1000 Implementation of the Regulatory Treatment of Nonsafety-Related Systems Process,” Revision 2, provide an appropriate level of seismic protection. The response further clarified that the design provides an alternate way of supporting long term operation of passive features using offsite supplied equipment that is independent of these RTNSS SSCs. Therefore, the applicant stated that there is no need to raise the level of seismic design requirements for these RTNSS SSCs to seismic Category I and concluded that the application of seismic Category II anchorages identified in DCD Table 3.2-3 will provide reasonable assurance that the SSCs identified by the RTNSS process as important for the post 72-hour operation are functional in the required time frame, even after the most limiting design basis earthquake.

The staff reviewed the basis for seismic requirements applicable to certain RTNSS SSCs cited in the response. SECY-96-128 and the associated memorandum referenced in the response is applicable to AP600 and states that the site be capable of sustaining all design basis events with onsite equipment and supplies for the long term. The equipment required after 72 hours need not be in automatic standby response mode, but must be readily available for connection and be protected from natural phenomena including seismic events (pursuant to GDC 2).

Therefore, staff disagrees with the applicant's position that offsite equipment may be credited for equipment needed post-72 hours. However, based on staff guidance, no dynamic qualification of this equipment is necessary and equipment is to be designed with seismic Category II anchorage and located within a seismic Category II structure.

Although the approach proposed in the SRM dated July 18, 1994, is applicable to AP600 rather than AP1000, this document proposed a review approach for RTNSS systems in passive designs where nonsafety-related systems designated to be important by the RTNSS process (IRP) are needed to perform their required function after an earthquake. For example, IRP systems and components should not be required to be classified as seismic Category I, but staff may consider the use of experience data for seismic qualification on a case-by-case basis. The SRM dated June 23, 1997, regarding SECY-96-128 for AP600, clarified a staff position that post-72 hour SSCs need not be safety-related, but equipment anchorages must be consistent with the SSE design equipment anchorages of seismic Category I items and there should be no adverse interactions. Further, this memorandum clarified that no dynamic qualification of active equipment is necessary. Although operability or functionality is not entirely ensured unless either classified as seismic Category I or otherwise justified, it is reasonable to expect that seismic Category II anchorage and location within a seismic Category II structure will afford some degree of structural integrity. Therefore, staff accepts the applicant's position that the seismic classification is basically consistent with previous positions for AP600 documented in documents related to SECY-96-128 and NUREG-1793. As a result of this review, Open Item OI-SRP3.2.1-EMB2-01 is closed.

Scope (RAI-SRP3.2.1-EMB2-02)

During the review of Revision 16, the staff was concerned that the scope of SSCs identified in DCD Section 3.2.1 does not appear to be complete and this was identified as an open item. In RAI-SRP3.2.1-EMB2-02, the applicant was requested to identify the seismic classification of any nonsite-specific SSCs, such as the circulating water system (CWS), electrical items, and reactor vessel insulation, within the scope of the DCD that are not included in the DCD tables.

The RAI response clarified that Table 3.2-3 does not include information on electrical, instrumentation or architectural elements and identified that Table 3.2-2 will be revised to include seismic requirements for various structures and that Table 3.2-3 will be revised for the FPSs. The response also clarified that, although the design of some of the SSCs is the responsibility of the combined license (COL) applicant, the seismic categorization is provided as part of the DC. The response identified the CWS and raw water system (RWS) as NS.

The staff reviewed Revision 17 and determined that the changes do not entirely resolve the staff's concerns. Relative to completeness of scope in the application, the applicant included the omitted ancillary diesel generators and the FPS components in the DCD and references DCD Section 3.7.2.8 for seismic requirements applicable to NS structures. However, the seismic classification of the CWS and RWS identified in the RAI response is not included in the revised DCD tables. Similarly, DCD Revision 17 does not include the seismic classification for the electrical and instrumentation components or other miscellaneous SSCs such as the reactor pressure vessel (RPV) insulation. This concern was identified during the review of Revision 16 as Open Item OI-SRP3.2.1-EMB2-02.

In an attempt to resolve this Revision 16 open item, staff performed an onsite review to examine detailed design documents that could define the additional information for staff to reach a reasonable safety conclusion. The results of the onsite review are documented in the NRC report dated March 17, 2009. The applicant responded to Open Item OI-SRP3.2.1-EMB2-01 by revising the DCD, referencing DCD Table 3.11-1 for seismic classification of electric and instrumentation equipment and stating that the detail for seismic classification in the AP1000 DCD is sufficient for DC. The revised DCD includes RPV insulation as seismic Category II and additional components, such as valves, the secondary core support structure and components associated with the reactor coolant system (RCS).

The staff reviewed the applicant's response. The response adequately justifies that the seismic classification of electrical items need not be included in Table 3.2-3 since they are outside the scope of NUREG-0800 Section 3.2.1, and the classification of these items in Table 3.11-1 as seismic Category I should be sufficient to support the seismic review of electric items addressed in Chapter 8. Although the response does not revise DCD Table 3.2-3 and piping and instrumentation drawings (P&IDs) to include the seismic classification of all SSCs, such as piping, other sections of the DCD do identify seismic classification for piping systems and specific equipment. It is understood that the interconnected piping has a seismic classification similar to that of equipment and components. The seismic classification of SSCs added in Table 3.2-3 is consistent with RG 1.29 and GDC 2. Therefore, the staff concludes that, although the scope of SSCs seismically classified in Table 3.2-3 is not complete, other sections of the DCD include the seismic classification of SSCs not included in Table 3.2-3. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue. As a result of this review, Open Item OI-SRP3.2.1-EMB2-02 is closed.

Augmented Quality Assurance (QA) Requirements for Seismic Category II SSCs (RAI-SRP3.2.1-EMB2-03)

In Revision 16 DCD Section 3.2.1.1.2 was revised to reference DCD Section 17.5 rather than Section 17.4 for the COL QA requirements for seismic Category II SSCs. During the review of Revision 16, the staff determined that DCD Table 3.2-3 included in Revision 16 did not identify specific augmented QA requirements that apply to seismic Category II SSCs. The staff was concerned that Section 3.2, Table 3.2-3 or Chapter 17 included in DCD Revision 16 do not adequately define specific augmented QA requirements of 10 CFR Part 50, Appendix B, "Quality Assurance Criteria for Nuclear Power Plants and Fuel Reprocessing Plants," for seismic Category II SSCs. It was not clear if the COL applicant is to provide these requirements for the procurement of nonsite-specific SSCs. In RAI-SRP3.2.1-EMB2-03, the applicant was requested to clarify to what extent the pertinent QA requirements of Appendix B to 10 CFR Part 50 apply to nonsite-specific seismic Category II SSCs and to identify the DCD section or other document that describes those requirements. The RAI response restated the DCD Section 3.2.1.1.2 statement that pertinent portions of 10 CFR Part 50, Appendix B apply to seismic Category II SSCs and that pertinent portions are those required to provide that unacceptable structural failure or interaction with seismic Category I items does not occur. The response further clarified that seismic Category II SSCs are covered by the same quality programs and procedures as seismic Category I and the extent of design activities are determined by the responsible engineers and are identified in the design specifications and design criteria documents.

The staff reviewed the changes included in Revision 17 and determined that neither DCD Section 3.2, Table 3.2-3 nor Section 17.5 has been revised to identify specific augmented QA requirements for seismic Category II SSCs. This concern was identified during the review of Revision 16 as Open Item OI-SRP3.2.1-EMB2-03.

In an attempt to resolve the Revision 16 open item, staff performed an onsite review to examine detailed design documents that could define the additional information for staff to reach a reasonable safety conclusion. The results of the onsite review are documented in the NRC report dated March 17, 2009. The applicant responded to Open Item OI-SRP3.2.1-EMB2-03 by stating that it does not agree that specific QA requirements for seismic Category II SSCs should be included in the DCD, but the DCD is to be revised to clarify that QA requirements are performed consistent with the applicant's quality plan as described in Section 17.3. In the response, the applicant identified three different approaches applied to nonsafety-related SSCs that are subject to seismic requirements and stated that AP1000 seismic Category II SSCs are subject to the AP1000 quality plan as described in NUREG-0800 Section 17.3 QA requirements.

In a subsequent response to the staff concerns, the applicant clarified its process to identify supplemental requirements for RTNSS SSCs and seismic Category II SSCs. The applicant stated that application of augmented QA is a function of the RTNSS assessment, not the seismic categorization. The response identifies that the Design Reliability Assurance Program (D-RAP) described in DCD Section 17.4 does not impose augmented design or quality requirements on SSCs and that DCD Table 3.2-1 includes adequate reference to seismic Category II design and quality requirements. The response recognizes that DCD Section 3.2.2.6 does not specifically allow for the use of pertinent portions of 10 CFR Part 50 Appendix B to seismic Category II applications and proposes a DCD revision for clarity.

Although the applicant does not impose quality requirements based on the D-RAP, the staff believes that reliability depends on the design and quality of the SSCs and that the purpose of the D-RAP is to ensure reliability using the design process. As stated in DCD Section 17.4, the AP1000 D-RAP is implemented as an integral part of the AP1000 design process to provide confidence that reliability is designed into the plant. NUREG-0800 Section 17.4 also states that the objective of the reliability assurance program (RAP) is to ensure that the reliability is properly considered and designed into the plant. Draft DC/COL-ISG-018, "Interim Staff Guidance on NUREG-0800 Standard Review Plan Section 17.4, 'Reliability Assurance Program,'" further states that the purpose of the RAP is that the reactor is designed consistent with key assumptions (including reliability) and key insights. During the DC phase, the applicant prepared details of the D-RAP and implemented appropriate graded controls related to design activities for nonsafety-related within the scope SSCs. Those supplemental requirements/graded controls (special treatment) for risk-significant SSCs may include short term availability controls, design requirements, seismic requirements, inspections, maintenance, or QA controls to ensure reliability. One of the design considerations in the AP1000 D-RAP is that the design reflects the reliability values assumed in the design and probabilistic risk assessment (PRA) as part of procurement specifications. DCD Sections 3.2.1.1.2 and 3.2.2.6 are to be revised to reference DCD Section 17.3 for augmented quality requirements for seismic Category II SSCs consistent with RG 1.29, without a specific reference to the D-RAP. The staff recognizes that the RTNSS process combined with the D-RAP should be used to establish reliability of risk-significant SSCs so that appropriate specific QA requirements may be established during the detailed design. Therefore, it is reasonable to expect appropriate QA requirements to be applied to risk-significant seismic Category II SSCs and that these requirements are to be included in the design or procurement specifications that can be verified when available. As a result, Open Item OI-SRP3.2.1-EMB2-03 is closed. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

List of SSCs Needed for Continued Plant Operation

10 CFR Part 50, Appendix S, “Earthquake Engineering Criteria for Nuclear Power Plants,” Section IV(a)(2)(I), states that SSCs necessary for continued operation without undue risk to the health and safety of the public must remain functional and within applicable stress, strain, and deformation limits when subject to the effects of the operating basis earthquake (OBE) ground motion. NUREG-0800 Section 3.2.1 states that, if the applicant has set the OBE ground motion to the value one-third of the SSE ground motion, then the applicant should also provide a list of SSCs necessary for continued operation that must remain functional without undue risk to the health and safety of the public and within applicable stress, strain and deformation limits, during and following the OBE. AP1000 DCD Section 3.7 states that the OBE for shutdown is considered to be one-third of the SSE.

10 CFR Part 50, Appendix S, Section IV(a)(3), states that if vibratory ground motion exceeding that of the OBE ground motion or if significant plant damage occurs, the licensee must shut down the nuclear power plant, and that, prior to resuming operations, the licensee must demonstrate to the Commission that no functional damage has occurred to those features necessary for continued operation without undue risk to the health and safety of the public and the licensing basis is maintained. Identification of the necessary SSCs and inclusion of the equipment at the appropriate seismic classification level in the DCD would allow the plant to address the requirements when the need exists.

In an attempt to obtain this information, staff performed an onsite review to examine detailed design documents that could define the additional information for staff to reach a safety conclusion. The results of the onsite review are documented in the NRC report dated March 17, 2009.

In RAI-SRP3.2.1-EMB2-06, the applicant was requested to provide this list of SSCs necessary for continued operation or an alternative to address the requirements. The applicant was requested to include in the DCD the list of SSCs necessary for continued operation. This concern was identified as Open Item OI-SRP3.2.1-EMB2-06.

The applicant’s response to Open Item OI-SRP3.2.1-EMB2-06 clarifies that the SSCs necessary to protect the public health and safety are the safety-related SSCs identified in Section 3.2.2 of the DCD and tabulated in DCD Table 3.2-3. The response does not address nonsafety-related SSCs that may be important to safety, such as RTNSS SSCs, but the applicant identifies that the capability of nonsafety-related SSCs to support power production following an OBE is an investment protection issue. The response further identifies that post earthquake planning is the responsibility of the operators and is not included in the design certification. The applicant proposes a revision to DCD Section 3.2.1.1 to add a statement regarding the safety-related SSCs in regard to 10 CFR 50 Appendix S. In response to further staff concerns relative to pre-earthquake planning and RG 1.166, “Pre-Earthquake Planning and Immediate Nuclear Power Plant Operator Postearthquake Actions,” applicability, the applicant revised its response to clarify that pre-earthquake planning is the responsibility of the COL holder and that DCD Section 3.7.5.2 identifies a COL information item for post-earthquake procedures. The response stated that post-earthquake procedures will follow Electric Power Research Institute (EPRI) guidance and it was noted that the COL applicant would be able to address RG 1.166 and the list of SSCs to be included in procedures.

The staff agrees that RG 1.166 is not applicable to the DC and post-earthquake planning is the responsibility of the operators and not included in the DC. Therefore, this is considered to be addressed in the procedures developed by the COL applicant. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

3.2.1.2 Conclusion

The seismic classification of SSCs is, in general, consistent with RG 1.29, with the exceptions identified in DCD Appendix 1A.

Therefore, on the basis of its review of DCD Revision 19 included in Tier 2 Section 3.2.1, Tables 3.2-2 and 3.2-3, the staff concludes that the AP1000 safety-related SSCs, including their supports, are properly classified as seismic Category I, in accordance with Position C.1 of RG 1.29. In addition, the staff finds that DCD Tier 2 includes acceptable commitments to Positions C.2, C.3, and C.4 of RG 1.29. This constitutes an acceptable basis for satisfying, in part, the portion of GDC 2 that requires that all SSCs important to safety be designed to withstand the effects of natural phenomena, including earthquakes.

3.2.2 Quality Group Classification

Revisions 16 and 17 of the DCD include a number of changes to Section 3.2.2 and Table 3.2-3 related to the AP1000 classification system and to Chapter 17 for QA requirements. The changes to Section 3.2.2 include a clarification regarding reference to 10 CFR 50.34 rather than 10 CFR Part 100 and clarifications regarding applicability of ASME Code Section III to pressure-retaining components. The changes to the Table 3.2-3 primarily involve the addition of components and their AP1000 classifications.

3.2.2.1 Evaluation

The staff reviewed the DCD Revisions 16 and 17 according to the guidance in NUREG-0800 Section 3.2.2, “Quality Group Classification,” which references RG 1.26, “Quality Group Classifications and Standards for Water-, Steam-, and Radioactive-Waste-Containing Components of Nuclear Power Plants,” for quality group (QG) classification of various SSCs. The staff review considered that additional detailed design information needed to be verified. An NRC audit of design specifications performed October 13-17, 2008, for risk-significant components was also considered relative to QG classification. The staff also reviewed TR-103, “Fluid System Changes,” APP-GW-GLN-019, Revision 2, and TR-106, “AP1000 Licensing Design Changes for Mechanical System and Component Design Updates,” APP-GW-GLN-106, Revision 1, which address various system changes that could have an impact on QG classifications.

The staff determined that the DCD Section 3.2.2.1 change referencing 10 CFR 50.34 rather than 10 CFR Part 100 was acceptable since 10 CFR 50.34 as well as 10 CFR Part 100 are referenced in the definition of the term safety-related. Both regulations provide similar acceptance criteria for offsite doses. The other DCD changes were primarily intended to resolve staff questions on RTNSS. The staff also determined that the clarifying notes concerning applicability of ASME Code Section III to pressure boundary components were acceptable with the understanding that ASME Code Section III also applies to supports for pressure boundary systems and components.

The staff’s review of the DCD changes determined that, in general, the specific changes identified in the application are acceptable, but that several potential errors and omissions in a number of technical areas need clarification in the DCD. During the Revision 16 review, the staff prepared RAIs to resolve these errors and omissions and these are discussed below under each topic. The technical review and resulting RAIs are intended to clarify statements in the DCD and address omissions in the application.

Supplemental Requirements for Nonsafety-Related Passive SSCs Important to Safety (RAI-SRP3.2.2-EMB2-01)

During the review of Revision 16, the staff was concerned that neither DCD Section 3.2 nor Table 3.2-3 adequately defines specific supplemental quality standards and QA programs applied to nonsafety-related passive SSCs that are important to safety and risk-significant. In RAI-SRP3.2.2-EMB2-01, the applicant was requested to clarify what supplemental quality standards and QA program are applied to nonsafety-related passive SSCs that are important to safety.

The RAI response clarified that codes and standards for Class D systems and components provide an appropriate level of integrity and functionality. The response also stated that the PRA did not identify SSCs that need a more rigorous code or standard than those identified in the DCD to provide improved reliability.

The staff reviewed the applicant's response to RAI-SRP3.2.2-EMB2-01 and determined that the response partially resolves its concerns. Although the PRA and RTNSS process did not apparently identify any supplemental requirements for passive components, the staff is concerned that supplementation may be appropriate, especially where there is insufficient operating history. For example, where high density polyethylene (HDPE) piping is to be used for underground plant service water system (SWS) piping that is considered a risk-significant defense in depth RTNSS system, additional special treatment should be imposed on design and QA requirements to ensure its integrity consistent with the system's safety function. Special treatment is appropriate for buried non-metallic piping that does not have a sufficient operating history in similar applications where failures are possible, unless special precautions are taken during design, fabrication, installation, and testing. Examples of supplementation applied to important to safety HDPE piping are addressed in ASME Code cases and relief requests. Although the plant service water piping is not considered safety-related, it is important to safety and GDC 1, "Quality Standards and Records," requires that, where generally recognized codes and standards are used, they shall be supplemented or modified as necessary to assure a quality product in keeping with the required safety function. Therefore, passive SSCs used in risk-significant RTNSS systems, such as the SWS piping should be supplemented or modified accordingly. This concern was identified during the Revision 16 review as Open Item OI-SRP3.2.2-EMB2-01.

In an attempt to resolve the Revision 16 open item, the staff performed an onsite review to examine detailed design documents that could define the additional information for staff to reach a reasonable safety conclusion. The results of the onsite review are documented in the NRC report dated March 17, 2009.

The applicant's response to Open Item OI-SRP3.2.2-EMB2-01 clarified that, in regard to HDPE piping used in the SWS, which is identified as a RTNSS system, HDPE will only be used in flow paths that are not required to support the important-to-safety function of decay heat removal. Therefore, the applicant concluded that supplementation or modification to meet GDC 1 is not required in the application of HDPE piping in the SWS.

The staff agrees that, if HDPE is only used in portions of the SWS that are not risk-significant, supplementation or modification to ensure reliability of HDPE need not be identified. However, the staff was concerned that supplementation or modification of other risk-significant passive SSCs has not been identified. The applicant's revised response clarified that the RTNSS process is independent of the D-RAP and the D-RAP does not impose supplementation as a requirement. However, the response identifies that RTNSS SSCs apply augmented QA in accordance with DCD Table 17-1, "QA Requirements for SSCs Important to Investment Protection." These QA requirements and scope of SSCs included in the D-RAP for RTNSS SSCs are reviewed in other sections of this safety evaluation report (SER) according to NUREG-0800 Section 17.4 and draft DC/COL-ISG-018. Although the applicant does not impose quality requirements based on the D-RAP, the staff's opinion is that reliability depends on the design and quality of the SSCs and that the purpose of the D-RAP is to ensure reliability using the design process. As stated in DCD Section 17.4, the AP1000 D-RAP is implemented as an integral part of the AP1000 design process to provide confidence that reliability is designed into the plant. NUREG-0800 Section 17.4 also states that the objective of the RAP is to ensure that reliability is properly considered and designed into the plant. DC/COL-ISG-018 concerning the D-RAP and implementing appropriate graded QA controls further states that the purpose of the RAP is to assure that the reactor is designed consistent with key assumptions (including reliability) and key insights. Supplemental requirements/graded controls (special treatment) for risk-significant SSCs may include short term availability controls, design requirements, seismic requirements, inspections, maintenance, or QA controls to ensure reliability.

One of the design considerations in the AP1000 D-RAP is that the design reflects the reliability values assumed in the design and PRA as part of procurement specifications. To be consistent with the Interim Staff Guidance (ISG), the application should specify the QA controls related to DC design activities in accordance with the provisions in Part V, "Non-safety-related SSC Quality Controls," of NUREG-0800 Section 17.5 for the nonsafety-related, within the scope of SSCs. Based on the ISG, the NRC verifies the DC applicant's D-RAP, including its implementation during the DC application phase, through the agency's safety evaluation review process, as well as audits. Therefore, the staff recognizes that the supplementation needed to ensure reliability assumed in the PRA is to be determined by the RTNSS process combined with the D-RAP and that the inspection, test, analyses, and acceptance criteria (ITAAC) in Table 3.7-3 of Tier 1 of the AP1000 DCD have been developed to allow review of this process. As a result, Open Item OI-SRP3.2.2-EMB2-01 is closed.

Application of Unendorsed ANS Standard (RAI-SRP3.2.2-EMB2-02)

DCD Revision 16 added American Nuclear Society (ANS) Standard 58.14-1993, "Safety and Pressure Integrity Classification Criteria for Light Water Reactors," as a reference for safety classifications and this standard continues to be referenced in Revision 17. The staff was concerned that withdrawn and outdated ANS 58.14-1993 is not NRC-endorsed and cannot be used as a basis for acceptability of classifications. In RAI-SRP3.2.2-EMB2-02, the applicant was requested to either reference an updated classification standard or adequately describe the classification criteria in the application.

In its response, the applicant clarified that the referenced documents provide background for the equipment classification, but the AP1000 classification approach does not rely on the endorsement of any particular standard as the basis of the classification approach.

The staff reviewed the applicant's response and concludes that, although the referenced classification standard is being included in the DCD, the staff will not rely on this standard or other unendorsed standards as a basis for acceptability of classifications. On this basis, RAI-SRP3.2.2-EMB2-02 is closed.

Codes and Standards (RAI-SRP3.2.2-EMB2-03)

The SRM dated July 31, 1993, concerning SECY-93-087, "Policy, Technical, and Licensing Issues Pertaining to Evolutionary and Advanced Light-Water Reactor (ALWR) Designs," identified that the staff will review passive plant designs using the newest codes and standards endorsed by the NRC and unapproved revisions to the codes and standards referenced in the DCD will be reviewed on a case-by-case basis. During the Revision 16 review, the staff was concerned that editions of codes and standards referenced in the DCD not otherwise endorsed by the NRC might not be current. In RAI-SRP3.2.2-EMB2-03, the applicant was requested to clarify which editions of various codes and standards were NRC-endorsed and to clarify if current editions of codes and standards would be applied to the detailed design and procurement of AP1000 SSCs so that these codes and editions might be reviewed on a case-by-case basis.

The applicant clarified that codes and standards were generally those in effect six months prior to the submittal of the application and these editions would be applied to the detailed design and procurement of AP1000 SSCs. The response identified that, in a limited number of cases, the applicant was updating the revisions of codes and standards and this change would be specifically identified in a DCD revision.

The staff agreed that editions of codes and standards in effect six months prior to the application are acceptable and noted that the staff will have the opportunity to review future changes. DCD Section 3.2.6, Revision 17 made no changes to the referenced codes and standards editions and on this basis RAI-SRP3.2.2-EMB2-03 is closed.

Classification of Fire Protection System (RAI-SRP3.2.2-EMB2-04)

During the DCD Revision 16 review the staff was concerned that DCD Section 3.2.2.7 had been revised to identify that both Class F and G are used for FPSs, but Table 3.2-3 did not identify FPS SSCs that were classified as Class F and G. The staff was concerned that the classification of the FPS in DCD Revision 16 was not complete and in RAI-SRP3.2.2-EMB2-04, the applicant was requested to submit the classifications for the entire FPS.

In the RAI response, the applicant submitted a revised Table 3.2-3 for additional FPS piping and components. The staff concurs that inclusion of the revised DCD Table 3.2-3 represents a generally complete scope of FPS piping and components and that the classification of these as consistent with RG 1.29 and NUREG-0800 Section 9.5.1 criteria is an acceptable regulatory basis. The classification of the standpipe system as AP1000 Class F constructed to American National Standards Institute (ANSI) B31.1, "Code for Pressure Piping," and categorized as NS with a seismic analysis consistent with ASME Code Section III Class 3 is consistent with the guidance in NUREG-0800 Section 9.5.1 and RG 1.189 (considered not applicable to AP1000) and is, therefore, acceptable. Therefore, RAI-SRP3.2.2-EMB2-04 is closed.

3.2.2.2 Conclusion

On the basis of its review of the DCD Amendment Section 3.2.2, and the above discussion, the staff concludes that the QG classifications of the important to safety pressure-retaining fluid systems and their supports, as identified in DCD Tier 2, Tables 3.2-1 and 3.2-3, and related P&IDs in the DCD, are consistent with RG 1.26, other than exceptions identified in DCD Appendix 1A, and are acceptable. These tables and P&IDs identify major components in fluid systems (i.e., pressure vessels, heat exchangers, storage tanks, piping, pumps, valves, and applicable supports). In addition, P&IDs in the DCD identify the classification boundaries of interconnecting piping and valves. All of the above SSCs will be constructed in conformance with applicable ASME Code and industry standards. Conformance to RG 1.26 as described above and applicable ASME Codes and industry standards provide assurance that component quality will be commensurate with the importance of the safety functions of these systems. Therefore, the staff concludes that the application meets the requirements of GDC 1 for QG classifications.

3.3 Wind and Tornado Loadings

3.3.1 Summary of Technical Information

With regard to wind and tornado loads on the seismic Category I structures, the AP1000 DCD, Revision 17 changes the shield building by reducing its height by 1.52 meters (m) (5 feet (ft)). As a result, the wind and tornado loads are also altered.

3.3.2 Combined License Information 3.3-1 and 3.5-1

The commitment to address combined operating and licensing information (DCD COL Information Items 3.3-1, “Wind and Tornado Site Interface Criteria,” and 3.5-1, “External Missile Protection Requirements,” concerning site interface criteria for wind and tornado by the COL applicant) is defined in TR-5, “AP1000 Wind and Tornado Site Interface Criteria,” APP-GW-GLR-020, Revision 4. Revision 17 of the DCD includes the following applicable changes:

- Evaluation of generic wind and tornado loadings on structures;
- Provision of the plant specific site plan and comparison with the typical site plan shown in Figure 1.2-2, “Site Plan,” of DCD Section 1.2;
- Discussion of missiles produced by tornadoes and other external events; and
- Evaluation of other buildings for collapse and missile generation.

Based on the above mentioned evaluations, the applicant is to demonstrate that any exceedances or differences in the evaluation results from what is specified in the DCD will not compromise the safety of the nuclear power plant.

3.3.3 Evaluation

The shield building is a seismic Category I structure located on the nuclear island (NI). The development of loads on the air baffle in the top portion of the shield building due to the design-basis wind and tornado is a safety concern. The methodology for load evaluation follows the AP600 approach combined with wind tunnel testing, which gives rise to the wind loads across the air baffle, assuming a constant tornado wind speed with the height of the building. This means that the total wind load on the structure increases with increasing height of the building. The proposed change to the DCD includes a 1.52 m (5 ft) reduction of the total height of the shield building. As a result, total wind loads applied to the building are altered. This alteration may influence important design parameters.

The staff reviewed the change with regard to the impact on the wind load to determine its acceptability. Since the wind loads are in direct proportion to the height of the structure, the total net load applied to the building will be less than before the change. This means that, for a fixed diameter, a reduction of 1.52 m (5 ft) in height will result in approximately 2.5 percent reduction in the wind loads applied to the building. The outcome of this change of design is an increase in safety margin due to decreasing applied loads. Thus, the design change increases the degree of conservatism and is, therefore, acceptable. The staff concludes that the application meets the requirements of GDC 2.

3.3.4 Development of COL Information Items

The DCD Revision 17 via TR-5, Revision 4 provides the detailed requirements specified in COL Information Items 3.3-1 and 3.5-1. In order to close out the COL Information Items 3.3-1 and 3.5-1, the following items must be addressed by the COL applicant:

With regard to site interface criteria for wind and tornado (Information Item 3.3-1), the DCD states:

> The site parameters wind speeds for which the AP1000 plant is designed are given in Table 2-1, “Site Parameters (Sheets 1 - 4), of the DCD. In addition, the design parameters applicable to tornado are given in DCD Section 3.3.2.1, including maximum rotational speed of 240 mph (385 km/h); max. translational speed of 60 mph (96 km/h); radius of max. rotational wind from center of tornado, 150 ft (45-3/4 m); atmospheric pressure drop of 2.0 psi (13.8 kPa) and rate of pressure change of 1.2 psi per sec (8.3 kPa per sec). Should the site parameters exceed those bounding conditions; the applicant will be required to demonstrate that the design conforms to the acceptance criteria.

DCD Section 3.3.3, “Combined License Information,” includes only the commitment that COL applicants referencing the AP1000 certified design will address site interface criteria for wind and tornado loadings. This change via TR-5 provides specific interface criteria, including necessary information items for the COL applicant. The COL information items include: development of site-specific parameters, verifications of bounding conditions, plant layout and site arrangement. Should the site parameters exceed those bounding conditions, the applicant will be required, either through analysis, testing or combined analysis and testing, to demonstrate that the design conforms to the acceptance criteria.

The staff reviewed the interface criteria for wind and tornado provided in TR-5 including evaluation of generic wind and tornado loadings on structures; discussion of missiles generated by tornadoes and extreme winds, and evaluation of missile generation and effects of building collapse on NI structures. Examination of those criteria revealed that they are necessary and sufficient in providing appropriate input to the design of safety-related SSCs. These COL

Information Items are deemed to show compliance with the Commission's regulations including GDC 2 in Appendix A to 10 CFR Part 50, and thus are acceptable.

With regard to tornado-initiated building collapse (Information Item 3.3-1) the DCD states:

> If the COL applicant has adjacent structures different from the typical site plan shown in Figure 1.2-2 of the DCD Section 1.2, a justification must be provided to show that they will not collapse, or their failure will not impair the structural integrity of the nuclear island safety-related structures. Now, the structures in the typical site plan have been evaluated for tornado-initiated failure or collapse. The analysis showed that they will not compromise the safety of the nuclear island structures or their seismic categories reclassified.

The staff reviewed the analysis and found it technically sound, except for one issue that requires further investigation. The radwaste building was evaluated for its potential collapse on the NI, demonstrating that it would not impair the structural integrity of the NI safety-related structures (see DCD Section 3.7.2.8.2, "Radwaste Building"). However, because of the addition of 3 liquid radwaste monitor tanks (see TR-106), which completely alters the structural dynamic characteristics of the building; it is not clear whether this conclusion is still valid. The staff reviewed the applicant's response to RAI-SRP3.7.2-SEB1-02, Revision 1, dated October 1, 2008, and determined that it was not acceptable because the staff's calculation of the maximum kinetic energy calculated using Method 3 in DCD Section 3.7.2.8.2 (6.8×10^7 joules (J) or 6.0×10^8 inch-pounds (in-lb)) for the water tank missile far exceeded that of the water tank missile (3.4×10^4 joules or 3.0×10^5 in-lb) claimed in the response. The staff's calculation was based on the assumptions adopted by the RAI response that the mass of a single water tank is 65,673 kilograms (kg) (144,781 pounds (lb))) and the velocity is 45.7 meters per second (m/s) (150 feet per second (fps) or 105 mph). This concern was identified as Open Item OI-SRP3.7.2-SEB1-02.

The applicant's approach to resolve the concern was to show that during a design-basis tornado event, the three water tanks will remain stationary, not result in a moving missile, then there would be no safety concern on the missile impact-induced damage to NI structures, and this open item could be closed. On May 13, 2010, the staff carried out an onsite audit on this report at the applicant's Twinbrook office. The safety analysis in APP-1000-CCC-007, "Further Evaluation of Potential Tornado Missiles on Nuclear Island," Revision 0, shows that during a tornado event with a design-basis wind speed of 134 m/s (300 mph), a total force of 12246 kilograms (kg) (27 kilopounds (kip)) will be produced by the tornado, and applied at each water tank, according to the American Society of Civil Engineers (ASCE) 7-98, "Minimum Design Loads for Buildings and Other Structures" that is acceptable to the NRC. Meanwhile, the six anchorage support bolts at each tank base were designed to resist a seismic force of up to 13607 kg (30 kip) based on the UBC. The conclusion was that because the applied tornado force on the tank is less than the resistance capability of the tank supports at the base, the tanks will remain stationary, and not become a damaging missile. The staff reviewed the calculations, and performed an independent confirmatory analysis using a new edition of ASCE 7-05, "Minimum Design Loads for Buildings and Other Structures," formula. The results showed that a tornado wind speed exceeding 141 m/s (316 mph) will break the anchor supports, resulting in high energy water tank missiles. Any wind speed higher than this limit will turn the tank into a missile, and therefore will not be acceptable. But because the design-basis tornado wind speed is only 134 m/s (300 mph) less than the limit with a safety margin of 5 percent, the water tanks will not become a moving missile. Based on the confirmatory analysis, the staff finds that the calculations provided by the applicant are acceptable. Thus, Open Item OI-SRP3.7.2-SEB1-02 is closed.

With regard to missiles generated by external events (COL Information Item 3.5-1) the DCD states:

> The AP1000 tornado missiles used for design are defined in Table 2.2-1 of the DCD Subsection 3.5.1.4 in terms of missile type vs energy spectrum, which is consistent with RG 1.76 (Reference 3). Other than tornado, missiles may be generated from external events such as transportation accidents or explosions. The COL applicant is responsible for identifying sources in the plant and the external events that could cause a producing missile to threaten the integrity of AP1000 safety-related SSCs. The missile energy should be compared with the Table in 3.5.1.4. If the external event missile has higher kinetic energy, the effect of the impact must be evaluated to show that it does not compromise the safety of the AP1000 safety-related structures.

In a letter dated December 23, 2008, the applicant responded to RAI-SRP3.3.2-SEB1-01 regarding the issue of missiles that are produced by the potential blow-off of the siding on the annex building as well as the turbine building. In its response, the applicant indicated that “The automobile in the missile spectrum included in the AP1000 would appear to bound the mass and energy of sheet metal siding. Also there are no safety-related structures, systems, and components outside of the Auxiliary Building and Shield Building. The walls of these buildings are reinforced concrete at least two feet thick. Tornado driven siding would not be expected to be a challenge to reinforced concrete walls.” The staff notes that the construction of the shield building is not reinforced concrete (RC) and can best be described as “steel-concrete-steel modular wall construction.” It is likely that the siding missile can penetrate the steel sheet of the modular wall of the shield building. The reanalysis of the shield building for a tornado-driven siding missile strike was identified as Open Item OI-SRP3.3.2-SEB1-01. An onsite audit meeting was held on February 24, 2010, at the applicant’s Twinbrook office where the penetration issue was discussed in detail based on the principles of mechanics in the areas of indentation, penetration and fracture. In a letter dated March 24, 2010, the applicant responded to Open Item OI-SRP3.3.2-SEB1-01 regarding the damage induced by siding missiles. In the response, it concluded that the penetration will be zero according to the basic assumptions, methodology and detailed calculations presented in APP-1000-CCC-007, Revision 0.

An onsite review of the report was performed by the staff on May 13, 2010 at the applicant’s Twinbrook office. The review reveals that there is a basic assumption in the analysis that all kinetic energy is converted to strain energy in the siding and the target wall or roof. The possibility of conversion to thermal energy or fracture energy is ruled out with no justification, and the penetration issue was not addressed. However, it is well-known that when two materials are brought into contact the harder material is bound to scratch or penetrate the softer material even if the velocity is very slow or buckling occurs at the high speed. Thus, as long as the hardness of the siding material is slightly higher than that of the building wall or the roof, a finite amount of penetration must occur. Indeed, in the confirmatory analysis performed by the staff, it was estimated, based on the data provided by the applicant on the siding missile, a penetration of about 2.54 centimeter (cm) (1 inch (in)) and 51 cm (20 in) will result from the impact on the steel panel and concrete roof respectively when steel siding weighing 7.8 kg (17.2 lb) travelling at a speed of 134 m/s (300 mph) makes a corner impact on the flat object. Those penetration depths were estimated using the appropriate formula given in NUREG-0800

Section 5.3.2 “Barrier Design Procedures.” There are no data available to confirm those estimates.

However, test data provided in a similar, but less severe, blast test carried out by J.R. McDonald using a timber plank missile travelling at 67 m/s (150 mph), weighing 6.8 kg (15 lb) with a 0.6 m by1.2 m (2 ft by 4 ft) contact area showed a penetration of 8.0 mm (5/16 in) for a steel panel and 15.2 cm (6 in) for a concrete slab. (References: (1) J.R. McDonald, “Impact Resistance of Common Building Materials to Tornado Missiles,” Journal of Wind Engineering and Industrial Aerodynamics,” Vol. 36, pp717-724, 1990; (2) M.K. Singhal and J.C. Walls: “Evaluation of Wind/Tornado-Generated Missile Impact,” in Table 3, ORNL Conference No. 9310102-18). Those data suggest that the penetration estimates using the NUREG-0800 Section 3.5.3 proposed formula are reasonable.

Given the potential local damage, a study was made in the confirmatory analysis to investigate whether the structural integrity of the NI structures would be compromised. First, from the geometry of the steel siding, those penetrations will produce a thru crack of 7.6-10.2 cm (3-4 in) long in the steel wall and up to 51 cm (20 in) long in the RC roof. It is important to note that the NI structure is under severe loads during a tornado event. The major loadings include a tornado wind load plus huge concentrated loads applied at a building location anywhere from grade to Elevation (El.) 293, resulting from the impacts by automobile missile strikes coming from the nearby raised parking lots (see Section 3.5.1.4). Thus, due to the resulting large bending moment created by the tornado loadings, tensile stress field is established in the structural components containing those flaws as the siding missile’s striking site is always located on the tensile side. In the worst-case scenario when the crack happens to be located in the critical section where the tensile stress is the maximum, it is possible, according to the principle of fracture mechanics, that the crack will immediately propagate unstably if the applied stress intensity factor (which is a function of the crack size, geometry and the applied stress), exceeds the toughness resistance of the material ~345 megapascal (MPa) (~50 kilopounds-force per square inch (ksi). Eventually the crack will be arrested in the compressive stress zone. Thus, potentially a crack several feet long with noticeable opening can result as a consequence of the local impact damage from the tornado missile strikes. However, because of the large dimensions of the structures, a total collapse of the building is not likely, due to the residual strength of the components (e.g., inner steel panel of the S-C wall or intact rebar in the RC roof). The structural integrity can still be maintained.

Based on the applicant’s assessment described above, the staff concluded that under the design-basis tornado wind loads, the structural integrity of the seismic Category I structures will not be compromised from the siding missile strikes in compliance with GDC 2 and GDC 4 in 10 CFR Part 50. Therefore, Open Item OI-SRP3.3.2-SEB1-01 is closed. However, after a tornado strike, the licensee is required to inspect and assess the damage to determine the plant’s operability. If significant damage occurs (such as that described herewith), remedial measures must be taken, including a shutdown. Furthermore, prior to resuming operations, the licensee must demonstrate that no functional impairment remains to those features necessary for continued operation without undue risk to the public health and safety, and that the licensing basis is maintained.

The staff reviewed COL Information Item 3.5-1, including all possible types of missiles generated and the associated kinetic energies produced as a result of external events. The staff determined that, in general, the kinetic energies produced fall within the scope of RG 1.76, “Design Basis Tornado and Tornado Missiles for Nuclear Power Plants,” guidelines and thus conform to GDC 4, “Environmental and Dynamic Effects Design Bases,” in Appendix A to

10 CFR Part 50, which requires that SSCs important to safety be protected from the effects of missiles.

3.3.5 Conclusions

There are two major revisions in the DCD Section 3.3. The first change involves the design change of the shield building geometry. The shield building height was reduced by 1.5 m (5 ft). As a result, the total design wind and tornado loads applied on the shield building are altered. The second change involves revision of COL Information Items 3.3-1 and 3.5-1.

The COL Information Item 3.3-1 defines site interface criteria for wind and tornado. Should the site parameters exceed the bounding conditions; the COL applicant will be required to demonstrate that the design conforms to the acceptance criteria.

The COL Information Item 3.5-1 defines acceptable missile type and energy consistent with RG 1.76. The COL applicant is responsible for identifying internal sources and external events. If the missile energy is higher than that depicted in RG 1.76, the effect of an impact must be evaluated to show that it will not impair the structural integrity of the NI safety-related structures. If significant damage occurs (such as that described herein), remedial measures must be taken, including a shutdown. Furthermore, prior to resuming operations, the COL applicant must demonstrate that no functional impairment remains to those features necessary for continued operation without undue risk to the public health and safety, and that the licensing basis is maintained.

The staff reviewed these two proposed changes to the wind and tornado loadings as documented in AP1000 DCD, Revision 16. The staff finds that these two changes do not alter the status of AP1000 wind and tornado loads with regard to meeting the applicable acceptance criteria, including the NUREG-0800 guidelines. The staff also finds that the changes have been properly incorporated into the appropriate sections of the AP1000 DCD, Revision 17. On the basis that the AP1000 wind and tornado loadings continue to meet all applicable acceptance criteria, and the changes are properly documented in the updated AP1000 DCD, the staff finds that all of the changes to Section 3.3 of the AP1000 DCD are acceptable.

3.4 External and Internal Flooding

3.4.1 Flood Protection

3.4.1.1 Protection from External Flooding

The proposed changes to the AP1000 DCD adds design features intended to prevent rainfall accumulation on the roofs of the annex, radwaste, and diesel generator buildings, increases the storage volume of one of the fire water tanks and also includes additional features to prevent or limit infiltration of groundwater into seismic Category I structures.

3.4.1.1.1 Evaluation

The staff reviewed all changes related to external flood protection, Section 3.4.1.1.1, in the AP1000 DCD Revision 17, in accordance with NUREG-0800 Section 3.4.2, “Analysis Procedures.” The regulatory basis for this section is documented in NUREG-1793. The staff reviewed the proposed changes to AP1000 DCD Section 3.4.1.1.1, “Protection from External Flooding,” against the applicable acceptance criteria of NUREG-0800 Section 3.4.2.

The staff reviewed the proposed changes to the roof drainage system to determine if it would impact the accumulation of water (ponding) on the roof. The applicant claimed that ponding of water on the roof is still precluded given the additional design features.

In RAI-SRP3.4.1-RHEB-01, the staff asked the applicant to discuss how the addition of parapets with weir openings to the roof drainage system would impact the potential for ponding of water on the roofs of the annex, radwaste and diesel/generator buildings. The applicant's response explained that these buildings are not safety-related seismic Category I structures and that there are no weir openings in the design. The applicant also committed to change the DCD to reflect the change. Given this information and commitment, the staff considers RAI-SRP3.4.1-RHEB-01 to be resolved. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

The staff reviewed the proposed increase in storage volume in the larger firewater storage tank. The amendment seeks to increase the tank volume from 1.514×10^6 to 1.854×10^6 Liters (400,000 to 490,000 gallons).

In RAI-SRP3.4.1-RHEB-02, the staff asked the applicant to assess the impact of the firewater tank failure on safety-related SSCs. The applicants responded in part by referring to DCD Figure 1.2-2. The applicant explained: (1) the distance from the fire water tank to the auxiliary building is 97.54 m (320 ft) and; (2) at that distance the calculated water depth would be 5.59 cm (2.2 in); and (3) that the base of the fire water tank is 30.48 cm (12 in) below the nominal plant grade of 30.48 m (100 ft). The applicant also explained that the site shall be graded with a minimum slope of 1 percent away from the reactor buildings. The applicant also committed to change the DCD to reflect the required site grading. Based upon the depth calculation and the required slope of the site in the vicinity of the tank and NI, along with the commitment to modify the DCD, the staff considers RAI-SRP3.4.1-RHEB-02 to be resolved. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

The staff also reviewed the additional features intended to prevent or limit infiltration of groundwater into seismic Category I structures. These features include embedding piping penetrations into the wall or welding the piping to a steel sleeve embedded in the wall. The amendment also specifies that no access openings or tunnels penetrating the exterior walls of the NI are below grade and that a waterproof membrane or waterproofing system will be installed for the seismic Category I structures below grade.

3.4.1.1.2 Conclusion

The staff reviewed the applicant's proposed changes to the AP1000 external flooding as documented in DCD, Revision 19. The staff finds that the proposed changes in the case of external flooding meet the applicable acceptance criteria defined in NUREG-0800 Section 3.4.1. The staff finds that all of the changes to the AP1000 external flooding are acceptable because they are in compliance with GDC 2 and GDC 4 in Appendix A to 10 CFR Part 50 and 10 CFR 52.63(a)(1)(vii), "Finality of standard design certifications."

3.4.1.2 Internal Flooding

3.4.1.2.1 Summary of Technical Information

In AP1000 DCD, Revision 17, Section 3.4.1.2.2, the applicant proposed the following changes associated with internal flooding to DCD Tier 2 of the certified design:

- The applicant proposed to modify AP1000 DCD Section 3.4.1.2.2.1, “Reactor Coolant System Compartment” to describe that a portion of the steam generator compartment has a low point at 24.38 m (80 ft, 0 in) versus the nominal elevation of 25.30 m (83 ft, 0 in). The basis for this change is described in TR-105, “Building and Structure Configuration, Layout, and General Arrangement Design Updates,” APP-GW-GLN-105, Revision 2, October 2007.

- The applicant proposed to modify AP1000 DCD Section 3.4.1.2.2.1, “Reactor Coolant System Compartment,” to reflect the use of three redundant Class 1E flood-up level indication racks (versus the two originally in the design). The applicant stated that this change was made to assure consistency with DCD Section 6.3.7.4.4.

- The applicant proposed to modify the AP1000 DCD Section 3.4.1.2.2.2, “Auxiliary Building Flooding Events, Level 5 (Elevation 135′-3″)” to remove the discussion of the 568 L (150 gallon) potable water system (PWS) tank rupture in the main mechanical heating, ventilation, and air conditioning (HVAC) equipment rooms, which drains to the turbine building via floor drains or to the annex building via flow under the doors. This change was due to the removal of the PWS from the Westinghouse AP1000 Scope of Certification and the basis for this change is described in TR-124, “Removal of PWS Source and Waste Water System (WWS) Retention Basins from Westinghouse AP1000 Scope Of Certification,” APP-GW-GLN-124, Revision 0, June 2007.

- The applicant proposed the following modifications to AP1000 DCD Section 3.4.1.2.2.2, “PCS Valve Room:”

  (a) The elevation of the PCS Valve Room is changed from 87.33 m (286 ft, 6 in) to 86.82 m (284 ft, 10 in).

  (b) “With the worst crack location being the 6-inch line between the valves and the flow control orifices. This leak is not isolable from the 2.858×10^6 L (755,000 gallon) passive containment cooling system water storage tank above the valve room.”

  (c) “Leakage will flow down to the landing at elevation 277’ 2” where the water will flow through floor drains or under doors to the upper annulus which is then discharged through redundant drains to the storm drain.”

- The applicant proposed to modify AP1000 DCD Section 3.4.1.2.2.3, “Adjacent Structures Flooding Events, Annex Building – Nonradiologically Controlled Areas” to read: “Water accumulation at elevation 100′-0″ is minimized by floor drains to the annex building sump and by flow under the access doors leading directly to the yard area.” This revision eliminates reference to the flow path through the turbine building because the access door at the 30.48 m (100 ft) elevation level was eliminated from the design. The basis for this change is described on page 6 of TR-105.

- The applicant proposed to modify AP1000 DCD Section 3.4.2.2.2.3, “Adjacent Structures Flooding Events, Radwaste Building” to read: “The potential sources of flooding in the radwaste building are the chilled water, hot water, and fire protection systems or from failure of one of the three waste monitor tanks.” The basis for this change is described in TR-116, “Additional Liquid Radwaste Monitor Tanks and Radwaste Building Extension,” APP-GW-GLN-116, Revision 0, May 2007.

- The applicant proposed editorial format changes to AP1000 DCD Section 3.4.1.3, “Permanent Dewatering System.” These editorial changes remove references to “COL applicant items.” The basis for this change is discussed in APP-GW-GLR-130, “Editorial Format Changes Related to ‘Combined License applicant’ and ‘Combined License Information Items,’” Revision 0, June 2007. The staff confirmed that these changes are editorial and that no further evaluation is required.

- The applicant also modified Section 4.4, TR-105, to describe structural changes performed to the auxiliary building.

3.4.1.2.2 Evaluation

The staff reviewed all changes related to the internal flooding analysis, Section 3.4.1.2, “Evaluation of Flooding Events,” in the AP1000 DCD, Revision 17, in accordance with NUREG-0800 Section 3.4.1, “Internal Flood Protection for Onsite Equipment Failures.” The staff reviewed the proposed changes to AP1000 DCD Section 3.4.1.2 against the applicable acceptance criteria of NUREG-0800 Section 3.4.1. The following evaluation discusses the results of the staff’s review.

3.4.1.2.2.1 Watertight Doors for Internal Flood Protection

In DCD Section 3.4.1.1.2, the applicant proposed a modification to state that watertight doors, in general, are not needed to protect safe shutdown components from the effects of internal floods with the exception of two watertight doors, those on the two waste holdup tank compartments. In NUREG-1793, Section 3.4.1.2, the staff concluded: “There are no watertight doors used for internal flood protection because they are not needed to protect safe-shutdown components from the effects of internal flooding.”

In its review of DCD Section 3.4.1.1.2, the staff identified areas in which additional information was necessary to complete its evaluation of the applicant’s change. In the DCD, the applicant does not describe those safety components that are protected via the added watertight doors on two waste holdup tank compartments, and does not reference a TR as justification. In RAI-SRP3.4.1-SBPA-01, the staff requested that the applicant demonstrate compliance with GDC 4, by addressing the following:

1) Identify the flood source(s) associated with the spent fuel pit flooding event and the potential flood volume;

2) Provide the volume of a waste hold-up tank compartment; and

3) Identify the safe shutdown components, which are protected by these watertight doors, and provide the design criteria applied for the proper functioning of these doors in the internal flood events considered.

In its July 3, 2008 response, the applicant modified the text of DCD Section 3.4.1.1.2 to reflect that the two watertight doors added during Revision 17 of the DCD were not added to protect safe-shutdown components from the effects of internal floods. These doors were added to provide additional defense-in-depth capability to retain spent fuel pool water within either a single waste holdup tank room or both waste tank rooms to limit consequences of a beyond-design-basis failure of the spent fuel pit. The applicant, in its response, also stated that the volume of a waste hold-up tank compartment is 1.9646×10^5 L (51,900 gallons). Finally, the applicant reiterated that the watertight doors are not used to protect any safe shutdown components. These watertight doors were only added to support the beyond-design-basis accident capability. The applicant stated that the watertight doors were sized to accommodate a water pressure equivalent of 20.73 m (68 ft 0 in) of head, which is conservatively based on the elevation head between the maximum spent fuel pool water level and the finished floor elevation of the tank rooms. No credit is taken for the pool's level being reduced due to the pool volume required to fill the room(s).

On the basis of its evaluation of the revised DCD Section 3.4.1.1.2, the staff finds that the applicant properly identified flood sources associated with the spent fuel pit flooding event, the potential flood volume, the volume of a waste hold-up tank compartment, and the safe shutdown components that are protected by these watertight doors, and the applicant provided an adequate means of protecting safety-related equipment from the identified flood hazards. Therefore, the staff concludes that the applicant's response is acceptable and the staff's concern described in RAI-SRP3.4.1-SBPA-01 is resolved.

3.2.1.1.1.1 Building Elevation Changes

In DCD Sections 3.4.1.2.2.1 and 3.4.1.2.2.2, the applicant proposed to make design updates or design description updates to reflect that the steam generator compartment low point elevation is at 24.38 m (80 ft, 0 in) and the passive containment cooling system (PCS) valve room elevation changed from 87.33 m (286 ft, 6 in) to 86.82 m (284 ft, 10 in).

Based on its evaluation of the DCD information, the staff finds that these changes do not affect the existing SER Section 3.4.1.2 assumptions or conclusions related to internal flooding events or protection and are, therefore, acceptable.

3.2.1.1.1.2 Addition of a Redundant Class 1E Flood-Up Level Indication Rack

In DCD Section 3.4.1.2.2.1, the applicant proposed to modify this section to reflect the use of three (versus two) redundant Class 1E flood-up level indication racks. There are no requirements for a specified level of redundancy for these sensors. Moreover, the proposed redundancy level provides an additional layer of protection and, thus, the staff considers that the proposed design demonstrates an increase in reliability when compared to the previously approved design. In addition, the staff notes that this change does not invalidate the evaluation in NUREG-1793 Section 3.4.1.2 because there is no reference to a specific redundancy level, only that redundancy is provided.

Based on its evaluation of the DCD information, the staff concludes that this change does not affect the existing SER Section 3.4.1.2 conclusions related to internal flooding events or protection in the RCS compartment.

3.2.1.1.1.3 Deletion of PWS Tank Rupture in the DCD

In DCD Section 3.4.1.2.2.2, the applicant proposed to delete the discussion of the 0.57 m3 (150 gallons) PWS tank rupture in the main mechanical HVAC equipment rooms that drains to the turbine building via floor drains or to the annex building via flow under the doors. The applicant made this change as a consequence of removing the PWS from the applicant's AP1000 scope of certification. The staff evaluated this change and concludes: 1) this area does not contain equipment whose failure could prevent safe shutdown of the plant or result in uncontrolled release of significant radioactivity; 2) the volume of water supplied by this tank is negligible; and 3) the volume of water from a postulated rupture of this tank or any other flooding source in this area would flow through floor drains to the turbine building or under doors leading to the annex building (which does not contain equipment required to be protected from internal flooding events).

However, since the PWS is no longer included in the scope of the DC, the staff determined that the applicant needed to confirm that this portion of the flooding analysis remains valid, as part of the interface requirements for the site-specific PWS. The staff requested that the applicant address this requirement in RAI-SRP3.4.1-SBPA-06.

In its response to RAI-SRP3.4.1-SBPA-06, the applicant stated that the PWS inside of the standard AP1000 plant is still included in the DCD and the DC and the discussion of the rupture of the 150 gallon PWS tank was inadvertently removed from the DCD. The applicant revised the text in DCD Section 3.4.1.2.2.2 for the potable water tank as follows:

> Water from fire fighting, postulated pipe or potable water storage tank (150 gallons) ruptures in the main mechanical HVAC equipment rooms drains to the turbine building via floor drains or to the annex building via flow under the doors. Therefore, no significant accumulation of water occurs in this room. Floor penetrations are sealed and a 6 inch platform is provided at the elevator and stairwell such that flooding in these rooms does not propagate to levels below.

Based on its evaluation of the revised DCD Section 3.4.1.2.2.2, the staff concludes that the change does not impact the NUREG-1793 Section 3.4.1.2 assumptions, findings, or conclusions related to internal flooding events or protection because the text was revised to match the staff accepted conclusions in DCD Revision 15. On the basis of its review, the staff finds the applicant's response to be acceptable and the staff's concern described in RAI-SRP3.4.1-SBPA-06 is resolved.

3.2.1.1.1.4 Volume of PCS Water Storage Tank

In DCD Section 3.4.1.2.2.2, the applicant corrected the volume of the PCS water storage tank above the valve room to a value of 2.858×10^6 L (755,000 gallons). Although the applicant did not specify the reason for this change, the staff performed its evaluation assuming it is a design change. Given that the proposed volume of water is smaller than the one previously approved, the staff concludes that its effect on the flooding analysis will be conservative.

However, the staff identified areas in which additional information was necessary to complete its evaluation. In NUREG-1793 Section 6.2.1.6, the staff presumed a usable volume of 2.8644×10^6 L (756,700 gallons), which is slightly more, for passive containment heat removal. In RAI-SRP3.4.1-SBPA-02, the staff requested that the applicant clarify and resolve the apparent discrepancy of the volume of water in the PCS water storage tank.

In its response dated July 3, 2008, the applicant stated that it agreed with the staff's conclusion that the AP1000 PCS usable PCS tank volume of 2.8644×10^6 L (756,700 gallons) is appropriate. The indicated value will be corrected in the next version of the DCD. The applicant modified the text to read "…This leak is not isolable from the 756,700 gallon passive containment cooling system water storage tank above the valve room."

Based on its evaluation of the revised DCD Section 3.4.1.1.2 text, the staff finds that the applicant clarified the PCS water storage tank design water volume available either for passive containment cooling or as a potential internal flood source and provided an adequate means of protecting safety-related equipment from the identified flood hazards. On the basis of its review, the staff finds the applicant's response to be acceptable and the staff's concern described in RAI-SRP3.4.1-SBPA-02 is acceptable.

3.2.1.1.1.5 Elimination of flow path through Turbine Building for flooding events in the Annex Building – NRCA

In DCD Section 3.4.2.2.2.3, the applicant eliminated reference to a flow path through the turbine building for flooding events in the annex building, a nonradiologically controlled area (NRCA).

The staff identified areas in which additional information was necessary to complete its evaluation of the applicant's change. In NUREG-1793 Section 3.4.1.2, page 3-21, the staff previously concluded the following:

> The mechanical equipment areas located in the NRCAs include the valve/piping penetration room (Level 3), two main steam isolation valve (MSIV) rooms, and mechanical equipment rooms (Levels 4 and 5). Flood water in these areas is routed to the turbine building or the annex building via drain lines, controlled access ways, or blowout panels which vent from the MSIV room to the turbine building.

In TR-105, the applicant did not justify the effect on the internal flooding analysis results of eliminating the route through the turbine building for flooding events. In RAI-SRP3.4.1-SBPA-03, the staff requested that the applicant clarify the effect of elimination of the turbine building drainage pathway on the internal flooding analysis results.

In its response dated July 3, 2008, the applicant stated that the elimination of the flow path to the turbine building at the 30.40 m (100 ft 0 in) level was compensated by an increase in the egress door opening to Area 4 of the annex building to match the opening previously credited to the turbine building and using the same number of alternate pathways to accommodate the flood source as previously assumed. Therefore, the applicant stated that the flood level has not been changed and remains the same as provided in Revision 15 of the DCD.

The staff identified an area in DCD Section 3.4.2.2.3 in which additional information was necessary to resolve an apparent inconsistency in the paragraph which states:

> The non-Class 1E dc and UPS system (EDS) equipment with regulatory treatment of non-safety-related systems important missions are located on elevation 100’ 0” in separate battery rooms. Water in one of these rooms due to manual fire fighting in the room is collected by floor drains to the annex building sump or flows to the turbine building under doors or to the yard area through doors.

In RAI-SRP3.4.1-SBPA-04, the staff requested that the applicant clarify the apparent discrepancy in the above paragraph. The applicant was requested to clarify whether a drainage path through the turbine building remains in the flood analysis. If there is no longer a drainage path, the applicant was asked to clarify the effect of eliminating this drainage pathway on the results of the internal flooding analysis and to verify that it does not result in any increased water level buildup that would require further evaluation.

In its response dated July 3, 2008, the applicant stated that the paragraph should have been updated consistent with the previous paragraph to reflect the elimination of the flow path to the turbine building at the 30.40 m-0.00 cm (100 ft-0 in) level. The applicant corrected the paragraph in DCD Section 3.4.2.2.3 as follows:

> The class 1E dc and UPS system (EDS) equipment with regulatory treatment of non-safety-related systems important missions is located on elevation 100’-0” in separate battery rooms. Water in one of these rooms due to manual fire fighting in the room is collected by floor drains to the annex building sump and by flow under the access doors leading directly to the yard area.

Based on its evaluation of the responses to RAI-SRP3.4.1-SBPA-03 and RAI-SRP3.4.1-SBPA-04 and the revised DCD Section 3.4.2.2.3 paragraph, the staff finds that the applicant justified that internal flooding analysis results were bounded by the change and provided an adequate means of protecting essential equipment from the identified flood hazards. On the basis of its review, the staff concludes that the applicant’s responses are acceptable and the staff’s concerns described in RAI-SRP3.4.1-SBPA-03 and RAI-SRP3.4.1-SBPA-04 are resolved.

3.2.1.1.1.6 Addition of Three Waste Monitor Tanks to Flooding Analysis

In DCD Section 3.4.1.2.2.3, the applicant included three additional potential sources of flooding, namely: “failure of one of the three waste monitor tanks.” The original design included three 56781 L (15,000 gallons) radwaste monitor tanks which are located in the auxiliary building. In TR-116, the applicant added three additional 56781 L (15,000 gallons) radwaste monitor tanks located in the radwaste building. The additional capacity resulted from evaluation of utility operational needs, and their addition required enlarging the building footprint of the radwaste building.

The staff finds that these changes do not affect the staff conclusions regarding flooding protection requirements in the radwaste building since this building does not house equipment required to be protected from the effects of flooding. Based on its evaluation of the DCD information, the staff concludes that the change does not impact the existing SER Section 3.4.1.2 assumptions, findings, or conclusions related to internal flooding and is acceptable.

3.2.1.1.1.7 Structural Changes Performed to the Auxiliary Building (Change 11)

In TR-105, Section 4.4, the applicant described structural changes performed to the auxiliary building. In RAI-SRP3.4.1-SBPA-05, the staff requested that the applicant clarify if these changes had any impact on the internal flooding analysis. The applicant was requested to confirm that the auxiliary building internal flooding analysis described in DCD Section 3.4.1.2.2.2 was updated to reflect these changes or remained valid. Further, the applicant was asked to discuss how these changes affect the auxiliary building analysis with initiating events in the annex building, given that some of the proposed changes involve additional connections between the annex building and the auxiliary building.

In its response dated July 3, 2008, the applicant stated that changes described in TR-105 Section 4.4 have no impact on the internal flooding analysis as described in DCD Section 3.4.1.2.2.2 and the analysis remains valid. The applicant stated that the structural changes in connections between the annex building and auxiliary building do not have any impact on the auxiliary building flooding analysis with initiating events in the annex building because the connection points are above the elevation of the drainage paths credited for these events.

On the basis of its evaluation, the staff finds that this is a design description update change which does not impact the auxiliary building internal flooding analysis because the revised connection points are above the elevation of the drainage paths credited for these events. Therefore, the staff finds the applicant's response to be acceptable and the staff's concern described in RAI-SRP3.4.1-SBPA-05 is resolved.

3.2.1.1.2 Conclusion

The staff identified acceptance criteria based on the design's meeting relevant requirements in 10 CFR Part 50, Appendix A, GDC 2 and GDC 4. The staff reviewed the AP1000 internal flooding design for compliance with these requirements, as referenced in NUREG-0800 Section 3.4.1, and determined that the design of the AP1000 internal flooding is acceptable because the design conforms to all applicable acceptance criteria.

The staff reviewed the applicant's proposed changes to the AP1000 internal flooding as documented in AP1000 DCD, Revision 17. The staff finds that the applicant's proposed changes do not affect the ability of the AP1000 internal flooding to meet the applicable acceptance criteria. The staff also finds that the design changes have been properly incorporated into the appropriate sections of AP1000 DCD, Revision 17. On the basis that the AP1000 internal flooding design continues to meet all applicable acceptance criteria and the changes are properly documented in the updated AP1000 DCD, the staff finds that all of the changes to the AP1000 internal flooding are acceptable.

3.4.2 Analytical and Test Procedures

The AP1000 is designed so that the maximum hydrodynamic water forces considered due to internal flooding, external flooding, and groundwater level changes caused by extreme environmental events do not jeopardize safety of the plant or the ability to achieve and maintain safe shutdown conditions. The analytical procedures for internal flooding are described in Section 3.4.1.2, "Evaluation of Flooding Events," where changes were reviewed with regard to their acceptability. In this subsection, the review will be focused on changes related to external flooding events and their impacts on the structural integrity of the safety related buildings.

3.4.2.1 Summary of Technical Information

With regard to adjacent structures flooding events involving the radwaste building, the proposed change to the DCD adds one more source of potential flooding from failure of one or more of the three added waste monitor tanks in the radwaste building. The basis for this change is described in TR-116.

3.4.2.2 Evaluation

The staff reviewed all changes related to the external flooding analysis, Section 3.4.1.1, “Flood Protection Measures for Seismic Category I Structures, Systems, and Components,” in the AP1000 DCD Revision 16, in accordance with NUREG-0800 Section 3.4.2, “Analysis Procedures.” The regulatory basis for this subsection is documented in NUREG-1793. The staff reviewed the proposed changes to AP1000 DCD Section 3.4.2.2 relevant to external flooding against the applicable acceptance criteria of the NUREG-0800 Section 3.4.2. The review of the internal flooding was described in Section 3.4.1.2, “Internal Flooding.”

The staff reviewed the change with regard to the impact on the hydrodynamic load to determine its acceptability. Since the proposed change adds three additional water tanks of 56781 L (15,000 gallon) capacity each, collapse of the radwaste building (which is a likely scenario) will have a consequence of both internal and external flooding due to the release of a large quantity of liquid from failed tanks. Since all SSCs contained in the building are non-safety related, damage by internal flooding is of no safety concern. Scenarios involving internal flooding are thus acceptable to the staff because of the evaluation contained herein. However, the release of large amounts of water from the three simultaneously failed tanks could result in external flooding to the NI structures important to safety, thereby generating extra hydrodynamic loads to the seismic Category I structures. An analysis showing these additional loads exerted from external flooding will not impair the structural integrity of the safety-related buildings is required. The staff requested that the applicant perform such an analysis in RAI-SRP3.4.2-SEB1-01:

> The design of the radwaste building has been changed to incorporate three new additional liquid waste monitor tanks and the associated piping systems (see TR-116). Provide an analysis to show that external flooding caused by the release of the liquid from tank rupture and collapse of the radwaste building due to safe shutdown earthquake (SSE) or other extreme environmental events will not impair the structural integrity of the adjacent nuclear island (NI) structures.

The applicant responded to RAI-SRP3.4.2-SEB1-01 in a letter dated December 1, 2009. The applicant stated that the increase in flood level would be 15 cm (6 in) more, added to the probable maximum flood (PMF) level due to the collapse of the 3 existing water tanks located in the auxiliary building. However, the associated extra hydrodynamic forces induced were simply stated as insignificant but not evaluated. A quantitative evaluation of the generated hydrodynamic loads showing they are insignificant on the impact to safety is needed to close this open item. This concern was identified as Open Item OI-SRP3.4.2-SEB1-01. In the response of this open item dated June 10, 2010, the applicant provided detailed calculations to arrive at additional water level of 15 cm (6 in), hydrostatic pressure of 1.53 kPa (0.032 kip per square foot (ksf)), and hydrodynamic pressure of 21.6 kPa (0.45 ksf) in APP-1000-CCC-0007, Revision 0. The staff performed an onsite review on the report regarding the methodology, input parameters and calculation procedure, and confirmed the acceptability of the report. The results of the analysis in the report showed that additional water pressures, static as well as dynamic, and increased flood level due to the rupture of water tanks are insignificant on the impact to safety or to impair safety functions needed to be performed by the NI structures. Accordingly, the staff concludes that the change meets the relevant requirements of 10 CFR Parts 50 and 52 and GDC 2 and GDC 4 to Appendix A of 10 CFR Part 50.

The staff reviewed AP1000 DCD Impact Document APP-GW-GLE-012, Revision 0, “Probable Maximum Precipitation Value Increase.” On August 26, 2008 an RAI-SRP2.4-RHEB-01 was presented to the applicant to clarify the maximum groundwater values. This information will affect design basis static and hydrodynamic effective loads applied to seismic Category I structures. This concern was identified as Open Item OI-SRP2.4-RHEB-01 regarding the PFM level and normal groundwater level. In a letter dated September 21, 2009 the response to this open item re-confirms the design-basis PFM at the grade 30.48 m (100 ft) El., and the normal groundwater level up to 29.87 m (98 ft) El. The surface water flooding may prevent outside access to the plant site. The AP1000 is designed to allow isolation for a period of seven days without an increase in safety risk. Thus, the maximum design groundwater elevation is set at 29.87 m (98 ft) El. The staff found that the clarifications in the response to the open item are acceptable and this open item is closed. Accordingly, based on the evaluations described above, the staff concluded that the change does not significantly impact the existing SER Section 2.4 assumptions and conclusions related to changes in ground water levels or protection based on 10 CFR Parts 50 and 52 and associated acceptance criteria GDC 2 and GDC 4 in the Appendix A to 10 CFR Part 50.

3.4.2.3 Conclusions

The staff reviewed the applicant’s proposed changes to the AP1000 external flooding as documented in DCD, Revision 17. The staff finds that the proposed changes in the case of external flooding meet the applicable acceptance criteria defined in the NUREG-0800 Section 3.4.2. The staff also finds that the design changes have been incorporated into the appropriate sections of the AP1000 DCD, Revision 19. Based on the evaluations performed herein, the staff finds that all of the changes to the AP1000 external flooding are acceptable because they are in compliance with the 10 CFR Part 50, Appendix A, GDC 2 and GDC 4.

3.5 Missile Protection

3.5.1.4 Missiles Generated by Tornadoes and Extreme Winds

3.5.1.4.1 Introduction

GDC 2, in part, requires that SSCs important to safety shall be designed to withstand the effects of natural phenomena such as tornadoes and hurricanes without loss of capability to perform their safety functions.

GDC 4, in part, requires that SSCs important to safety shall be appropriately protected against the effects of missiles that may result from events and conditions outside the nuclear power unit.

With respect to protection of SSCs from missiles generated by tornadoes and extreme winds, the staff reviews the design of nuclear power facilities and considers the design to be in compliance with GDC 2 and GDC 4 if it meets the guidance in RG 1.76, Positions C.1, “Design-Basis Tornado Parameters,” and C.2, “Design-Basis Tornado-Generated Missile Spectrum.”

In RG 1.76, automobile missiles generated by tornadoes are considered to impact at an altitude of less than 9.14 m (30 ft) above plant grade.

The staff reviewed the design of protection of SSCs from missiles generated by tornadoes and extreme winds for an AP1000 facility. In NUREG-1793, the staff concluded that the AP1000 design meets the requirements of GDC 2 and 4 with respect to protection against the effects of natural phenomena such as tornadoes and hurricanes and tornado generated missiles. The design also meets the guidance of RG 1.76 with respect to the identification of missiles generated by natural phenomena. In the initial Virgil C. Summer Nuclear Station (VCSNS) Units 2 and 3 COL application Final Safety Analyses Report (FSAR) Section 3.5.1.4, “Missiles Generated by Natural Phenomena,” the applicant incorporated by reference Section 3.5.1.4 of the DCD, Revision 16, with one departure that a postulated automobile tornado missile impact is not limited to the height of 9.14 m (30 ft) above grade on the NI. The applicant stated that the effects of a postulated automobile tornado missile impact above the height of 9.14 m (30 ft) above grade on the NI had been evaluated by the applicant.

3.5.1.4.2 Evaluation

During its review of VCSNS COL FSAR Section 3.5.1.4, the staff identified areas in which it needed additional information to complete the evaluation of the departure stated in VCSNS COL FSAR Section 3.5.1.4. Therefore, in an RAI (RAI COL03.05.01.04-1), the staff requested that the applicant describe/provide its evaluation of the postulated automobile tornado missile striking plant structures at elevations higher than 9.14 m (30 ft) above plant grade due to elevated local topography located within 804.67 m (1/2 mile) of the facility. In its responses dated September 10, 2009 and October 21, 2009, the VCSNS applicant discussed TR-133, APP-GW-GLR-133, “Summary of Automobile Tornado Missile 30' above Grade,” Revision 0, dated August 2007. The VCSNS applicant stated that TR-133 envelops the impact analysis of the automobile missile above elevation 39.63 m (130 ft) at VCSNS.

Subsequently, the DCA applicant communicated to the staff that the issue regarding the effects of a postulated tornado generated automobile missile would be addressed generically in the AP1000 DCD rather than in the VCSNS COL FSAR. Accordingly, in its response dated February 16, 2010 to RAI COL03.05.01.04-1, the DCA applicant stated that the postulated tornado-generated automobile missile could impact the plant structures up to the junction of the outer wall of the passive containment cooling water storage tank with the roof of the shield building. The applicant proposed a revision to AP1000 DCD Tier 2 Section 3.5.1.4 to reflect this change and stated that the proposed change, as evaluated in TR-133, would envelop all of the referenced AP1000 sites.

On March 3, 2010, the staff conducted an audit of the automobile tornado missile calculations at the applicant’s Twinbrook office in Rockville, Maryland. The staff issued its audit report on March 24, 2010, which identified nine audit findings. Most of these audit findings were in the nature of requesting clarifications of discrepancies between TR-133 and the DCD and more detailed descriptions regarding the protection provided for the AP1000 facility against tornado generated automobile missiles (i.e., justification for why the passive containment cooling water tank was excluded from the automobile missile, justification for why the y-axis label was blacked out from Figure 1 in APP-GW-GLR-133, justification for why temporary blockage of the air-inlets in the shield building was not a concern, etc.). The most significant area of concern is the evaluation of the global effect of an automobile impact on the shield building including stress.

In addition, during the structural review of TR-133, Revision 0, the staff identified an issue related to the forcing function used in the report as an input for assessing damage due to the automobile impact in the safety analysis, and found that the report did not provide any basis or justification for the input of the forcing function used for the automobile missile impact. To address this concern, the applicant committed to update TR-133 to justify the use of the forcing function. Based on the review, the staff agreed that, because of the similarity of the impact, it is appropriate to use the same forcing function to perform the damage assessment. Accordingly, the applicant committed to add this report as a reference in TR-133, Revision 1. On May 28, 2010, the applicant submitted Revision 1 of TR-133. The staff reviewed TR-133, Revision 1, and confirmed that the forcing function used as a basis for the analysis was added to the report.

Also, in its letter of May 27, 2010, the applicant provided responses to the staff's concerns regarding the evaluation of the global effect of an automobile impact on the shield building, including stress. These staff concerns, the applicant's responses, and the staff's evaluation of the applicant's responses are described below:

In the event of an automobile missile strike on the nuclear island structures 9.14 m (30 ft) above grade, there would be two safety concerns for the seismic Category I structures: (1) local damage; and (2) global damage. The staff reviewed the analysis of local damage in APP-1000-CCC-015, Revision 0 entitled: "Nuclear Island-Tornado Missile Automobile Impact 30' Above Grade." In the report, the applicant considered an impact area 2.01 m by 1.31 m (6.6 ft by 4.3 ft) by the automobile missile with a shear area 0.39 m x 0.60 m (1.29 ft x 1.98 ft) at the weakest location. The shear resistance of the RC wall was assessed at 112.99 pounds per square inch (psi), and the maximum shear stress induced by the impact was calculated to be 89.15 psi. Since the applied shear stress is less than the concrete wall shear resistance, the applicant concluded that the wall is able to resist the impact from being punched through. On this basis, the staff considers that the local damage concern at the impact spot is resolved. Another local damage concern is the crack initiation at the siding missile strike site. If the site is located at a critical section, the crack may grow unstably under the maximum stress induced by the automobile missile impact force as well as the strong tornado wind load. This safety concern was addressed in Section 3.3.4.

In addressing the global damage concern, the applicant provided a safety analysis under Audit Item 8, page 6 of 7 in its Response to RAI COL03.05.01.04-1, Revision 1, dated March 24, 2010. In the report, the possibility of failure at the connector joints of the shield building structure was considered. The analysis showed that an impact force of 3425 kilonewtons (kN) (770 kip) from the automobile missile strike will give rise to a shearing force of 3425 kN (770 kip) and a bending moment of 155.3 meganewton-meter (MN-m) (114,540 kip-ft) at the RC/ steel and concrete composite (SC) connection. The shear resistance at the weakest SS site is 104.1 MN (23,400 kip) and bending moment resistance 3929 MN-m (2,898,000 kip-ft), far exceeding the applied load exerted by the missile. This provided assurance that the connector will not fail under the automobile missile strikes.

The safety concerns of global failure due to sliding and overturning at the base were addressed in the May 13, 2010 audit. The safety analysis was provided in APP-1000-CCC-007, Revision 0 entitled: "Further Evaluation of Potential Tornado Missiles on Nuclear Island." In the report, the resistant shear and bending moment of the building were shown to far exceed the applied shear and bending moment induced by the auto impact with a safety factor of up to 300. However, the review by the staff revealed that the analysis used an incorrect bending moment arm: the center of rotation should be at the base rather than at the connector. The analysis also failed to take the tornado load of 1586 MPa (230 ksi) into account. As a result, the safety factor was dramatically reduced to less than 30 after the corrections. The applicant committed to make the corrections to APP-1000-CCC-007. The staff reviewed APP-1000-CCC-007, Revision 1 and confirmed that the corrections were made.

Based on the safety analysis performed by the applicant against global as well as local failure due to an automobile missile strike 58 m (193 ft) above grade, the staff reviewed and accepted that assurance has been provided that the structural integrity of the NI structures will not be compromised and that the change complies with 10 CFR Part 50 Appendix A, GDC 2 and GDC 4.

In addition, in Enclosure 1 to the letter dated May 27, 2010, the applicant proposed to revise the first bullet under AP1000 DCD Section 3.5.1.4 as follows:

> A massive high-kinetic-energy missile, which deforms on impact. It is assumed to be a 4000-pound automobile impacting the structure at normal incidence with a horizontal velocity of 105 mph or a vertical velocity of 74 mph. This missile is considered at all plant elevations up to 30 feet above grade. In addition, to consider automobiles parked within half a mile of the plant at higher elevations than the plant grade elevation, the evaluation of the automobile missile is considered at all plant elevations up to the junction of the outer wall of the passive containment cooling water storage tank with the roof of the shield building. This elevation is approximately 193 feet above grade. This evaluation bounds sites with automobiles parked within half a mile of the shield building and auxiliary building at elevations up to the equivalent of 163 feet above grade.

Based on its review and audit of the applicant's responses to the above-cited RAI and the applicant's proposed revision to the AP1000 DCD Section 3.5.1.4, the staff finds that the AP1000 design continues to meet the requirements of GDC 2 and GDC 4 with respect to its ability to withstand the effects of natural phenomena and contains plant features that adequately protect against the postulated automobile tornado missile. Therefore, the staff considers its concerns described in RAI-COL03.05.01.04-01 resolved. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

3.5.1.4.3 Conclusions

The staff reviewed the applicant's proposed changes to the AP1000 postulated tornado automobile missile analysis. The staff finds that the proposed changes related to the postulated tornado-generated automobile missile analysis meet the applicable acceptance criteria defined in NUREG-0800 Section 3.5.1.4. The staff finds that the changes related to postulated tornado automobile missiles are acceptable because they are in compliance with 10 CFR Part 50, Appendix A, GDC 2 and GDC 4.

3.5.3 Barrier Design Procedures

3.5.3.1 Summary of Technical Information

The commitment to address in the combined license information (DCD COL Information Items 3.3-1, "Wind and Tornado Site Interface Criteria" and 3.5-1, "External Missile Protection Requirements"), onsite interface criteria for missile generation and wind and tornado loadings by the COL applicant is met in TR-5, Revision 4. The proposed changes to supply the details of the Information Items are incorporated into the DCD as follows:

- Evaluation of generic wind and tornado loadings on structures,
- Provision of the plant specific site plan and comparison with the typical site plan shown in Figure 1.2-2 of the DCD Section 1.2,
- Discussion of missiles produced by tornadoes and other external events, and
- Evaluation of other buildings for collapse and missile generation.

The staff evaluations are focused on the demonstration that any exceedances or differences in the evaluation results from those specified in the DCD do not compromise the safety of the nuclear power plant.

3.5.3.2 Evaluation

The AP1000 DCD Revision 16, Tier 2, proposed closure of COL Information Items 3.3-1 and 3.5-1 in Section 3.5. In order to close out the COL Information Items, the following items must be addressed by the COL applicant:

(1) Tornado-Initiated Building Collapse (Information Item 3.3-1)

If the COL applicant has adjacent structures different from the typical site plan shown in Figure 1.2-2 of DCD Section 1.2, a justification must be provided to show that they will not collapse or that their failure will not impair the structural integrity of the NI safety-related structures. The structures in the typical site plan have now been evaluated for tornado-initiated failure or collapse. The analysis shows that they will not compromise the safety of the NI structures or result in reclassification of their seismic categories.

The staff reviewed the analysis and found that the procedure followed NUREG-0800 Section 3.5.3, "Barrier Design Procedures," and conformed to applicable codes and RG 1.142, "Safety-Related Concrete Structures for Nuclear Power Plants (Other than Reactor Vessels and Containments)." This is acceptable; however, there is one issue that requires further investigation: The radwaste building was evaluated for the potential impact of its collapse on the NI structures to demonstrate that it would not impair the structural integrity of the NI safety-related structures (see DCD Section 3.7.2.8.2). However, because of the addition of three liquid radwaste monitor tanks (see TR-116), which completely alters the structural dynamic characteristics of the building, it is not clear whether this conclusion is still valid. This concern was identified as Open Item OI-SRP3.7.2-SEB1-02. Additional information on this open item is in Section 3.3.4 of this report. As discussed in Section 3.3.4, the safety concern in this open item was that, in the event of a collapse of the radwaste building during a design-basis tornado strike, the three water tanks inside the building were identified as a potential threat to safety if they were allowed to get loose to become a high energy damaging missile. In an attempt to close this open item, the applicant provided a safety analysis in APP-1000-CCC-007, Revision 0 titled, "Further Evaluation of Potential Tornado Missiles on Nuclear Island," showing that during a design-basis tornado event the anchor supports for the three water tanks have adequate resistant strength to prevent the tanks from breaking away to become missiles. On May 13, 2010, the staff performed an onsite review on this TR at the applicant's Twinbrook office. The staff conducted an independent confirmatory analysis and confirmed that so long as the tornado wind speed does not exceed 141.3 m/s (316 mph), the water tanks will not become damaging missiles. Since the design-basis tornado wind speed is set at 134.1 m/s (300 mph) in the DCD, a safety margin of 5 percent is obtained. Detailed reviewed results were discussed in Section 3.3.4. Based on the assurance provided by the TR submitted by the applicant, the staff finds that it is acceptable, and this open item is closed.

(2) Missiles generated by external events (Information Item 3.5-1)

The AP1000 tornado missiles used for design are defined in Table 2.2.-1 of the DCD Section 3.5.1.4 in terms of missile type versus energy spectrum, which is consistent with RG 1.76. Other than by tornado, missiles may also be generated from external events such as transportation accidents or explosions. The COL applicant is responsible for identifying sources in the plant and the external events that could produce missile(s) that threaten the integrity of AP1000 safety-related SSCs. The missile energy should be compared with the table in Section 3.5.1.4. If the external event missile has higher kinetic energy than that given in the table, the effect of the impact must be evaluated to show that it does not compromise the safety of the AP1000 safety-related structures.

The staff reviewed this item, and found that this extra requirement in the barrier design procedure demanded in the Information Item 3.5-1 conforms to the procedure outlined in NUREG-0800 Section 3.5.3 and the criteria dictated by GDC 4 of Appendix A to 10CFR Part 50, which require that SSCs important to safety be protected from the effects of missiles, and GDC 2 concerning the capability of the structures, shields and barriers to protect SSCs important to safety from the effects of natural phenomena. However, there is one remaining issue that requires further evaluation. The issue is related to the missiles that are produced by the potential blow-off of the siding. In the annex building as well as turbine building, metallic insulated siding is permitted to blow off during the extreme environmental event. It appears that the resulting missile in this case does not belong to any missile types listed in Table 2.2-1. Moreover, it is not clear whether the energy spectrum in the table bounds the missile energies associated with the siding-generated missiles.

By letter dated December 23, 2008, the applicant responded to RAI-SRP3.3.2-SEB1-01 regarding the issue of missiles that are produced by the potential blow-off of the siding on the annex building as well as the turbine building. In its response, the applicant indicated that “The automobile in the missile spectrum included in the AP1000 would appear to bound the mass and energy of sheet metal siding. Also there are no safety-related structures, systems, and components outside of the Auxiliary Building and Shield Building. The walls of these buildings are reinforced concrete at least 2 ft thick. Tornado driven siding would not be expected to be a challenge to reinforced concrete walls.” The staff notes that the construction of the shield building is not RC and can best be described as “steel-concrete-steel modular wall construction.” It is likely that the siding missile can penetrate the steel sheet of the modular wall of the shield building and the RC roof. Thus, the reanalysis of the shield building for a tornado-driven siding missile was Open Item OI-SRP3.3.2-SEB1-01. In a letter dated March 24, 2010, the applicant responded to Open Item OI-SRP3.3.2-SEB1-01 regarding the issue of damage induced by siding missiles. In the response, it is concluded that the penetration will be zero according to the basic assumptions, methodology and detailed calculations presented in the TR, APP-1000-CCC-007, Revision 0, “Further Evaluation of Potential Tornado Missiles on Nuclear Island.”

An independent confirmatory analysis performed by the staff showed that for a metallic plank missile, with a mass of 7.8 kg (17.2 lb), flying at a velocity of 134.1 m/s (300 mph), the corner impact on the shield building could cause substantial damage in the form of major cracks several feet long and that a noticeable opening might take place. Details of the analysis are discussed in Section 3.3.4. Nevertheless, because of the large dimensions of the structures, a total collapse of the building is not likely, due to the residual strength of the components (e.g., inner steel panel of the S-C wall or intact rebar in the RC roof). Thus, the structural integrity would still be maintained.

Based on the evaluations described above, the staff concluded that, under the design-basis tornado wind loads, the structural integrity of the seismic Category I structures will not be compromised by the siding missile strikes and that those structures are, thus, in compliance with GDC 2 and GDC 4 in Appendix A to 10 CFR Part 50. However, after a tornado strike, the licensee is required to inspect and assess the damage to determine the plant's operability. If significant damage occurs (such as that described herewith), remedial measures must be taken, including shutdown. Furthermore, prior to resuming operations, the licensee must demonstrate that no functional impairment remains to those features necessary for continued operation without undue risk to the public health and safety, and that the licensing basis is maintained.

3.5.3.3 Conclusions

COL Information Item 3.3-1 defines the design procedure in the case of tornado-initiated building collapse. Should the nonsafety-related building collapse, the COL applicant will be required to demonstrate that the design procedure for the barriers to protect the neighboring Category I structures conforms to the acceptance criteria dictated by NUREG-0800 Section 3.5.3 and GDC 2 and GDC 4 in Appendix A to 10 CFR Part 50.

COL Information Item 3.5-1 defines acceptable missile type and energy consistent with RG 1.76. The applicant is responsible for identifying internal sources and external events that have potential of generating hazardous missiles. If the missile energy is higher than that specified in RG 1.76, the effect of impact must be evaluated as an extra requirement in the barrier design procedure to show that it will not impair the structural integrity of the adjacent NI safety-related structures.

The staff reviewed these two changes in Section 3.5.4, COL Information against the NUREG-0800 guidelines and acceptance criteria regarding the barrier design procedure. Based on the discussion described above by letter dated December 23, 2008, the applicant responded to RAI-SRP3.3.2-SEB1-01 regarding the issue of missiles that are produced by the potential blow-off of the siding on the annex building as well as the turbine building. In its response, the applicant indicated that "The automobile in the missile spectrum included in the AP1000 would appear to bound the mass and energy of sheet metal siding. Also there are no safety-related structures, systems, and components outside of the Auxiliary Building and Shield Building. The walls of these buildings are reinforced concrete at least two feet thick. Tornado driven siding would not be expected to be a challenge to reinforced concrete walls." The staff notes that the construction of the shield building is not RC and can best be described as "steel-concrete-steel modular wall construction." It is likely that the siding missile can penetrate the steel sheet of the modular wall of the shield building and the RC roof. Thus, the reanalysis of the shield building for a tornado-driven siding missile is Open Item OI-SRP3.3.2-SEB1-01. By letter dated March 24, 2010, the applicant responded to Open Item OI-SRP3.3.2-SEB1-01 regarding the damage issue induced by siding missiles. In the response, it is concluded that the penetration will be zero according to the basic assumptions, methodology and detailed calculations presented in the APP-1000-CCC-007, Revision 0, “Further Evaluation of Potential Tornado Missiles on Nuclear Island.”

3.6 Protection against the Dynamic Effects Associated with the Postulated Rupture of Piping

3.6.1 Plant Design for Protection Against Postulated Piping Failures in Fluid Systems Outside Containment

3.6.1.1 Summary of Technical Information

Section 3.6.1, “Postulated Piping Failures in Fluid Systems Inside and Outside Containment,” of the AP1000 DCD, Revision 15, was approved by staff in the certified design. In the AP1000 DCD, Revision 17, the applicant has proposed to make the following changes to this section of the certified design:

1. In DCD Section 3.6.1.1, “Design Basis,” paragraph J, the applicant proposed to revise those secondary, nonsafety-related components that are used to mitigate postulated line ruptures. The applicant’s justification characterized this change as an editorial change that provides consistency with TR-86, “Alternate Steam and Power Conversion Design,” (APP-GW-GLN-018).

2. In DCD Section 3.6.1.3.3, “Special Protection Considerations,” the applicant proposed to delete the following statement in the criterion for instrumentation required to function following a pipe rupture: “In the event of a high-energy line break outside containment, the only safety-related instrumentation that could be affected is the pressure and flow instrumentation in the MSIV compartment conditions resulting from a 1-square-foot break from either main steam or feedwater line in the MSIV compartment as required in order to perform its safety functions.” The bullet now states that instrumentation required to function following a pipe rupture is protected. The justification for this change is discussed in TR-125, “Corrections to Tier 1 ITAAC 2.2.4 and Tier 2 Section 3.6.1.3.3 and 10.3,” APP-GW-GLR-125, Revision 0, May 2007.

3. In DCD Section 3.6.4.1, “Pipe Break Hazards analysis,” the applicant provided COL actions that reference back to the design basis criteria in Section 3.6.1. The applicant has proposed to revise this COL item to direct the COL applicant to address the completion of the as-designed pipe break hazards analysis.

3.6.1.2 Evaluation

The staff reviewed all changes to the Section 3.6.1 in the AP1000 DCD Revision 17 in accordance with NUREG-0800 Section 3.6.1, “Plant Design for Protection Against Postulated Piping Failures in Fluid Systems Outside Containment.” The regulatory basis for Section 3.6.1 of the AP1000 DCD is documented in NUREG-1793. The staff reviewed the proposed changes to the AP1000 DCD Section 3.6.1 against the applicable acceptance criteria of NUREG-0800 Section 3.6.1. The staff’s review of DCD Section 3.6.1 was limited to postulated piping failures outside containment. The staff’s evaluation of the postulated piping failures inside containment is discussed in Section 3.6.2 of this report.

The following evaluation discusses the results of the staff’s review.

3.6.1.2.1 Design Basis Assumptions

In DCD Revision 16, Tier 2, Section 3.6.1, the applicant provided the design basis and criteria for the analysis needed to demonstrate that safety-related systems are protected from pipe ruptures. This DCD section enumerates the high- and moderate-energy systems, which are potential sources of the dynamic effects associated with pipe ruptures. It also defines separation criteria.

One of the design-basis assumptions used in the dynamic effects analysis for pipe failures included the secondary components (e.g., turbine stop, moisture separator reheater stop, and turbine bypass valves). These valves are credited with mitigating the consequences of a postulated steamline break (given a single active component failure).

In its review of DCD Revision 16, Section 3.6.1, the staff identified areas in which additional information was necessary to complete its evaluation of the applicant's change. In Revision 16 to the DCD Section 3.6.1.1 to paragraph J, the applicant amended the list of secondary components to include the turbine control and stop, the turbine interceptor and reheat stop, and the turbine bypass (steam dump) valves. However, in DCD Section 3.6.1.3.3, the secondary components list consisted of the turbine stop, the moisture separator reheater stop, and the turbine bypass valves, which was inconsistent with paragraph J of DCD Section 3.6.1.1. In RAI-SRP3.6.1-SBPA-01, the staff requested that the applicant resolve the inconsistency identified between Sections 3.6.1.1 and 3.6.1.3.3.

In its response dated July 3, 2008, the applicant acknowledged the inconsistency and confirmed that the non-safety-related valves used to mitigate postulated line ruptures, given the failure of no more than one MSIV, are:

- Turbine Control and Stop Valves
- Turbine Bypass Valves
- Moisture Separator Reheat Supply Steam Control Valves

These valves are identified in the AP1000 Technical Specification (TS) Bases (DCD Section 16.1, B3.7.2), which states that "[t]he non-safety related turbine stop or control valves, in combination with the turbine bypass, and moisture separator reheat supply steam control valves, are assumed as a backup to isolate the steam flow path given a single failure of an MSIV."

In addition, the applicant stated, that based on their review, the inconsistency was not only in Section 3.6.1.1, paragraph J and in Section 3.6.1.3.3 of the DCD, but also in Section 10.3.1.1 of the DCD.

As part of its response, the applicant provided a markup of the AP1000 DCD, Revision 16, Sections 3.6.1.1, 3.6.1.3.3, and 10.3.1.1 to rectify the inconsistencies. The staff has confirmed that the AP1000 DCD, Revision 17 has included these changes.

On the basis of its review and evaluation, the staff finds that the revisions to the DCD have corrected the inconsistencies in the application; therefore, the staff finds the applicant's response to be acceptable and the staff's concern described in RAI-SRP3.6.1-SBPA-01 is resolved.

3.6.1.2.2 Protection Mechanisms

In DCD Revision 16, Tier 2, Section 3.6.1, the applicant provided the measures used in the AP1000 design to protect safety-related equipment from the dynamic effects of pipe failures. These measures include physical separation of systems and components, barriers, equipment shields, and pipe whip restraints. The specific method used depends on objectives such as adequate allowance for equipment accessibility and maintenance.

Separation between redundant safety systems is the preferred method used to protect against the dynamic effects of pipe failures. Separation is achieved using the following design features:

- locating safety-related systems away from high-energy piping
- locating redundant safety systems in separate compartments
- enclosing specific components to ensure protection and redundancy
- providing drainage systems for flood control.

The staff identified an area in which additional information was necessary to complete its evaluation of the applicant's change. There was an inconsistency between TR-125 and the DCD revision that needed to be resolved. In DCD Revision 16, Section 3.6.1.3.3, the applicant provided specific protection considerations and provided the justification for revising the DCD. However, in TR-125, the applicant deleted the entire second bullet, while in Revision 16 to the DCD, the first sentence of the second bullet remained (e.g., "Instrumentation required to function following a pipe rupture is protected.") In RAI-SRP3.6.1-SBPA-02, the staff requested that the applicant resolve this inconsistency.

In its response dated July 3, 2008, the applicant stated that in developing the markup for TR-125, Revision 0, the entire second bullet of DCD Section 3.6.1.3.3 as reflected in Section 5 of TR-125, was erroneously deleted. When preparing the DCD text, however, the first sentence of the second bullet was correctly retained since it is applicable to all safety-related instrumentation located in a harsh environment.

The applicant further stated that TR-125 Section 5.0 will be revised to be consistent with DCD Section 3.6.1.3.3 Revision 16.

On the basis of its review and evaluation, the staff finds that the change to the second bullet in DCD Section 3.6.1.3.3, Revision 19, is accurate with respect to the design specifications. The proposed change ensures that all safety-related instrumentation in a harsh environment is protected from the consequences of a pipe break. Therefore, the staff finds the applicant's response to be acceptable and the staff's concern described in RAI-SRP3.6.1-SBPA-02 is resolved.

3.6.1.2.3 COL Actions

In DCD Revision 17, Section 3.6.4.1, the applicant modified COL actions with respect to pipe break hazard analysis to address the completion of the as-designed pipe hazards analysis report. While this COL information item does not change the design basis criteria as discussed in Section 3.6.1, the modified COL Information confirms that the piping design meets the criteria provided in Section 3.6.1.3.2 (AP1000 DCD, Table 1.8-2, COL Information Item 3.6-1). The staff evaluation of the modified COL Information Item is contained in Section 3.6.2 of this report. The staff finds that the changes to the AP1000 DCD Section 3.6.4.1 COL action are acceptable, as they relate to the protection of safety related components outside containment from the effects of a pipe break. The protection of safety related components inside containment, from the effects of a pipe break, is discussed in Section 3.6.2 of this report.

3.6.1.3 Conclusions

In NUREG-1793 and its Supplement 1, the staff documented its conclusions that the AP1000 design and DCD (up to and including Revision 15 of the DCD) were acceptable and that the applicant's application for design certification met the requirements of Subpart B to 10 CFR Part 52, "Licenses, certifications, and approvals for nuclear power plants," that are applicable and technically relevant to the AP1000 standard plant design.

In its previous evaluations of the AP1000 DCD, Section 3.6.1, "Postulated Piping Failures in Fluid Systems Inside and Outside Containment," the staff identified acceptance criteria based on the design meeting relevant requirements in 10 CFR Part 50, Appendix A, GDC 2 and GDC 4. The staff reviewed the AP1000 postulated piping failures in fluid systems outside containment design for compliance with these requirements, as referenced in NUREG-0800 Section 3.6.1 and determined that the design of the AP1000 postulated piping failures, as documented in AP1000 DCD, Revision 15, was acceptable because the design conformed to all applicable acceptance criteria.

The staff reviewed the applicant's proposed changes to the AP1000 protection of safety related component inside containment as documented in AP1000 DCD, Revision 19. The staff finds that the applicant's proposed changes do not affect the ability of the AP1000 postulated piping failures in fluid systems outside containment to meet the applicable acceptance criteria. The staff also finds that the design changes have been properly incorporated into the appropriate sections of AP1000 DCD, Revision 19. On the basis that the AP1000 postulated piping failures in fluid systems outside containment design continue to meet all applicable acceptance criteria and the changes are properly documented in the updated AP1000 DCD, the staff finds that all of the changes to the AP1000 DCD Section 3.6.1 are acceptable.

3.6.2 Determination of Rupture Locations and Dynamic Effects Associated with the Postulated Rupture of Piping

3.6.2.1 Summary of Technical Information

AP1000 DCD Section 3.6.4.1 identifies a COL Information Item 3.6-1. The original Combined License Information Item commitment was:

> Combined License applicants referencing the AP1000 certified design will complete the final pipe whip restraint design and address as-built reconciliation of the pipe break hazards analysis in accordance with the criteria outlined in DCD Subsections 3.6.1.3.2 and 3.6.2.5. The as-built pipe rupture hazards analysis will be documented in an as-built Pipe Rupture Hazards Analysis Report.

Subsequent to the issuance of NUREG-1793, in a letter dated January 14, 2008, APP-GW-GLR-134 through Revision 4 and AP1000 DCD Revisions 16 and 17, the applicant made some DCD changes related to COL Information Item 3.6-1.

3.6.2.2 Evaluation

The staff's review of the changes made to COL Information Item 3.6-1 are based on the pertinent information included in DCD Revisions 16 and 17, TR-6, "AP1000 As-Built COL Information Items," APP-GW-GLR-021; APP-GW-GLR-074, "Pipe Break Hazards Analysis"; and APP-GW-GLR-134, "AP1000 DCD Impacts to Support COLA Standardization," through Revision 4 as well as the proposed DCD Revision 17 changes included in the applicant's letter dated January 14, 2008, and December 5, 2008. In APP-GW-GLR-021 and APP-GW-GLR-074, the applicant proposed to modify the COL information item and provided a pipe rupture hazards analysis report for staff's review. The applicant stated that the report addressed and documented, on a generic basis, design activities required to complete COL Information Item in DCD Section 3.6.4.1 in the AP 1000 DCD. The applicant further stated that when the NRC review of APP-GW-GLR-074 is complete, the included activities to address the COL information item in Section 3.6.4.1 will be considered complete for COL applicants referencing the AP1000 DC. On the basis of its review of that report, the staff found that there were numerous areas in the report that were incomplete (e.g., ASME Code Class 1 piping fatigue evaluation, the complete design of the jet shields and pipe whip restraints, use of seismic response spectrum, etc.). The staff therefore, determined that the pipe rupture analysis documented in APP-GW-GLR-074 could not be considered complete and the proposed revision to the COL Information Item 3.6-1 concerning the COL applicant's responsibility was not acceptable.

Subsequently, in a letter dated January 14, 2008, the applicant proposed to revise AP1000 DCD Revision 16, Section 3.6.4.1 to address the staff's comments on the completeness of APP-GW-GLR-074. Based on its review of the information included in DCD Revisions 16 and 17, the staff determined that the following additional information concerning the acceptability of the proposed COL holder item is needed:

1a. The staff maintains that the pipe rupture hazards analysis report in APP-GW-GLR-074 is incomplete. 10 CFR 52.79(d)(3), "Contents of applications; technical information in final safety analysis report," and RG 1.206, "Combined License Applications for Nuclear Power Plants (LWR [Light-Water Reactor] Edition)," Section C.III.4.3 allows the applicant to propose an alternative to the COL information item that cannot be resolved completely before the issuance of a license. It requires the applicant to provide sufficient information to justify why that item cannot be completed before the issuance of a license. Furthermore, it states that the applicant should provide sufficient information on this item to support the NRC licensing decision and also to propose a method for ensuring the final closure of the item including implementation schedules to allow the coordination of activities with the NRC construction inspection program following issuance of the COL. The current DCD and APP-GW-GLR-134 do not cover the level of detail described in 10 CFR 52.79(d)(3) and RG 1.206, Section C.III.4.3. The applicant is requested to propose an alternative along with the described justification including implementation schedules to allow the coordination of activities with the NRC construction inspection program.

1b. In some of the DCD Tier 1 tables of the system based design description and ITAAC, the applicant includes an acceptance criterion, which states that for the as-built piping, a pipe rupture hazards analysis report exists and concludes that protection from the dynamic effects of a line break is provided. It should be noted that the pipe rupture hazards analysis report is required for all the piping systems (with the exception of leak-before-break (LBB) piping) that are within the scope of NUREG-0800 Section 3.6.2. The staff's concern is that the current AP1000 system based ITAAC tables do not reflect that. The applicant is requested to address how the system based ITAAC approach addresses all the piping systems which are within the scope of NUREG-0800 Section 3.6.2 and are required to be included in a pipe rupture hazards analysis performed in accordance with the criteria outlined in DCD Sections 3.6.1.3.2 and 3.6.2.5.

2. In DCD Revision 16, Section 3.6.2.5 under high energy break locations, the applicant stated that for ASME Class 1 piping terminal end locations are determined from the piping isometric drawings. Intermediate break locations depend on the ASME Code stress report fatigue analysis results. These results are not available at design certification. For the design of the AP1000, breaks are postulated at locations typically associated with a high cumulative fatigue usage factor. The applicant further stated that these locations are part of the as-built reconciliation as discussed in Section 3.6.4.1. As discussed in this RAI question 1a, the determination of break locations is a part of the as-designed pipe rupture hazards analysis and is not part of the as-built reconciliation. The applicant is requested to address this concern and to revise the DCD Section 3.6.2.5 accordingly.

In a letter dated December 5, 2008, the applicant provided its response to the above RAIs. Based on its review of the applicant's response, the staff agreed with the applicant that the as-built reconciliation of the pipe rupture hazards analysis report is included in the ITAAC tables of the DCD which was previously reviewed and found acceptable by the staff. However, with respect to the as-designed pipe rupture hazards analysis, the staff found that the applicant has not yet adequately addressed the staff's concern relating to the completion of the as-designed pipe rupture hazards analysis report issue. Specifically, it is not clear that the as-designed pipe rupture hazards analysis report will include all piping systems within the scope of NUREG-0800 Section 3.6.2 and the report will include all the information as outlined in AP1000 DCD Sections 3.6.1.3.2 and 3.6.2.5. Moreover, it did not clearly address the process including the milestone for the completion of the as-designed pipe rupture hazard analysis report for all piping systems within the scope of NUREG-0800 Section 3.6.2. Furthermore, based on the review of the RAI response provided by some AP1000 COL applicants, the staff found that there is a difference of opinion between the applicant and the COL applicants as to what will be completed and, at this point, the design is not adequately addressed.

On April 9, 2009, the staff, in an AP1000 Design Centered Working Group meeting, conveyed these specific concerns to the applicant and AP1000 COL applicants. Subsequently, the applicant requested a meeting with the staff to discuss its plan, schedule and scope of the as-designed pipe rupture hazard analysis report. The meeting was held on May 20, 2009, at the applicant's Twinbrook office. During the meeting, the applicant indicated that it would complete an as-designed pipe rupture hazard analysis in accordance with the criteria outlined in DCD Sections 3.6.1.3.2 and 3.6.2.5 for all the piping systems within the scope of NUREG-0800 Sections 3.6.1 and 3.6.2 by the end of 2009 with the exception of the completion of the design for some pipe whip restraints. The remaining pipe whip restraint design would be completed by COL applicants referencing the AP1000 certified design. In addition, the applicant indicated that it would include all the above information in an RAI response to address the staff's concerns related to the as-designed piping rupture hazard evaluation issue. In response to the applicant's proposed approach, the staff indicated that it is important that all the representative AP1000 pipe whip restraint designs be completed by the applicant in its as-designed pipe rupture hazards analysis report. Also, the applicant was requested to include a discussion in its RAI response to explain what pipe whip restraints design will be completed to support staff's audit and how they are representative of the ones that will be used in the AP1000 design.

By letters dated June 30 and July 22, 2009, the applicant provided its response to RAI-SRP3.6.2-EMB2-01 R3, RAI-SRP3.6.4-EMB2-01 R3, and RAI-SRP3.6.2-EMB2-01 R4, respectively. Based on its review of these RAI responses, the staff found that the applicant had not clearly and adequately addressed all the issues discussed in the May 20, 2009, meeting and, for some areas, the information included in these RAI responses was different from what the applicant stated in that meeting.

In its response to RAI-SRP3.6.2-EMB2-01 R4, the applicant stated that the as-designed pipe rupture hazards analysis report, with the exception of some pipe whip restraint and jet shield designs, would be completed by December 31, 2009, and that some pipe whip restraint and jet shield designs were not expected to be completed in time to support the advanced SER with no open items. Completion of the remaining pipe whip restraint and jet shield designs will require a modified COL information item to be addressed in the COL applications. The applicant further indicated that portions of the evaluation to complete the COL Information Item might be completed during the COL application review or after the license was issued. It should be noted that during the May 20, 2009, meeting, the applicant indicated that to support the staff's audit, it would complete an as-designed pipe rupture hazard analysis in accordance with the criteria outlined in DCD Sections 3.6.1.3.2 and 3.6.2.5 for all the piping systems (including nonsafety-related piping systems, were not addressed in the applicant's RAI responses) within the scope of NUREG-0800 Sections 3.6.1 and 3.6.2, with the exception of the completion of the design for some pipe whip restraints (as opposed to pipe whip restraints and jet shields indicated in the applicant's RAI responses). Furthermore, based on the information included in the RAI responses, it was not clear what pipe whip restraints and jet shields design would be completed by December 31, 2009, and how they are representative of the ones that would be used in the AP1000 design. The applicant was, therefore, requested again to describe in detail which pipe whip restraint and jet shield designs would be completed to support staff's audit and how these completed pipe whip restraints and jet shield designs are representative of for the AP1000 design.

In its response to RAI-SRP3.6.2-EMB2-01 R4, the applicant also proposed some changes to DCD Sections 3.6.2.5 and 3.6.4.1. The proposed changes did not make clear that the effects of leakage and through-wall cracks in both high and moderate energy pipes (as opposed to moderate energy pipes identified in the RAI response) are to be evaluated as part of the as-designed pipe rupture hazards analysis. It should be noted that both dynamic effects and environmental effects resulting from breaks/leakage cracks need to be evaluated for high energy pipes, while only environmental effects resulting from leakage cracks need to be evaluated for moderate energy pipes. Moreover, based on the review of the proposed DCD Section 3.6.4.1 changes, it appeared that the final completion of all pipe whip restraint and jet shield designs is a COL information item; however, it was not clearly labeled as one. The applicant was requested to clearly identify it as a COL information item or to make it an ITAAC item. This item was considered as Open Item OI-SRP3.6.2-EMB2-01.

In its response to Open Item OI-SRP3.6.2-EMB2-01, the applicant submitted a letter dated April 16, 2010. The applicant proposed that the full scope of the as-designed pipe rupture hazards analysis be addressed in COL Information Item 3.6-1. The revised COL Information Item 3.6-1 would state that COL applicants referencing the AP1000 design would complete the as-designed pipe rupture hazards analysis according to the criteria outlined in DCD Sections 3.6.1.3.2 and 3.6.2.5. SSCs identified (in DCD Tier 2, Table 3.6-3) to be essential targets protected by associated mitigation features would be confirmed as part of the evaluation, and updated information would be provided as appropriate. The pipe whip restraint and jet shield design included the properties and characteristics of procured components connected to the piping, components, and walls at identified break and target locations. The design would be completed prior to installation of the piping and connected components. The COL Information Item 3.6-1 would be addressed by the COL applicant in a manner that complies with NRC guidance provided in RG 1.215, “Guidance for ITAAC Closure Under 10 CFR Part 52,” and outlined in Appendix 14.3A of the DCD. The applicant further stated that the applicant would continue to work towards completion of the as-designed pipe rupture hazards analysis, and would submit a licensing topical report to the staff documenting completion of the effort and referencing the applicable design documents. The report would support the closure of the COL Information Item for the reference standard plant.

In addition, in its response to Open Item OI-SRP3.6.2-EMB2-01, the applicant also revised DCD Tier 1, Table 3.3-6 Line Item 8, which requires an as-built reconciliation of the pipe rupture hazards analysis be completed prior to fuel load. The as-built reconciliation of the pipe rupture hazards analysis is to conclude that systems, structures and components identified as essential targets are protected from dynamic and environmental effects of postulated pipe ruptures.

Based on its evaluation of the above information, the staff determines that the applicant’s response adequately addressed the staff’s concerns described in Open Item OI-SRP3.6.2-EMB2-01. Specifically, the proposed COL Information Item 3.6-1 and the guidance outlined in Appendix 14.3A of the DCD will ensure that the COL applicants referencing the AP1000 design will complete the as-designed pipe rupture hazards analysis report and will make it available for staff’s verification in accordance with the guidance outlined in Appendix 14.3A of the DCD. In addition, the as-designed pipe rupture hazards analysis will be performed for all the piping systems within the scope of NUREG-0800 Sections 3.6.1 and 3.6.2 in accordance with the criteria outlined in DCD Sections 3.6.1.3.2 and 3.6.2.5. Therefore, the applicant’s RAI response adequately addressed all the staff’s safety questions/concerns identified in Open Item OI-SRP3.6.2-EMB2-01. In addition, the revised DCD Tier 1, Table 3.3-6 Line Item 8, provides an acceptable as-built reconciliation of pipe rupture hazards analysis and will ensure that systems, structures and components identified as essential targets are protected from dynamic and environmental effects of postulated pipe ruptures. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

3.6.2.3 Conclusion

The staff concludes that the applicant’s proposed changes to the COL information item are acceptable because they meet the applicable 10 CFR Part 52 requirements. Specifically, the applicant has provided an acceptable alternative along with the technical justification as described in 10 CFR 52.79(d)(3) and RG 1.206 Section C.III.4.3 regarding COL information items that cannot be resolved before the issuance of a license.

3.6.3 Leak-Before-Break

3.6.3.1 Introduction

In Revision 16 to the AP1000 DCD, the applicant proposed to resolve COL Information Item 3.6-2 by addressing the as-designed LBB evaluation in TR-8, “AP1000 Leak-Before-Break Evaluation of As-Designed Piping,” APP-GW-GLR-022, Revision 1. COL Information Item 3.6-2 in the DCD, which is also discussed in NUREG-1793, as COL Action Item 3.6.3.1-2, specifies requirements for the as-designed evaluation of LBB characteristics in AP1000 LBB piping systems. The applicant submitted TR-8 for the staff’s review to demonstrate that it has met the requirements of COL Information Item 3.6-2. In Revision 15 to the AP1000 DCD, Section 3.6.4.2 states:

> Combined License applicants referencing the AP1000 certified design will complete the leak-before-break evaluation by comparing the results of the as-designed piping stress analysis with the bounding analysis curves documented in Appendix 3B. The Combined License applicant may perform leak-before-break evaluation for a specific location and loading for cases not covered by the bounding analysis curves. Successfully satisfying the bounding analysis curve limits in Appendix 3B may necessitate lowering the detection limit for unidentified leakage in containment from 0.5 gpm to 0.25 gpm. If so, the Combined License holder shall provide a leak detection system capable of detecting a 0.25 gpm leak within 1 hour and shall modify appropriate portions of the DCD including subsections 5.2.5, 3.6.3.3, 11.2.4.1, Technical Specification 3.4.7 (and Bases), Technical Specification Bases B3.4.9, and Technical Specification 3.7.8 (and Bases). The leak-before-break evaluation will be documented in a leak-before-break evaluation report.

In Revision 16 of the AP1000 DCD, the applicant proposed to resolve COL Information Item 3.6-2 by addressing the as-designed LBB evaluation in TR-8. The revision to Section 3.6.4.2 of the DCD states:

> The Combined License information requested in this subsection has been completely addressed in APP-GW-GLR-022, and the applicable changes are incorporated into the DCD. No additional work is required by the Combined License applicant.
>
> The following words represent the original Combined License Information item commitment, which has been addressed as discussed above:
>
> Combined License applications referencing the AP1000 certified design will complete the leak-before-break evaluation by comparing the results of the as-designed piping stress analysis with the bounding analysis curves [BACs] documented in Appendix 3B. The Combined License applicant may perform leak-before-break evaluation for a specific location and loading for cases not covered by the bounding analysis curves. Successfully satisfying the bounding analysis curve limits in Appendix 3B may necessitate lowering the detection limit for unidentified leakage in containment from 1.9 L/m (0.5 gpm) to 0.9 L/m (0.25 gpm). If so, the Combined License holder shall provide a leak detection system capable of detecting a 0.9 L/m (0.25 gpm) leak within 1 hour and shall modify appropriate portions of the DCD including subsections 5.2.5, 3.6.3.3, 11.2.4.1, Technical Specification 3.4.7 (and Bases), Technical Specification Bases B3.4.9, and Technical Specification 3.7.8 (and Bases). The leak-before-break evaluation will be documented in a leak-before-break evaluation report.

The scope of this evaluation does not include piping stress analysis reports whose outputs are used as inputs to this LBB evaluation.

In Revision 16 to the AP1000 DCD, the applicant proposed to delete COL Information Item 3.6-3 for the LBB evaluation. COL Information Item 3.6-3 in the applicant DCD, which is also discussed in NUREG-1793 as COL Action Item 3.6.3.1-1, specifies requirements for the as-built evaluation of LBB characteristics in certain AP1000 piping systems. The applicant submitted APP-GW-GLR-021, Revision 0, for staff review to demonstrate that COL Information

Item 3.6-3 may be deleted. In Revision 15, Section 3.6.4.3 to the AP1000 DCD, COL Information Item 3.6-3 states:

> Combined License applications referencing the AP1000 certified design will address: 1) verification that the as-built stresses, diameter, wall thickness, material, welding process, pressure, and temperature in the piping excluded from consideration of the dynamic effects of pipe break are bounded by the leak-before-break bounding analysis; 2) a review of the Certified Material Test Reports or Certifications from the Material Manufacturer to verify that the ASME Code, Section III strength and Charpy toughness requirements are satisfied; and 3) complete the leak-before-break evaluation by comparing the results of the final piping stress analysis with the bounding analysis curves documented in Appendix 3B. The leak-before-break evaluation will be documented in a leak-before-break evaluation report.

In Revision 16 to the AP1000 DCD, the applicant proposed to resolve COL Information Item 3.6-3 by deleting the text in Section 3.6.4.3. The applicant provided TR-6 as justification to delete COL Information Item 3.6-3.

In Revision 17 of the AP1000 DCD, the applicant proposed to change the composition of the main steam line (MSL) piping material. Previously, in Table 3B-1 of the DCD (Revision 15), the applicant identified the MSL material to be utilized as ASME SA-333 Grade 6. In Revision 17 of the DCD, the applicant revised its DCD in Section 3.6.3 and Appendix 3B to reflect the use of ASME SA-335 Grade 11 Alloy steel. The applicant stated that the composition of the main steam lines was revised to minimize the potential for erosion-corrosion.

3.6.3.2 Evaluation

3.6.3.2.1 COL Information Item 3.6-2

GDC 4 of Appendix A to 10 CFR Part 50 requires that SSCs important to safety shall be appropriately protected against environmental and dynamic effects. The staff reviewed changes related to this section as it relates to the LBB analysis.

The applicant has designated TR-08 to be the “LBB Evaluation Report,” as referenced in the COL information item. This report has reproduced, with limited modifications due to minor piping design changes, DCD BACs documented in Appendix 3B for the AP1000 LBB piping subsystems. For each AP1000 LBB piping subsystem, there is, however, extra information added to the BAC in TR-08: a point showing the normal stress (the horizontal axis) and the maximum stress (the vertical axis) based on the piping stress analysis report for the system. The normal stress is defined as the stress at the critical location of a AP1000 LBB piping subsystem due to normal loads (deadweight + pressure + thermal expansion), which are combined by the algebraic sum method. The maximum stress is defined as the stress at the critical location of a AP1000 LBB piping subsystem due to maximum loads (deadweight + pressure + thermal expansion + safe shutdown earthquake/inertia + safe shutdown earthquake/anchor motion), which are combined by the absolute sum method. The objective of this review is to verify that the stress pair (the normal stress and the maximum stress) for each AP1000 LBB subsystem has been calculated appropriately by the applicant based on the piping stress report results.

An RAI was issued on August 29, 2006. A revision for one of the RAI questions was issued on September 11, 2006. RAI-TR08-001 is related to the revised BAC for the 20.3 cm (8 in) automatic depressurization system (ADS) Stages 2 and 3 (upper tier) piping. RAI-TR08-002 is related to the LBB evaluation process which starts with the piping stress report results and ends with the stress pairs for all the AP1000 LBB piping subsystems. RAI-TR08-003 is related to a design change to remove the reducing tee and to add a 35.6 cm x 20.3 cm (14 in x 8 in) reducer in the upper tier of the ADS piping. The applicant provided responses to the staff RAIs in a letter dated September 29, 2006. Since quantitative information was provided for the revised BAC requested in RAI-TR08-001, this RAI is resolved. In RAI-TR08-003 the staff requested that the applicant confirm the piping design changes and their effect on the corresponding BACs. In its September 29, 2006, response, the applicant clarified the specific changes made to the piping design and confirmed that the changes do not require additional BACs because the BACs for 15.2 cm, 20.3 cm, and 35.6 cm (6 in, 8 in, and 14 in) piping were developed for the ADS upper tier piping, and are, thus, bounding. Therefore, RAI-TR08-003 is resolved.

RAI-TR08-002 requested additional information regarding the process of calculating the stress pair for each AP1000 LBB piping subsystem based on the corresponding piping stress report results. This involved computer software examinations, LBB calculation demonstrations, and on-site documents review. Consequently, an audit was conducted on August 29 and 30, 2006. During the audit, the staff examined line by line two post processing software designed by different applicant subcontractors for LBB evaluations. In addition, the staff audited the LBB stress-pair calculations for one software application using an as-designed AP1000 ADS upper-tier piping and calculations for another software application using a sample passive core cooling (PXS) piping system. As a result of this audit, the staff found that the two post-processing software applications result in accurate stress pairs for the LBB evaluation, and the use of the software procedure, which does not rely on manual input of technical data, would minimize human error.

The staff's evaluation was based on the piping stress analysis results using seismic loadings associated with an AP1000 plant situated on a hard-rock (HR) site. At that time, the applicant was considering revising the AP1000 seismic design to include plants situated on soil sites as well. Because the seismic loadings for a plant situated on a soil site are likely to be higher than those for a plant situated on a HR site, the LBB analyses for AP1000 plants situated on soil sites (or other sites other than HR) would likely be affected. Thus, the staff's evaluation of the LBB analyses considered seismic loadings for HR sites only. The staff confirmed that each added stress point is enveloped by the BAC curve of its piping system, indicating that all piping systems have met the requirements of COL Information Item 3.6-2. Hence, the applicant has demonstrated that all as-designed AP1000 LBB subsystems for plants situated on HR sites meet the GDC 4 requirements for LBB applications so that the dynamic effects of postulated high-energy line pipe breaks need not be evaluated for these systems.

In addition, the proposed justification for eliminating COL Information Item 3.6-2 is based on the staff's review of the applicant's detailed design information that demonstrates that the LBB calculations are bounded by the bounding analysis curves in the AP1000 DCD. The LBB as-designed analyses as described in TR-08 (APP-GW-GLR-022) are applicable to all COL applications referencing an AP1000 plant situated on a HR site. The final as-built LBB analyses will be verified by the staff as part of its verification of ITAAC.

TR-08 also confirmed that the leak detection capability limit for unidentified leakage inside containment is 1.9 Lpm (0.5 gpm) as described in the DCD.

By letter dated June 20, 2008, the applicant addressed the LBB evaluation for AP1000 plants situated on other-than-HR sites as follows:

> The other-than-hard-rock site seismic spectra are included in the piping analysis that is within the piping DAC review. The LBB evaluation results will indicate that the bounding analysis curves for piping that was evaluated for the other-than-hard-rock seismic input are acceptable and can be addressed as part of the piping DAC review.

The staff reviewed the applicant's response to address LBB for as-designed piping using other than HR site seismic spectra. The applicant stated that for plants situated on other-than-HR-sites, the as-designed LBB analyses would be completed in conjunction with piping design acceptance criteria (DAC), now a COL item (see Section 3.6.2). The staff will review the final as-built LBB analyses results as part of its review of the COL item to verify that the LBB acceptance criteria are met. On the basis of its review of APP-GW-GLR-022 (TR-08), the staff finds that the LBB analysis in TR-08 meets the requirements of GDC 4 and is acceptable; COL Information Item 3.6-2 is closed.

3.6.3.2.2 COL Information Item 3.6-3

GDC 4 of Appendix A to 10 CFR Part 50 requires that SSCs important to safety shall be appropriately protected against environmental and dynamic effects. The staff reviewed changes related to this section as it relates to the LBB analysis.

TR-06 states that the as-built evaluation of LBB characteristics will be completed after construction of the associated piping systems, as required by the ITAACs, and deletion of the COL Information Item, which requires completion of the as-built evaluation, does not alter the as-designed LBB evaluation. Since the applicant's justification did not address all three requirements in COL Information Item 3.6-3, the staff requested, in a letter dated August 29, 2006, that the applicant justify the proposed deletion of this COL information item in accordance with the following RAI (RAI-TR06-002):

> On page 4 of the report, you propose to delete COL Information Item 3.6-3 regarding the as-built evaluation of leak-before-break piping systems. COL Information Item 3.6-3 has three elements: "1) verification that the as-built stresses, diameter, wall thickness, material, welding process, pressure, and temperature in the piping are bounded by the leak-before-break bounding analysis; 2) a review of the Certified Material Test Reports or Certifications from the Material Manufacturer to verify that the ASME Code, Section III strength and Charpy toughness requirements are satisfied; and 3) complete the leak-before-break evaluation by comparing the results of the final piping stress analysis with the bounding analysis curves documented in Appendix 3B." Report APP-GW-GLR-022 addressed only the third requirement in COL Information Item 3.6-3, and the ITAAC regarding LBB piping systems does not specifically address the first and the second requirements. Please justify your proposed deletion of this COL Information Item by explaining how the first and second requirements (Elements 1 and 2 above) are addressed by your phrase "several ITAAC items."

The applicant's response, dated September 27, 2006, to RAI-TR06-002 states that the relevant ITAACs that specify the requirements for LBB evaluations are located in the DCD as Item 6 in

Table 2.1.2-4 for the RCS, Item 6 in Table 2.2.3-4 for the passive core cooling system, Item 6 in Table 2.2.4-4 for the steam generator system, and Item 6 in Table 2.3.6-4 for the normal residual heat removal systems. The following is the ITAAC requirement on LBB for these systems:

> 6. Each of the as-built lines identified in Table x.x.x-x as designed for LBB meets the LBB criteria, or an evaluation is performed of the protection from the dynamic effects of a rupture of the line.

Except for the referenced component table number, the ITAAC requirements regarding LBB evaluation are identical for all systems mentioned above. Since the above standard ITAAC requirement regarding an LBB system is not specific enough, it might not be interpreted as including the activities specified in Items 1 and 2 of COL Information Item 3.6-3 if this COL information item were deleted. To relieve this concern, the applicant modified its technical justification for TR-06 by adding the following statement in its September 27, 2006 response:

> The activities that require procurement or fabrication include verification of the stresses, diameter, wall thickness, material, welding process, pressure, and temperature of the as-built piping. The activities that require procurement or fabrication also include a review of the Certified Material Test Reports or Certifications from the material manufacturer to verify that the ASME Code, Section III strength and Charpy toughness requirements are satisfied.

The above statement in TR-06 is essentially a restatement of the first and second requirements in COL Information Item 3.6-3. The third requirement requires applicants to complete the LBB evaluation by comparing the results of the final piping stress analysis with the bounding analysis curves documented in Appendix 3B of the AP1000 DCD. To address this, a separate report, TR-08, APP-GW-GLR-022, Revision 1, dated July 2006, was submitted by the applicant and provides an evaluation for every as-designed LBB piping. The staff has completed its evaluation of TR-08 in Section 3.6.3.1 of this supplement and finds it acceptable. Although TR-08 significantly simplifies the work related to meeting the ITAAC LBB requirements, it is not meant to replace the ITAAC activity related to LBB. When the as-built piping information becomes available after the COL phase, a final LBB evaluation will be performed by the staff in accordance with the ITAAC scope.

Therefore, the staff found that the DCD changes, as proposed by the applicant in TR-06, meet the requirements of GDC 4 and are acceptable. COL Information Item 3.6-3 is resolved.

3.6.3.2.3 Composition of MSL Material

GDC 4 of Appendix A to 10 CFR Part 50 requires that SSCs important to safety shall be appropriately protected against environmental and dynamic effects. GDC 4 allows the use of analyses reviewed and approved by the Commission to eliminate from the design basis the dynamic effects of postulated pipe ruptures when the analyses demonstrate that the probability of pipe rupture is extremely low. The staff reviewed the DCD Revision 17 changes in Section 3.6.3 and Appendix 3B as they relate to affecting the LBB methodology and analysis results.

The identification of SA-335 Grade 11 Alloy material for the MSL is a change from the certified design (Revision 15 of the DCD), which identified the MSL material in Table 3B-1 as SA-333 Grade 6. The applicant stated that SA-335 Grade 11 was selected for the MSL material to minimize the potential for erosion-corrosion. This material contains 1-1/4 percent Chromium that is sufficient to preclude erosion-corrosion degradation in the MSL located inside containment. The staff also reviewed Appendix 3B and Figure 3B-4 in Revision 17 in which the applicant revised its LBB analysis for this material, provided a revised bounding analysis curve for the MSL, and verified that the LBB analysis for this material remained bounding for the AP1000 DCD. On this basis, the staff finds the changes to the DCD associated with the use of SA-335 Grade 11 Alloy material for the MSL to be acceptable.

3.6.3.3 Conclusion

On the basis of its review of the AP1000 report APP-GW-GLR-02 (TR-06), the staff finds that the proposed deletion of COL Information Item 3.6-3 meets the requirements of GDC 4 and is acceptable based on the following: (1) the first two requirements in COL Information Item 3.6-3 are preserved in TR-06, and (2) the third requirement is maintained by meeting ITAAC requirements, as described in Item 6 of Table 2.1.2-4 for the RCS, Item 6 of Table 2.2.3-4 for the passive core cooling system, Item 6 of Table 2.2.4-4 for the steam generator system, and Item 6 of Table 2.3.6-4 for the normal residual heat removal systems. Furthermore, the staff finds that the TR-06 conclusions regarding LBB characteristics in certain AP1000 piping systems are generic and are expected to apply to all COL applications referencing the AP1000 design certification. Therefore, COL Information Item 3.6-3 is deleted.

On the basis of its review of the changes in Revision 17 of the AP1000 DCD, the staff finds that the LBB analysis meets the requirements of GDC 4 and is acceptable.

3.7 Seismic Design

The staff has conducted a detailed technical review of the seismic design and analysis of the AP1000 structures, as documented in AP1000 DCD, Revision 19 and the TRs discussed below. The staff used the guidance provided in Sections 3.7.1, 3.7.2, and 3.7.3 of NUREG-0800 to conduct its review.

In September 2004, the staff issued NUREG-1793 for the AP1000 DCD, Revision 15. In Section 3.7 of NUREG-1793, the staff concluded that the AP1000 seismic Category 1 structures located on the NI were capable of withstanding the AP1000 generic SSE ground response spectra. The SSE (now referred to as the CSDRS) is based on RG 1.60, “Design Response Spectra for Seismic Design of Nuclear Power Plants,” Revision 1, for a peak ground acceleration (PGA) of 0.3g. An additional control point at 25 Hz is included as a modification to the RG 1.60 ground response spectral shape. The current AP1000 design certification is applicable only to HR sites. An HR site is defined as having a shear wave velocity (Vs) of the supporting media ≥ 2438.4 m/s (8,000 fps). The staff also concluded that the in-structure response spectra (ISRS) were developed in accordance with staff-accepted methods described in NUREG-0800 Sections 3.7.1 and 3.7.2; and that the applicant had identified and/or implemented analytical methods for seismic system analysis and seismic subsystem analysis, consistent with NUREG-0800 Sections 3.7.2 and 3.7.3.

Subsequent to the issuance of NUREG-1793, the applicant submitted Revisions 16 through 19 to the AP1000 DCD. The applicant also submitted the following TRs:

(1) APP-GW-S2R-010, AP1000 Standard (STD) COL TR-03, “Extension of Nuclear Island Seismic Analyses to Soil Sites,” Revisions 0 through 5. The contents of this report are summarized in the new AP1000 DCD Appendix 3G, “Nuclear Island Seismic Analyses.”

(2) APP-GW-GLR-115, AP1000 STD COL TR-115, “Effect of High Frequency Seismic Content on Structures, Systems, and Components,” Revisions 0 through 3. The contents of this report are summarized in the new AP1000 DCD Appendix 3I, “Evaluation for High Frequency Seismic Input.”

The AP1000 seismic design changes introduced in the revised AP1000 DCD and supporting TRs are discussed in the following paragraphs:

1. Extension to soil sites

   The AP1000 DCD, Revision 15 only addresses the seismic design of AP1000 for an HR site. The AP1000 certified seismic design response spectra (CSDRS) for an HR site are RG 1.60 spectra anchored at 0.3g PGA, with an additional control point specified at 25 Hertz (Hz). The same CSDRS are specified in the AP1000 DCD, Revisions 16 through 19, in which the applicant introduced soil-structure interaction (SSI) analysis to evaluate the seismic response for a range of site conditions, from firm rock (FR) to soft soil (SS). For the original HR case, the applicant applies the seismic design input at the foundation El. 18.3 m (60 ft); for the FR to SS cases, the applicant applies the seismic design input at the finished grade in the free field (El. 30.5 m (100 ft)). The applicant evaluated the structures and developed the ISRS using the enveloped response of the multiple analyses. To support the technical basis for the extension of the AP1000 design to FR and soil sites, the applicant submitted TR-03, and summarized the report in AP1000 DCD Appendix 3G. The staff’s detailed evaluation of AP1000 DCD Appendix 3G and TR-03 is described in Section 3.7.2 of this report.

2. Use of 3-D finite element shell models

   In the AP1000 DCD, Revision 15, the applicant used three dimensional (3D) lumped mass stick models to represent the auxiliary building, containment internal structures (CISs), shield building, and steel containment. In the AP1000 DCD, Revisions 16 through 19, the applicant uses 3D finite element shell models for all NI buildings, except the steel containment. These models are used for the SSI and fixed-base seismic analyses. The detailed descriptions of the models and results of the new analyses are provided in TR-03, and summarized in AP1000 DCD Appendix 3G. The staff’s detailed evaluation of these models is described in Section 3.7.2 of this report.

3. Effect of High Frequency Ground Motion

   The seismic analysis and design of the AP1000 plant is based on the CSDRS, which have dominant energy content in the low frequency range (2-10 Hz). However, recent probabilistic hazard-based, site-specific spectral shapes for the Central and Eastern United States (CEUS) show significant amplification above 10 Hz. This high-frequency amplification exceeds the RG 1.60 spectral amplification upon which the AP1000 CSDRS is based. The applicant has determined that for several candidate CEUS rock sites, the site-specific ground motion response spectra (GMRS) show significant increased amplitude in the high frequency range, which exceeds the CSDRS for the AP1000. The applicant has defined generic AP1000 hard rock high frequency (HRHF) spectra, which exceed the CSDRS above 15 Hz in the horizontal direction and above 20 Hz in the vertical direction. To address the exceedances, the applicant has performed an evaluation to demonstrate that, in general, the high frequency ground motion represents a lower seismic demand on AP1000 SSCs than the CSDRS.

The applicant compared the responses for a sample of SSCs, using both the CSDRS and the HRHF response spectra as seismic inputs. The evaluation included building structures, RPV internals, primary component supports, primary loop nozzles, piping, and electro-mechanical equipment. The applicant's evaluation of HRHF ground motion is described in TR-115, and briefly summarized in the new AP1000 DCD Appendix 3I. The staff's review of the applicant's evaluation of high frequency effects is described in Section 3.7.2 of this report.

4. Application of Incoherency Effects

   The incoherency of seismic waves has been recognized for several decades as having an effect on structures with large dimensions, separate supports, or large distances between supports (e.g., bridges). Until recently, data to support analytical models were scarce. Luco, Abrahamson, Zerva, and others, using data from surface recordings from dense arrays located in Taiwan, Japan, and California, developed coherency models to characterize local variations in free-field ground motions to analytically capture these incoherent effects sustained by structural foundations. These data were previously based on recordings at soil sites. Recently, Abrahamson (2006) extended these coherency models to include the effects at rock sites. This coherency function approximates the known changes of motion based on spatial separation and frequency and has been incorporated into several SSI analysis codes.

   The incoherency of seismic waves generally results in a reduction of structural translational responses when compared with coherent seismic motion, especially in higher frequency ranges (e.g., frequencies greater than 10 Hz). For structures of large dimensions typical of nuclear power plants designs, these translational modes can be reduced due to wave scattering, but torsion and rocking modes can be induced that can result in increased response at locations remote from the center-of-mass.

   The applicant has used seismic motion incoherency in its evaluation of HRHF ground motion effects on AP1000 SSCs. The staff issued DC/COL-ISG-1, "Interim Staff Guidance on Seismic Issues Associated with High Frequency Ground Motion in Design Certification and Combined License Applications," in May 2008, identifying an acceptable approach to consider the effects of incoherency on the NI foundation, specifically for HRHF seismic ground motion. The staff accepted the seismic ground motion coherency function as described in an EPRI report entitled, "Hard-Rock Coherency Functions Based on the Pinyon Flat Array Data," dated July 5, 2007. The applicant indicated that its evaluation is consistent with the staff's ISG. Because this is a first-time implementation of the staff's ISG, the staff conducted independent confirmatory analysis. The staff's detailed evaluation of the applicant's use of incoherency is described in Section 3.7.2 of this report.

3.7.1 Seismic Input

NUREG-0800 Section 3.7.1, "Seismic Design Parameters," provides guidelines for the staff to use in reviewing issues related to the development of seismic input ground motions, percentage of critical damping values, and supporting media for seismic Category I structures. The following evaluation addresses the proposed changes to the seismic design, as described in the amendment to the AP1000 DC. As such, this evaluation revises and supplements the evaluation in corresponding sections of NUREG-1793.

3.7.1.1 Design Ground Response Spectra

In AP1000 DCD Tier 1, Section 5.0, the applicant described the AP1000 CSDRS. The staff verified that the AP1000 CSDRS remain unchanged from the AP1000 DCD, Revision 15. In AP1000 DCD Tier 2, Section 3.7.1.1, the applicant indicated that the AP1000 CSDRS have been established with a PGA of 0.3g for the AP1000 design, in both the horizontal and vertical directions. The design response spectra are based on RG 1.60 with an additional control point specified at 25 Hz. The spectral amplitude at 25 Hz is 30 percent higher than the RG 1.60 spectral amplitude.

In AP1000 DCD, Tier 2, Section 2.5.2, the applicant provided a description of how the AP1000 CSDRS are compared to the site-specific GMRS. The CSDRS are compared to the site-specific GMRS at different locations depending on the site characteristics. In AP1000 DCD Section 3.7.1.1, the applicant states that the CSDRS are applied at the foundation level (El. 18.44 m (60 ft 6 in)) in the free field at HR sites and at the finished grade (El. 30.48 m (100 ft)) in the free field at FR and soil sites. Applying the design response spectra at the foundation level in the free field for the HR sites was accepted by the staff during its AP1000 DCD, Revision 15 review. With respect to the FR and soil sites, the staff finds that the applicant's approach of applying the design response spectra at the surface (in the free field) for both FR and soil sites is acceptable, because it is in accordance with the guidance described in NUREG-0800 Section 3.7.1.

The staff noted, however, that AP1000 DCD Section 3.7.1, Revision 17, did not provide a basis for satisfying 10 CFR Part 50, Appendix S, "Earthquake Engineering Criteria for Nuclear Power Plants," which requires the horizontal component of the SSE ground motion in the free field at the foundation elevation to have a PGA of at least 0.1g and an appropriate response spectrum. To address this concern, the staff issued RAI-SRP3.7.1-SEB1-18, requesting the applicant to provide free field in-column response spectra and associated PGA generated for each of the generic-site columns (FR and soil sites) considered. This was identified as Open Item OI-SRP3.7.1-SEB1-18 in the SER with open items.

In a letter dated May 14, 2010, the applicant provided the in-column response spectra at the basemat elevation for each of the generic sites, in Figure RAI-SRP3.7.1-SEB1-18-1, attached to the response. The horizontal PGA at the basemat elevation is above 0.1g for all generic sites. On this basis, the staff determined that the requirements of 10 CFR Part 50, Appendix S, are satisfied; therefore, RAI-SRP3.7.1-SEB1-18 and the associated open item are resolved.

3.7.1.2 Critical Damping Values

In AP1000 DCD, Tier 2, Section 3.7.1.3, the applicant described the critical damping values assigned to seismic Category I SSCs. The staff reviewed the critical damping values specified for seismic analysis of Category I SSCs, and noted that the applicant made no changes to the critical damping values in AP1000 DCD Section 3.7.1.3, between Revision 15 and Revision 17. However, the staff has updated the NUREG-0800 Section 3.7.1 guidance on critical damping, to reference Revision 1 of RG 1.61, "Damping Values for Seismic Design of Nuclear Power Plants." Both documents were issued in March 2007. RG 1.61, Revision 1, now addresses response-compatible structural damping, electrical distribution system damping (e.g., cable trays), and electrical component damping (e.g., cabinets, panels). The staff noted that the applicant's specified damping values were higher than the RG 1.61, Revision 1, values in these areas.

The staff issued RAI-SRP3.7.1-SEB1-16, requesting the applicant to specify whether it planned to use the RG 1.61, Revision 1, damping values; or to provide the technical basis for concluding that the damping values the applicant is using will provide sufficient conservatism. In a letter dated May 14, 2009, the applicant submitted its response for each area questioned by the staff:

Response-Compatible Structural Damping

The applicant stated that the HRHF ISRS generated from the analysis are used in evaluating the acceptability of safety-related equipment and components that might be susceptible to HRHF seismic excitation. Acceptability of the equipment is demonstrated by performing an HRHF ISRS seismic test run, after seismic testing to the AP1000 CSDRS ISRS.

In order to address the possibility that the HRHF ISRS may have been underestimated, the applicant included an additional seismic test margin of approximately 30 percent in the HRHF seismic screening evaluation of safety-related equipment vulnerable to HRHF excitation. This is accomplished by using the 3 percent damping HRHF ISRS in place of the 5 percent damping HRHF ISRS as the required response spectra (RRS) for testing. This approach compensates for the increase in structural response that would have been predicted if the HRHF seismic structural analysis had used 4 percent structural damping instead of 7 percent structural damping.

The staff determined that the 30 percent increase in the RRS is sufficient to compensate for the potential under-prediction of structural response, and is acceptable to meet the intent of the guidance in RG 1.61, Revision 1 (i.e., to use response-compatible structural damping when developing ISRS).

Cable Tray Damping

The applicant stated that the AP1000 design for cable tray support configurations uses construction (Unistrut with bolted connections) covered by the Systematic Evaluation Program (SEP) test program (conducted by ANCO Engineers Inc.). Based on observations during the tests, the high damping values within the cable tray system are provided mainly by the movement, sliding, or bouncing of the cables within the tray. The applicant also stated that the limiting condition for design of the AP1000 standard cable tray supports is for full cable tray weight. The damping value being used for the design of this condition is 10 percent, which is consistent with the value listed in AP1000 DCD Table 3.7.1-1 for full cable trays and related supports. The staff noted that seismic design of full cable trays using 10 percent damping is consistent with the guidance in RG 1.61, Revision 1, and is acceptable.

Electrical Cabinet and Panel Damping

The applicant stated that electrical cabinets and panels employed in safety-related applications are an assembly of structures, subassemblies, and individual components. The electrical cabinets and panels are generally constructed of carbon steel framing members, angle support channels, and panels with a combination of bolted and welded connections designed to support subassemblies and components mounted within. The structural damping of cabinets and panels is a function of the materials, design, mass distribution, and method of interconnection (bolted/welded).

The applicant noted that RG 1.61, Revision 0, defines SSE level damping values as 4 percent for welded steel structures and 7 percent for bolted steel structures; and it is reasonable to perform the analysis of combined bolted and welded structures using an average of the structural damping associated with the bolted or welded steel structures as defined in RG 1.61, Revision 0. In Section 3.7, Table 3.7.1-1 of the AP1000 DCD, Revision 17, the applicant specifies 5 percent damping for electrical cabinets and panels.

The applicant further stated that dynamic structural finite element analyses employ models validated through the use of qualification test program results. The response of the finite element method (FEM) is developed and validated against test data and used as the basis for any modifications that are needed. The results of seismic testing are used in the correlation of dynamic in-equipment response, and the modal and structural damping results from the resonant search test data are used to determine the natural frequency of vibration and associated structural damping used in model correlation process. In most instances, this leads to the use of 4 percent and 5 percent critical damping in the finite element analysis.

The staff concluded that, although the RG 1.61, Revision 1, guidance is 3 percent damping for electrical cabinets and panels at the SSE analysis level, the applicant has provided an acceptable technical basis for use of higher damping values. For FEM analyses, damping values of 4 to 5 percent are validated by test results. For static coefficient analyses, the use of 5 percent damping is acceptable, when used in conjunction with a 1.5 multiplier on the spectral peak. Although the 1.5 multiplier is intended to provide margin when a multidegree of freedom system or component is analyzed by the static coefficient method, in the case of electrical cabinets and panels, the response is single-mode dominant; the 1.5 multiplier on the 5 percent damping spectral peak would compensate for the difference between 3 percent damping and 5 percent damping.

Based on the applicant’s responses and the staff’s evaluation, the response to RAI-SRP3.7.1-SEB1-16 is considered acceptable. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

Shield Building Structural Damping

In the AP1000 DCD, Revision 17, the applicant changed the design of the shield building from RC construction (7 percent SSE damping in AP1000 DCD Table 3.7.1-1) to steel and concrete composite (SC) -filled module construction (5 percent SSE damping in AP1000 DCD Table 3.7.1-1). The staff issued RAI-SRP3.7.1-SEB1-19, part (a), requesting the applicant to define the damping value(s) used for the SC module walls, and to describe how this value is assigned in the ANSYS and SASSI models.

The staff also noted that the applicant reduced the shield building concrete modulus (Ec) to 80 percent of nominal value, to account for concrete cracking. The 80 percent value is recommended by the Federal Emergency Management Agency (FEMA) when there is minimal load-induced cracking. Since the 80 percent factor is associated with minimal cracking, the staff noted that use of reduced damping may be appropriate, because damping has been recognized as being a function of the structural response level. At low response levels, lower effective viscous damping has been observed; at high response levels, higher effective viscous damping has been observed. In RAI-SRP3.7.1-SEB1-19, part (b), the staff requested that the applicant submit the technical basis for the damping values assumed. This was identified as Open Item OI-SRP3.7.1-SEB1-19 in the SER with open items.

In its response dated August 26, 2010, the applicant stated that 5 percent structural damping was assumed for the SC modules, including the shield building wall, and 7 percent structural damping was assumed for RC structures. The applicant also stated that these damping values were defined in ANSYS and SASSI as a material property defined for each element.

To demonstrate that the assumed damping values for SC and RC are appropriate, the applicant relied on the results of a nonlinear time-history analysis using the ABAQUS finite element code. In this analysis, concrete was allowed to crack in tension. In Figures RAI-SRP3.7.1-SEB1-19-06 through RAI-SRP3.7.1-SEB1-19-09 of the response, the applicant provided plots of maximum principal stress versus time in the SC, and showed that the predicted stresses either were close to, or reached, the tensile cracking limit of 2.06 MPa (43 ksf) during the progress of the analyzed SSE event. The applicant stated that the use of 5 percent damping was justified if element stresses approached this limit. The applicant also provided a contour plot of maximum principal stresses in the shield building, in Figure RAI-SRP3.7.1-SEB1-19-14 of the response. The applicant stated that the results, at 11.33 seconds, indicate cracking in most of the west side of the shield building wall. Similar contour plots for the RC auxiliary building were provided in Figures RAI-SRP3.7.1-SEB1-19-15 through RAI-SRP3.7.1-SEB1-19-17 of the response, at 7.22 seconds, 8.34 seconds, and 10.28 seconds, respectively. The staff's review of these figures identified that stresses reach the RC tensile cracking limit 1.72 MPa (36 ksf) in large expanses of the auxiliary building during the SSE event. Based on the applicant's calculations, indicating tensile cracking of concrete for significant portions of the AP1000 NI, the staff finds the applicant's use of SSE-level damping values of 5 percent for the shield building SC wall and 7 percent for RC to be acceptable. Therefore, Open Item OI-SRP3.7.1-SEB1-19 is resolved.

In its August 26, 2010 response, the applicant also addressed the use of concrete stiffness reduction in linear analysis, to account for the effect of concrete cracking. To demonstrate that using a reduced concrete modulus of 0.8 x Ec in the design-basis seismic analysis of the NI is appropriate to account for stiffness reduction due to concrete cracking, the applicant performed nonlinear ABAQUS analysis, using a smeared concrete cracking model, and compared the results to the results of a linear ABAQUS analysis, which assumed 0.8 x Ec for the concrete modulus. The applicant submitted additional details of this comparison in its response to related Open Item OI-SRP3.8.3-SEB1-03.

The applicant compared the ABAQUS results (linear and nonlinear) to linear ANSYS NI20 results, in order to validate that the ABAQUS models are dynamically similar to the ANSYS design-basis model. The applicant presented response spectra comparisons, in three orthogonal directions, at the shield building roof in Figures RAI-SRP3.7.1-SEB1-19-11 through RAI-SRP3.7.1-SEB1-19-13 of the response. The comparisons show that the nonlinear ABAQUS model results are very similar to and are enveloped by the linear model results, which assume 0.8 x Ec. The applicant also provided a plot of stress-strain for a highly stressed element in the shield building (West wall location), in Figure RAI-SRP3.7.1-SEB1-19-02 of the response. The applicant stated that while principal stress values are at or near the assumed cracking threshold 2.06 MPa (43 ksf), the concrete strains are relatively small; and further stated that the associated secant stiffness would be close to 0.8 x Ec, as shown in Figure RAI-SRP3.7.1-19-01 of the response.

The staff reviewed the applicant's analysis results presented in the response to this open item and in the response to OI-SRP3.8.3-SEB1-03, and determined that the applicant has provided a sufficient technical basis for using a reduced concrete modulus of 0.8 x Ec, to account for stiffness reduction due to cracking. The response is acceptable on the basis that the applicant's comparison of linear (0.8 x Ec) and nonlinear (concrete cracking model) analysis results showed a very good correlation, with the linear model being conservative.

3.7.1.3 Supporting Media for Seismic Category I Structures

In AP1000 DCD, Appendix 3G and accompanying TR-03, the applicant described the supporting media, which define the characteristics of the material providing support for the AP1000 NI. The AP1000 DCD, Revision 15 was certified for supporting media consisting of HR. In the AP1000 DCD, Revisions 16 through 19, the applicant included a range of FR to SS profiles. For each rock/soil profile, the applicant performed SSI analysis in order to demonstrate the seismic adequacy of the AP1000 plant for the range of soil and rock sites. For the design of seismic Category I structures, a set of six design soil profiles of various Vs values were established from parametric studies, as described in AP1000 DCD Appendix 3G and TR-03. The applicant stated that these six profiles are sufficient to envelop sites where the Vs of the supporting medium at the foundation level exceed 304.8 m/s (1000 fps). The design soil profiles include an HR site, an FR site, a soft rock (SR) site, an upper bound soft-to-medium (UBSM) soil site, a soft-to-medium (SM) soil site, and an SS site. The Vs profiles and related governing parameters of the six sites are:

- Hard-rock site - an upper bound case for rock sites using a Vs of 2438.4 m/s (8000 fps).

- Firm-rock site - a Vs of 1066 m/s (3500 fps) to a depth of 36.7 m (120 ft) and base rock at the depth of 36.7 m (120 ft).

- Soft-rock site - a Vs of 731.5 m/s (2400 fps) at the ground surface, increasing linearly to 975.4 m/s (3200 fps) at a depth of 73.12 m (240 ft), and base rock at the depth of 36.7 m (120 ft).

- Upper bound soft-to-medium soil site - a Vs of 430.9 m/s (1414 fps) at ground surface, increasing parabolically to 1034.45 m/s (3394 fps) at 73.2 m (240 ft), base rock at the depth of 36.7 m (120 ft), and ground water at grade level. The initial soil shear modulus profile is twice that of the SM soil site.

- Soft-to-medium soil site - a Vs of 304.8 m/s (1000 fps) at ground surface, increasing parabolically to 731.5 m/s (2400 fps) at 73.15 m (240 ft), base rock at the depth of 36.7 m (120 ft), and ground water is assumed at grade level.

- Soft-soil site - a Vs of 304.8 m/s (1000 fps) at ground surface, increasing linearly to 365.8 m/s (1200 fps) at 73.2 m (240 ft), base rock at the depth of 36.7 m (120 ft), and ground water is assumed at grade level.

The staff reviewed the range of soil profiles and properties identified in AP1000 DCD Revision 17, Section 3.7.1.4, and the iterated Vs profiles presented in Table 3.7.1-4 and Figure 3.7.1-17. In TR-03, Section 4.4, the applicant stated that the range of soil profiles and properties are based on a survey of 22 commercial nuclear power plant sites in the United States. The applicant's survey included sites with Vs ranging from 304.8 m/s (1,000 fps) (SS) to 2438.4 m/s (8,000 fps) (HR). Based on its review, the staff concluded that the applicant has selected a suitable range of site profiles for extending the AP1000 seismic design basis.

3.7.1.4 Conclusion

The staff concludes that Revision 19 to the AP1000 DCD continues to support the seismic design parameters, seismic system analysis, and seismic subsystem analysis for Category I SSCs to meet NRC regulations applicable to the AP1000 DC. The application to amend the AP1000 certified design provides sufficient information to satisfy the applicable requirements of 10 CFR Part 50, Appendix A, GDC 1; 10 CFR Part 50, Appendix S; and 10 CFR Part 100, Appendix A, "Seismic and Geologic Siting Criteria for Nuclear Power Plants," for the seismic design and analysis aspects for Category I SSCs to be used in the AP1000 reactor.

The changes to the DCD implementing the revised AP1000 design meet the standards of Criterion vii of 10 CFR 52.63(a)(1) in that they contribute to increased standardization; without these DCD changes each applicant would have to address these issues individually.

3.7.2 Seismic System Analysis

NUREG-0800 Section 3.7.2, "Seismic System Analysis," provides guidelines for the staff to use in reviewing issues related to seismic system analysis. The AP1000 DCD, Revisions 16 through 19, introduced the following significant changes related to AP1000 DCD Section 3.7.2: (1) the applicant performed SSI analysis using the SASSI computer code to extend the AP1000 certified seismic HR design basis to include a range of soil and rock sites; (2) the applicant used 3D shell models instead of 3D stick models for performing dynamic analysis of the NI; (3) the applicant evaluated the effects of HRHF ground motion on the design of AP1000 SSCs; and (4) the applicant used a seismic wave incoherency model in the HRHF analysis, to reduce the effective demand.

The applicant's technical discussion of these changes is incorporated in several sections of the AP1000 DCD and the applicable TRs. The applicant added AP1000 DCD Appendix 3G to document the extension of the seismic design basis to a wide range of soil and rock sites. AP1000 DCD Appendix 3G summarizes the content of TR-03. The applicant also added AP1000 DCD Appendix 3I to briefly summarize the HRHF analysis documented in TR-115. The staff's evaluations of TR-03 and TR-115 are included in Section 3.7.2 of this SER.

The applicant also moved most of the analysis details previously in AP1000 DCD, Revision 15, Section 3.7.2, to the new AP1000 DCD Appendix 3G. The building stick models used in the original HR DC analyses, described in the AP1000 DCD, Revision 15, have been replaced by 3D shell FEMs for the SSI analyses (using SASSI) and for the updated fixed-base analyses (using ANSYS). In addition, the equivalent static acceleration methodology, described in the

AP1000 DCD, Revision 15 for the detailed design of the buildings, has been replaced by response spectrum analysis (RSA) for the auxiliary/shield building (ASB) and for the CISs.

The applicant's use of a seismic wave incoherency model to effectively reduce HRHF ground motion represents the first application of the ISG-1 on this subject. As a result, the staff performed an independent confirmatory analysis using the applicant's NI20 SASSI model and NI10/NI20 ANSYS models. The purpose of the staff's confirmatory analysis was to: (1) evaluate the adequacy of NI20 model for seismic analysis of soil sites and the representative HRHF site; (2) verify the correct implementation of an incoherency model; (3) assess the adequacy of the structures sample set selected by the applicant for HF analysis; and (4) assess overall compliance with ISG-1. The results of the staff's confirmatory analysis effort are described in Section 3.7.2.3.4.2 of this SER.

3.7.2.1 Seismic Analysis Methods

In AP1000 DCD, Revision 17, Section 3.7.2.1, the applicant describes the methods used for performing seismic analyses. The applicant stated that the seismic analyses of the NI are performed in conformance with the criteria in NUREG-0800 Section 3.7.2. RSA, the equivalent static acceleration method, the mode superposition time-history method, and the complex frequency response analysis method are performed for the SSE to determine the seismic force distribution for use in the design of the NI structures, and to develop in-structure seismic responses (accelerations, displacements, and floor response spectra [FRS]) for use in the analysis and design of seismic subsystems. In TR-03, Table 4.2.4-1, the applicant provided a summary of the models and analysis methods used by the applicant in the seismic analyses.

The staff reviewed AP1000 DCD Section 3.7.2.1, and related information in Appendices 3G and 3I, and determined that the applicant's seismic analysis methods are not completely consistent with the latest staff guidance in NUREG-0800 Section 3.7.2, Revision 3 (March 2007). This is discussed in detail in Section 3.7.2.7 of this SER.

The applicant accounted for the effects of SSI by using the SASSI analysis code and used 3D models that accounted for the effects of torsional, rocking and translational responses. The staff finds the SASSI analysis code acceptable for performing SSI analysis because it has been independently benchmarked to standard problems for this type of analysis.

As part of the review of the applicant's SSI analysis methods, the staff performed independent confirmatory analysis using FEMs provided by the applicant. As a result of this effort, the staff identified several modeling errors made by the applicant. The staff's confirmatory analysis is described in Section 3.7.2.4.2 of this SER.

3.7.2.2 Natural Frequencies and Responses

In AP1000 DCD, Revision 17, Section 3.7.2.2, the applicant stated that modal analyses are performed for the shell and lumped-mass stick models of the seismic Category I structures on the NI, as described in Appendix 3G.

The staff reviewed the applicant's seismic analyses models described in AP1000 DCD Section 3.7.2.2, Appendix 3G, and TR-03. The staff issued RAI-TR03-32 and RAI-SRP3.7.1-SEB1-06, requesting the applicant to demonstrate the capability of the NI20 and NI10 models to accurately predict all natural frequencies up to the 33 Hz for the AP1000

CSDRS and up to 50 Hz for the HRHF evaluation spectra. The staff's evaluation for these RAIs is in Section 3.7.2.4 of this report.

3.7.2.3 Procedures Used for Analytical Modeling

The staff reviewed AP1000 DCD, Revision 17, Section 3.7.2.3, and related information in Appendix 3G. The staff also reviewed TR-03, which provides the detailed information supporting Appendix 3G. In AP1000 DCD Section 3.7.2.3, the applicant indicated that 3D finite element shell models were developed for the coupled shield and auxiliary buildings, and for the CIS. An axisymmetric finite element shell model of the steel containment vessel (SCV) was also developed. These models provide the basis for the development of the dynamic model of the NI structures. In the dynamic model, the SCV is represented by a lumped mass stick model with properties developed from the SCV axisymmetric model. A separate detailed 3D finite element model of the shield building roof was also developed for detailed design.

The applicant stated that the models of the coupled shield and auxiliary buildings and the CIS are based on the gross concrete section, with the modulus of elasticity reduced to 0.8 times the nominal value, to consider the effect of cracking.

The applicant further stated that seismic subsystems coupled to the overall dynamic model of the NI include the reactor coolant loop model coupled to the CIS model, and the polar crane model coupled to the SCV model. The criteria used for decoupling seismic subsystems from the NI model are taken from Section II.3.b of NUREG-0800 Section 3.7.2, Revision 2.

In TR-03, Section 1.0, the applicant identified the information included in TR-03, in order to update the seismic design basis for AP1000: (1) description of the new 3D shell finite element ANSYS and SASSI models; (2) minor structural changes that are significant; (3) the seismic analysis results for a specified range of soil sites; (4) revised envelope ISRS at six reference locations; and (5) the effect of extending the seismic design basis on the seismic design of the NI structures. The staff noted that the only structural change described in TR-03 was the pressurizer compartment redesign. Therefore, in RAI-TR03-001, the staff requested that the applicant describe the other "minor structural changes that are significant" and explain why the changes to the AP1000 design are necessary.

In its response dated January 18, 2007, the applicant stated that the seismic analysis models, NI10 and NI20, have been revised from those reviewed during the HR DC for two types of changes. There are design changes to the AP1000 that include the shorter pressurizer, an increase in spent fuel storage within the existing pit and a revision to the bracing of the shield slab below the discharge stack. There are also changes to the FEM to better reflect the structural configuration. The changes that have been incorporated into the dynamic models, in addition to the redesign of the pressurizer compartment, are:

<u>Design changes</u>

- A design change was made in the spent fuel pool area to permit heavier fuel racks. Masses reflecting the racks and spent fuel were updated. In addition, the water in the fuel pits was modeled as lumped masses instead of solid elements.

- The shield building roof slab bracing was modified from tie rods to cross bracing to improve the seismic response.

Model improvements

- The dish model was modified to incorporate changes in the annulus configuration included in existing AP1000 DCD figures. The annulus tunnel on the west side was deleted and replaced by concrete. In addition, nodes and elements were modified in the lower shield building and upper CIS basemat to be compatible with the revised dish model.

- The core makeup tanks (CMTs) were added as stick models.

- Floors in the CIS model were refined to provide better member force results for use in design.

- Polar Crane Model - Changes made to the model weight (3 percent reduction), updated SCV local stiffness, and inclusion of polar crane truck stiffness.

The applicant stated that these changes were considered minor since the NI building basic configuration was not modified. They reflected structural and model changes that were made during design development.

The staff considered RAI-TR03-001 to be resolved, based on the additional description of changes that the applicant added in Revision 1 and Revision 2 of TR-03. However, the applicant subsequently proposed major design changes to the shield building cylindrical wall, air inlets, and roof in "Design Report for the AP1000 Enhanced Shield Building," March 22, 2010. The staff reviewed the most recent revision of TR-03 (Revision 4, March 2010), and noted that the modeling assumptions used in the dynamic models to simulate the new SC cylindrical wall design are not described. Since this is critical information that is not documented in any of the applicant's formal submittals, the staff requested that the details be added to the next revision of TR-03. This was identified as Open Item OI-TR03-01 in the SER with open items.

In its revised response dated August 26, 2010, the applicant stated that the shield building SC modules are modeled by 3D shell elements using modified stiffness and thickness values to simulate equivalent response in the structure. Equations from AP1000 DCD Section 3.8.3.4.1 were provided in response Figure RAI-TR03-001-01, to describe the procedure for calculating equivalent shell element stiffness and thickness values. In its response, in Figure RAI-TR03-001-02, the applicant provided specific values used in the equations. The staff reviewed the equations used and the numerical results obtained, and concluded that the applicant had properly simulated the stiffness of the SC wall in the ANSYS NI10, ANSYS NI20, ANSYS NI05, and SASSI NI20 models. The applicant also provided a proposed revision to TR-03 to incorporate this information. The staff has confirmed that these changes have been incorporated into TR-03. Therefore, RAI-TR03-01 and the associated open item are resolved.

In TR-03, Section 4.0, the applicant discussed the dynamic modeling of seismic Category I structures constituting the AP1000 NI. The staff reviewed the applicant's modeling assumptions with respect to concrete material characterization. For the NI, the applicant stated that the concrete modulus of elasticity was reduced to 80 percent of its nominal value, in order to reduce stiffness to simulate cracking. The staff's review of this section found insufficient technical basis for the 20 percent reduction of the modulus of elasticity. In RAI-TR03-05, the staff requested that the applicant clarify whether this reduced stiffness was used in the dynamic seismic response analyses for generation of FRS, and in the equivalent static acceleration analyses for design of the structural members. If different stiffness assumptions were used, the staff asked the applicant to provide the technical basis. The staff also requested that the applicant provide the technical basis for using 80 percent, by comparing this to guidance in industry documents such as ASCE 4-98, “Seismic Analysis of Safety-Related Nuclear Structures and Commentary,” and to describe any sensitivity studies conducted to determine the effect of varying the concrete stiffness on ISRS and design of structural members.

In its response dated January 18, 2007, the applicant stated that the reduction to 80 percent is to account for the effects of cracking, as recommended in Table 6-5 of FEMA 356 (Reference: FEMA 356, “Pre-standard and Commentary for the Seismic Rehabilitation of Buildings,” (FEMA, November 2000) and that the staff had accepted this basis as part of the AP1000 DCD, Revision 15 review.

The staff evaluated the response and confirmed that during the DC review of the AP1000 founded on HR, the staff had accepted FEMA’s recommendation regarding the application of a structural stiffness factor of 0.8 for the seismic analysis of the NI structures.

During the April 2007 audit, the staff requested that the applicant revise its response to clarify that the 0.8 factor for concrete stiffness correlates with test results for essentially uncracked concrete, and does not account for observed or predicted significant cracking (for which a 0.5 factor is more appropriate).

In its revised response dated June 15, 2007, the applicant added that the reduction to 80 percent reflects the observed behavior of concrete when stresses do not result in significant cracking. The applicant also proposed a revision to TR-03, Section 4.0, indicating that concrete structures are modeled with linear elastic uncracked properties, but the modulus of elasticity is reduced to 80 percent of its value to reduce stiffness, to reflect the observed behavior of concrete when stresses do not result in significant cracking, as recommended in Table 6-5 of FEMA 356.

The staff evaluated the response and accepted the applicant’s clarification that the use of 0.8 stiffness factor applies when stresses do not result in significant cracking. The staff confirmed that the changes were properly documented in TR-03, Revision 1.

Subsequent to the resolution of RAI-TR03-05, the applicant made major design changes to the cylindrical wall, air inlets, and roof of the shield building. The staff’s separate review of the shield building redesign raised questions about the acceptability of the 0.8 factor, since preliminary results presented by the applicant indicate that significant concrete cracking occurs in some areas under seismic loading. The staff requested that the applicant study the sensitivity of the shield building seismic response to a 0.5 stiffness reduction, which is more appropriate when there is significant concrete cracking. The staff had concern that significant concrete cracking could shift the fixed-based frequencies of the shield building, potentially leading to an increase in the seismic demand on the shield building structure and on any systems and components attached to the shield building structure. In its review of TR-03, Revision 4 (March 2010), the staff noted that the 0.8 factor was used for the shield building reanalysis without any discussion or technical justification. This issue was identified as Open Item OI-TR03-05.

In its response dated August 3, 2010, the applicant stated that OI-TR03-05 is addressed in the response to OI-SRP3.7.1-SEB1-19. The staff reviewed the applicant’s response to OI-SRP3.7.1-SEB1-19, dated August 26, 2010, and confirmed that it addresses the use of a

0.8 factor for concrete modulus in the design-basis linear seismic analyses. To demonstrate that using a reduced concrete modulus of 0.8 x Ec in the design-basis seismic analysis of the NI is appropriate to account for stiffness reduction due to concrete cracking, the applicant performed nonlinear ABAQUS analysis, using a smeared concrete cracking model, and compared the results to the results of a linear ABAQUS analysis, which assumed 0.8 x Ec for the concrete modulus. The applicant submitted additional details of this comparison in its response to related OI-SRP3.8.3-SEB1-03.

The applicant compared the ABAQUS results (linear and nonlinear) to linear ANSYS NI20 results, in order to validate that the ABAQUS models are dynamically similar to the ANSYS design-basis model. The applicant presented response spectra comparisons, in three orthogonal directions, at the shield building roof in Figures RAI-SRP3.7.1-SEB1-19-11 through RAI-SRP3.7.1-SEB1-19-13 of the response. The comparisons show that the nonlinear ABAQUS model results are very similar to and enveloped by the linear model results, which assume 0.8 x Ec. The applicant also provided a plot of stress-strain for a highly stressed element in the shield building (West wall location), in Figure RAI-SRP3.7.1-SEB1-19-02 of the response. The applicant stated that while principal stress values are at or near the assumed cracking threshold 2.1 MPa (43 ksf), the concrete strains are relatively small; and further stated that the associated secant stiffness would be close to 0.8 x Ec, as shown in Figure RAI-SRP3.7.1-19-01 of the response.

The staff reviewed the applicant's analysis results presented in the response to this RAI and in the response to OI-SRP3.8.3-SEB1-03, and determined that the applicant has provided a sufficient technical basis for using a reduced concrete modulus of 0.8 x Ec to account for stiffness reduction due to cracking. The response is acceptable on the basis that the applicant's comparison of linear (0.8 x Ec) and nonlinear (concrete cracking model) analysis results showed a very good correlation, with the linear model being conservative. Therefore, RAI-SRP3.7.1-SEB1-19 is resolved. On the basis that OI-SRP3.7.1-SEB1-19 is resolved, OI-TR03-005 is also resolved.

In TR-03, Section 4.1, the applicant described the modeling assumptions used in the seismic analysis for the water inside the passive containment cooling water storage tank (PCCWST) on the shield building roof. The applicant indicated that a significant percentage of the water mass responds at very low frequency (sloshing), and does not affect the overall building seismic response. Consequently, the applicant concluded that the sloshing water mass could be excluded in the two horizontal directions.

The staff's review of this section found that there was insufficient basis for accepting the applicant's exclusion of sloshing water mass in the dynamic analysis models. In RAI-TR03-007, the staff requested that the applicant provide a detailed technical basis for excluding the low-frequency, water-sloshing mass and to quantify the percentage of water mass in the PCCWST that was excluded.

In a letter dated January 29, 2007, the applicant stated that sloshing of the water in the AP1000 PCCWST was analyzed using a formula for toroidal tanks (Reference J.S. Meserole, A. Fortini, "Slosh Dynamics in a Toroidal Tank," Journal Spacecraft, Volume 24, Number 6, November-December 1987). The fundamental sloshing frequency given by the formula is 0.136 Hz with a modal mass equal to 65 percent of the water mass.

The applicant further stated that AP600 analyses by formula gave frequencies and effective masses similar to those in the AP1000 analyses, and the sloshing formula was confirmed for the

AP600 by analyses of a 3D FEM of the water in a rigid tank. For the AP600 design models of the ASB, the applicant found that:

- 60 percent of the water mass was in a sloshing mode. This was included in the AP600 stick model at the elevation of the tank with two masses each with 2 horizontal degrees of freedom.
- The total sloshing mass is 2.6 percent of the mass of the ASB. The stick model results show a maximum absolute acceleration of the sloshing masses of 0.13g, at a frequency of 0.136 Hz.
- The fundamental frequency of the ASB is between 2 and 3 Hz, and the acceleration is 1.1g at the base of the tank.

As a result of the above, the applicant concluded that the low-frequency sloshing mode is not significant to the response of the NI away from the shield building roof and that this conclusion could be extended to the AP1000 design. The horizontal mass participating in the sloshing mode was excluded from the AP1000 3D shell dynamic model of the shield building. However, the applicant considered sloshing in the hydrodynamic loads for the tank wall design.

The staff reviewed the applicant's response and discussed it with the applicant during the April 2007 audit. The applicant stated that the effect of the low-frequency sloshing mode was confirmed to be negligible by performing an analysis of the AP1000 NI stick model without the low-frequency mass, and comparing these results to the results obtained with the low-frequency masses included, provided in Revision 15 of the AP1000 DCD. Comparisons of maximum absolute accelerations, member forces, and FRS indicated there were no significant changes in any of the responses. The staff reviewed the tank sloshing reference and the applicant's calculation. The staff questioned why the percentage of sloshing mass does not go down for the AP1000 versus the AP600, since the increased volume is achieved primarily by making the tank deeper. The applicant agreed to check its estimate of sloshing mass, and provide its conclusions in a supplemental response.

In its revised response dated July 5, 2007, the applicant provided the key dimensions, frequencies and effective masses of the AP600 and AP1000 tanks as shown below.

Parameter	AP600	AP1000	Units
Inside radius of tank	5.3 (17.5)	5.3 (17.5)	m (ft)
Outside radius of tank	11.6 (38.0)	12.9 (42.5)	m (ft)
Average water depth	6.355 (20.85)	6.92 (22.7)	m (ft)
Sloshing frequency	0.139	0.136	Hertz
Ratio of sloshing to total mass	0.66	0.65	none

The staff evaluated the response, and concluded that the explanation provided by the applicant to address why the sloshing mass ratio remained unchanged between AP600 and AP1000 was acceptable.

The applicant subsequently made design changes to the PCCWST on top of the shield building. The staff noted that the applicant needed to recalculate the sloshing frequency and sloshing mass to account for any changes in the tank geometry, water depth, and/or free board above the water surface. The staff had concern that overestimating the water sloshing mass could result in an under-prediction of seismic demand for the tank structure. This issue was identified as Open Item OI-TR03-07.

In a letter dated July 12, 2010, the applicant submitted a supplement to its previous RAI-TR03-07 response, stating that the dimensions of the PCCWST were not changed in the enhanced shield building design. The only change affecting the PCCWST is a reduction in elevation by about 1.52 m (5 ft). The applicant also conducted an updated fluid sloshing analysis of the PCCWST, using an ANSYS model of the fluid in a rigid tank. The results of the ANSYS analysis support the 60 percent assumption for low frequency sloshing modes, as shown below.

Parameter	AP1000		Units
Water weight in 180 degree model	1.154×10^6 (3,337)		kg (kip)
Frequency	0.119	0.321	Hertz
Participating weight	$7{,}253 \times 10^5$ (1,599)	1.623×10^5 (358)	kg (kip)
Ratio of sloshing to total mass	47.93	10.73	%

The staff evaluated the applicant's updated analysis results, and concluded that the PCCWST response has a very significant water sloshing component, which has a negligible effect on the overall seismic response of the ASB. On this basis, OI-TR03-07 is resolved.

3.7.2.4 Soil-Structure Interaction

The staff performed a review of the applicant's SSI analyses described in AP1000 DCD Section 3.7.2.4, AP1000 DCD Appendix 3G, and TR-03, using the guidance in NUREG-0800 Section 3.7.2. The design-basis SSI analyses use the AP1000 CSDRS as the seismic input motion; the acceptability of these analyses is evaluated in Section 3.7.2.4.1 of this report. The staff also performed a review of the applicant's evaluation of HRHF ground motion effects described in AP1000 DCD Appendix 3I and TR-115. Since the staff addressed special considerations for seismic evaluation of HRHF sites in NUREG-0800 Section 3.7.2, under acceptance criteria for SSI, the staff has included the HRHF evaluation in Section 3.7.2.4.2 of this SER.

3.7.2.4.1 Nuclear Island Seismic Analyses using CSDRS Input Motion

In AP1000 DCD Section 3.7.2.4, the applicant stated that the SSI analyses for the FR and soil sites are described in AP1000 DCD Appendix 3G. In AP1000 DCD Sections 3G.4.1 and 3G.4.2, the applicant described the 3D SSI and fixed based analyses. Additional details of these analyses are described in TR-03.

The applicant performed SSI analyses using the computer program SASSI and the NI20 3D finite element shell model. The SSI analyses were performed for the five soil conditions described in AP1000 DCD Section 3G.3, and reviewed in Section 3.7.1.3 of this SER. The SASSI model included a surrounding layer of excavated soil, as shown in AP1000 DCD Figures 3G.4-3 and 3G.4-4. The seismic input consisted of three statistically independent acceleration time histories (north-south, east-west, and vertical directions), each applied separately. The three resulting time history responses (one for each direction) are combined algebraically at each instant in time. AP1000 DCD Figures 3G.4-5X through 3G.4-10Z provide comparisons of ISRS for the soil cases analyzed. The applicant also performed fixed-base analysis using the ANSYS NI20 model, to simulate HR conditions (i.e., Vs greater than 2438 m/s (8,000 fps)).

Selection of Soil Cases

The staff reviewed the applicant's description of site studies and selection of soil cases described in Section 4.4.1.2 of TR-03. The staff's review of Tables 4.4.1-1A and 4.4.1-1B of TR-03 identified that the applicant used three soil/rock degradation models in its parametric studies for selecting site conditions: Seed and Idriss 1970 soil/rock degradation curves; Idriss 1990 soil degradation curves; and EPRI 1993 soil degradation curves. In RAI-TR03-10, the staff requested that the applicant provide the technical basis for using these different soil degradation models for its parametric studies.

In its response dated January 18, 2007, the applicant stated that SSI analyses on rock sites for both the AP600 and the AP1000 use the rock degradation curve recommended by Seed and Idriss (Reference: Seed, H.B. and I.M. Idriss, "Soil Moduli and Damping Factors for Dynamic Response Analysis," Report Number. EERC [Energy and Environmental Research Center] 70-14, Earthquake Engineering Center, University of California, Berkeley, CA, 1970). This was applied in SSI analyses for the HR, FR and SR sites. The applicant further stated that SSI analyses on soil sites for the AP1000 used the latest soil degradation curve recommended by EPRI (Reference EPRI TR-102293, "Guidelines for Determining Design Basis Ground Motions," 1993). This was applied in SSI analyses for the UBSM, SM, and SS sites. Two sets of degradation curves were used in the AP600 studies. The early analyses used the degradation curve recommended by Seed and Idriss. Later analyses performed to address NRC questions used the later soil degradation curve recommended by Idriss (Reference Idriss, I.M., "Response of Soft Soil Sites during Earthquakes," H. Bolton Seed Memorial Symposium Proceedings, May 1990). The applicant provided a proposed revision to AP1000 DCD Section 3.7.1.4 and additional figures for inclusion in the AP1000 DCD.

The staff evaluated the response and noted a number of issues in need of further clarification:

1. The EPRI 1993 model shown in the proposed AP1000 DCD Figure 3.7.1-16 indicates hysteretic damping levels greater than 15 percent. In NUREG-0800 Section 3.7.2.4, the staff imposed a limit of 15 percent on hysteretic damping. The applicant should provide the final iterated Vs profile and damping levels reached throughout the soil column, for each case analyzed for site response, and show that damping levels do not exceed the 15 percent limit.

2. The EPRI 1993 model is generally considered appropriate for cohesionless soils. The model is not considered appropriate for cohesive fine-grained soils. The AP1000 DCD should indicate the criteria to be used by the COL applicant to evaluate the appropriateness of this degradation model for site-specific application.

3. The AP1000 DCD should include the strain-iterated Vs profiles that need to be compared to the site-specific velocity profiles generated by the COL applicant.

During the April 2007 audit, the applicant agreed to supplement its response by identifying the bounds of the strain-iterated Vs profiles. The applicant also agreed to describe how a COL applicant confirms that its site is enveloped by the generic seismic design basis. In its revised response dated July 5, 2007, the applicant stated that: (1) the soil profiles used in the generic analyses will be added to AP1000 DCD Section 3.7.1.4; (2) additional clarification of how to confirm that a specific site is enveloped by the generic seismic design basis will be provided in proposed revisions to AP1000 DCD Section 2.5.2; and (3) TR-03, Section 4.4.1.2, will be revised to include the description and table of degraded properties for each soil profile.

During the May 2008 audit, the staff and the applicant agreed that the site-specific Vs profile should be based on low-strain minimum measured values; and that a criterion is needed to define the acceptable variation in Vs when the site-specific soil profile shows an inversion (i.e., soft material under hard material). These issues are addressed under RAI-SRP2.5-RGS1-15.

During the April 2009 audit, the staff requested that the applicant provide clarification in the AP1000 DCD concerning limitations on the use of two dimensional (2D) SASSI analyses to address site-specific deviations from the certified design site parameter envelope. In a letter dated May 15, 2009, the applicant submitted a proposed revision to AP1000 DCD Section 2.5.2.3 to provide this clarification:

> The Combined License applicant may identify site-specific features and parameters that are not clearly within the guidance provided in subsection 2.5.2.1. These features and parameters may be demonstrated to be acceptable by performing site-specific seismic analyses. If the site-specific spectra at foundation level at a hard rock site or at grade for other sites exceed the certified seismic design response spectra in Figures 3.7.1-1 and 3.7.1-2 at any frequency (or Figures 3I.1-1 and 3I.1-2 for a hard rock site), or if soil conditions are outside the range evaluated for AP1000 design certification, a site-specific evaluation can be performed. These analyses may be either 2-D or 3-D.
>
> - 3-D SASSI analyses will be used to quantify the effects of exceedances of site-specific GMRS compared to the CSDRS, or the HRHF GMRS at a hard rock site (DCD Figures 3I.1-1 and 3I.1-2), or in cases where the site specific velocity soil profiles do not fall within the range evaluated for the standard design.
>
> - 2-D analyses are performed for parameter studies.
>
> - Results will be compared to the corresponding 2-D or 3-D generic analyses.

The staff reviewed the applicant's proposed revision to AP1000 DCD Section 2.5.2.3, and the applicant's response to RAI-SRP2.5-RGS1-15, and concluded that the open technical issues had been adequately addressed. The applicant clarified the limitations on the use of 2D [ ] analyses to address site-specific deviations from the certified design site parameter envelope; and also provided additional criteria that must be satisfied at a specific site in order to be covered by the AP1000 generic soil site analyses. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

In Section 4.4.1 of TR-03, the applicant stated that many results and conclusions from the AP600 soil studies are applicable for the AP1000. In RAI-TR03-14, the staff requested that the applicant describe which results and conclusions from the AP600 soil studies are applicable to the AP1000.

In a letter dated January 18, 2007, the applicant stated that the AP600 design is based on enveloped results from analyses for four soil conditions (HR, SR, UBSM, and SM). These four soil cases were selected from the parametric analyses summarized in Section 4.4.1 of TR-03. The AP600 soil studies demonstrated that these four cases would bound sites having soil with Vs exceeding 1,000 fps. Parameters selected for the design soil cases from these analyses were:

- Depth to bedrock of 36.7 m (120 ft)
- Water table for the UBSM and SM cases up to grade
- Parabolic variation of Vs with depth for the UBSM and SM cases

The applicant stated that parametric analyses of the AP1000 were performed for six soil cases, as described in TR-03, Section 4.4.1.2. These analyses used the same assumptions for depth-to-bedrock, depth-to-water table, and variation of Vs with depth as used in the AP600 analyses. These analyses confirmed that the response of the AP1000 was similar to that of the AP600 for these soil cases, with the AP1000 fundamental response occurring at lower frequencies due to its increased height 7.6 m (25 ft) and mass (10 percent).

The staff evaluated the RAI response and concluded that the applicant provided a sufficient description of the design parameters derived from the AP600 analyses in TR-03, Section 4.4. On this basis, RAI-TR03-14 was resolved.

In TR-03, Section 4.4.1, the applicant concluded that some effects (water table, soil layering, soil-degradation model, etc.) are not significant for the seismic response of the NI structures. The staff's review of this section found that the applicant did not provide sufficient basis for making the above conclusions. In RAI-TR03-15, the staff requested that the applicant provide the technical basis for drawing these conclusions for the AP1000. In addition, the staff requested that the applicant demonstrate that the combination of these effects is also insignificant for the seismic response of the NI structures.

In a letter dated August 20, 2008, the applicant submitted a comprehensive response to address the staff's questions. The referenced figures and tables were submitted as part of the RAI response. Paraphrasing the applicant's response:

> Revised TR-03 Section 4.4.1.1 provides additional technical basis for the selection of the soil parameters used in the AP1000 3D SASSI design cases. The soil cases selected for the AP1000 use the same parameters on depth-to-bedrock, depth-to-water table and variation of Vs with depth as those used in the AP600 design analyses. The parameters used for the AP1000, based on the results and conclusions from the AP600 soil studies, are summarized in Table 4.4.1-1A. The AP600 soil studies considered variations of the parameters and combinations thereof in establishing the design soil profiles. AP1000 has a footprint identical to that of the AP600 and is similar in overall mass. The height of the shield building is increased by about 6.1 m (20 ft). The total weight of the NI increases by about 10 percent. Parametric analyses of the AP1000 were performed for six soil cases, as described in Section 4.4.1.2. The AP1000 response is very similar to AP600, except that the fundamental response occurs at lower frequencies due to the

increased height and mass of the NI. Based on the similar response in these analyses, it is concluded that the governing parameters obtained for the AP600 soil studies are also applicable to the AP1000.

The applicant addressed soil degradation in RAI-TR03-10. Tables of strain-iterated Vs used in the generic analyses are shown in Table 4.4.1-3 of TR-03.
Figure RAI-TR03-15-1 shows the bounds of these strain-iterated Vs profiles. The combination of effects of the different soil parameters is reflected in these bounds. Figure RAI-TR03-15-2 shows how a COL applicant could demonstrate that the site is enveloped by generic seismic design basis. The applicant would define its site geotechnical parameters as defined in AP1000 DCD Section 2.5 and would justify why the site is within the bounds of the AP1000 generic analyses that have been considered in this TR. These parameters would include the soil profiles used in the probabilistic seismic hazard analysis (PSHA), which could then be compared to Figure RAI-TR03-15-1. Subsequent discussions between the COL applicant and the NRC may uncover a parameter for which more justification is required, in order to show that the impact of this parameter on the response is small. This justification could be done with the AP1000 2D model. An example of how a 2D parametric study would be used is shown in Figure RAI-TR03-15-3 and RAI-TR03-15-4. If the parametric 2D SASSI studies show that the effect could be significant (e.g., 90 percent of the design spectrum, see Figure RAI-TR03-15-4) when compared to the 2D design spectra, a 3D SASSI study would then be performed. If the 3D SASSI analyses show some exceedances at the critical locations, the applicant would then proceed to show that sufficient margin exists in the design to accommodate these exceedances.

The effect of water table on the seismic response of the NI structures is shown in Figures RAI-TR03-15-5 through RAI-TR03-15-7. Case 1 (SM) shows the results for the SM generic case profile, which assumes water table at grade. Case 2 (SM-NW) results are for the same soil condition except the water table is below the bottom of the soil profile at 36.7 m (120 ft) below grade. As can be seen, there is negligible difference between the two cases for the horizontal response. The vertical response due to the design profile with the water table at grade (Case 1) is more conservative than that for the dry soil profile (Case 2). This result is similar to the results in the AP600 study, which are summarized in TR-03, Section 4.4.1.1. Thus, the generic analyses are conservative for sites with a lower water table.

The staff determined that the information presented in the applicant’s revised response to RAI-TR03-15, and supplementary information in the RAI-TR03-10 response related to soil degradation models, are sufficient to address the staff’s questions. The staff also confirmed that all proposed revisions to TR-03 have been formally submitted in Revision 4. Therefore, RAI-TR03-15 is resolved.

Seismic Analysis Results

During its review of TR-03, the staff identified that equivalent static analysis was employed to calculate maximum member forces for detailed design of the NI structures, using acceleration versus height profiles obtained from the time history analyses. The staff’s separate review of TR-09, “Containment Vessel Design Adjacent to Large Penetrations,” identified that the SCV is designed for equivalent static accelerations determined from the fixed-base NI stick model, tabulated in AP1000 DCD Table 3.7.2-6, which are representative of the HR condition. In RAI-TR03-16, the staff requested that the applicant: (1) identify the site condition(s) selected to develop the equivalent static acceleration profile used to perform the equivalent static analysis; and (2) discuss whether the seismic loads used for design of the SCV envelop both the fixed-base HR condition and the worst-case condition from all soil sites considered.

The applicant's initial responses to this RAI did not fully address the staff's concern. As an alternative, the staff requested that the applicant provide a direct comparison of the equivalent static analysis results to time history analysis or RSA results. During the October 2007 audit, the applicant indicated it had switched the detailed evaluations of the CIS and ASB from equivalent static analysis to RSA. However, for the SCV, the applicant did not address whether the equivalent static acceleration method yields conservative results, when compared to RSA or time history analysis.

At the April 2009 audit, the applicant presented a comparison of results for the SCV, between equivalent static analysis and a mode superposition time history analysis, at major containment penetrations. The comparison showed that the equivalent static analysis results are higher than the time history results. The applicant agreed to revise its RAI response, to include the information presented at the audit.

In its revised response dated May 15, 2009, the applicant stated that the equivalent static acceleration analyses of the containment vessel (CV), described in TR-09, use a finite element shell model with a refined mesh in the area adjacent to the large penetrations (Figure 2-6 of TR-09). A reanalysis was performed using the same methodology on the coarse-mesh model of the SCV. The applicant performed a time history analysis of the coarse-mesh model, selecting information for the regions immediately surrounding the large penetrations, as shown in Figure RAI-TR03-016-001, for the purpose of comparing the loads from equivalent static analysis and time history analysis. The effects of the missing mass in the time history analysis were incorporated by an algebraic sum of the stress intensities from a run with the left-out mass accelerated at zero period acceleration (ZPA) and the modal superposition time history analysis. Figures RAI-TR03-016-002 through RAI-TR03-016-005 (attached to the RAI response) compare the stress intensity for individual elements surrounding the major penetrations. The applicant stated that the results from these analyses show that equivalent static analysis consistently produced higher stresses than the time history results. The staff reviewed the analysis comparisons and concluded that the equivalent static acceleration results for the SCV are conservative, when compared to time history results. Therefore, RAI-TR03-16 is resolved.

During its review of Section 6.2 of TR-03, the staff identified a number of editorial and technical items in need of clarification or explanation. In RAI-TR03-21, parts (b), (c), and (e), the staff requested that the applicant provide technical clarifications. Parts (a) and (d) were editorial.

> (b) TR-03, Section 6.2, states "For those local flexible structures that are amplified, apply an additional acceleration to these structures equal to the difference between the average uniform amplified component accelerations and rigid body component equivalent static accelerations. These accelerations are to be considered in local design of the flexible portion of the structure but do not need to be considered in areas of the structure away from the local flexibility. They can be applied in a series of individual load vectors." The applicant has not shown how this methodology has been implemented, and whether the effects of increased accelerations on locally flexible structures can be ignored in areas of the structure away from the locally flexible structures. The sum total of all the flexible masses times the corresponding acceleration increments may impose greater-than-negligible additional loads on the overall structure, in the two horizontal directions and in the vertical direction. Therefore, the applicant is requested to

(1) describe in greater detail the implementation of this methodology, including a numerical example; and (2) provide a quantitative technical basis for the conclusion that the effects of increased accelerations on locally flexible structures can be ignored in areas of the structure away from the locally flexible structures."

(c) TR-03, Section 6.2, states "The vertical equivalent static seismic accelerations at (Shield Bldg) elevations 89.9 m (294.93 ft) and 101.5 m (333.13 ft) are obtained directly from the maximum time history results by taking the average of locations at opposite ends of a diameter. The vertical accelerations from the 3D finite element model at the shield building edges at these elevations are significantly influenced by the horizontal loading. If they are used for the vertical equivalent accelerations, the horizontal response would be double counted in the vertical direction." The applicant has not shown how this methodology has been implemented or its basis. Therefore, the applicant is requested to submit a numerical example, based on elevation 101.5 m (333.13 ft) of the SB, to demonstrate the implementation of this methodology. In this example, please also include the vertical acceleration value that would be obtained if this methodology was not implemented."

(e) TR-03, Section 6.2, under the heading "Seismic Accelerations for Evaluation of Building Overturning," states "The dynamic response of the structure affecting overturning and basemat lift off is primarily the first mode response at about 3 Hertz on hard rock. This reduces to about 2.4 Hertz on soil sites as shown in the 2D ANSYS and SASSI analyses. The higher auxiliary building accelerations of Table 6.2-2 are not considered in overturning since they are from higher frequency modes greater than 2.4 Hertz. Amplified response of individual walls in the Auxiliary Building and the IRWST [In-Containment Refueling Water Storage Tank] need not be considered since they are local responses that do not effect overturning." For the overturning analysis, the staff is concerned that the methodology employed may not predict an overall moment on the basemat that envelops the maximum overturning moment for all site conditions. The applicant is requested to provide its technical basis for the conservatism of the methodology employed.

In a letter dated April 5, 2007, the applicant provided its initial response to this RAI. For part (b), the staff required additional clarification concerning how the applicant determined the uniform acceleration values applied to the whole structure and the additional acceleration increments applied to the flexible areas.

For part (c), the applicant stated that a seismic component associated with the rotational response of the PCCWST should also be included, in addition to the translational seismic acceleration component, and that the rotational response of the PCCWST would be addressed in the redesign of the shield building roof.

For part (e), the applicant proposed that it be deferred to the staff's review of TR-85, APP-GW-GLR-044, Revision 0, "Nuclear Island Basemat and Foundation."

At the October 2007 audit, partly in response to part (b) of this RAI, the applicant presented results from an RSA of the coupled ASB/CIS, using the refined ANSYS NI05 model. The applicant had decided to use these RSA results as the basis for detailed design of the ASB and CIS. At the time, the applicant stated that switching to RSA resolved parts (b) and (c) of this RAI.

During the May 2008 audit, the staff requested that the applicant demonstrate that the seismic RSA using the fixed base NI05 model is sufficient to capture additional amplification due to rocking. The applicant agreed to compare loads at the top of the shield building, between time history analysis, which includes rocking, and RSA, which does not.

On August 20, 2008, the applicant submitted its revised response to parts (b) and (c) of this RAI. The staff concluded that the questions raised in part (b) of this RAI were no longer applicable. The staff confirmed that TR-03, Revision 2, Section 6.4, clearly identified that RSA is used for the ASB design and the CIS design. Therefore, part (b) was resolved.

For part (c), the applicant presented a comparison of the bending moments in the beams at the top of the shield building, and the forces and moments in the PCS vertical wall, between time history and RSA results. In all cases, the RSA is conservative when compared to the time history analysis, confirming that conservatism in the RSA that will account for rocking. The staff concluded that the comparisons sufficiently demonstrated the conservatism of the RSA results. Therefore, part (c) was resolved.

Part (e) of this RAI, concerning the conservatism of the overall moment on the basemat, is addressed in Section 2.6.1.2 of TR-85 and is tracked under the staff's TR-85 evaluation. This issue is considered resolved with respect to the TR-03 evaluation. Therefore, RAI-TR03-21 was resolved.

The staff reviewed the applicant's seismic displacement results presented in TR-03, Section 6.3. The maximum seismic deflections obtained from the fixed-base time history analysis and the SASSI analyses are given in Tables 6.3-1 to 6.3-3 for the ASB, CIS, and SCV, respectively. The staff determined that a number of clarifications were needed before the staff could complete its review. In RAI-TR03-22, the staff requested that the applicant: (1) clarify whether the deflections in the tables are a consistent set, based on the worst-case time history result, or are an envelope of maximum deflections from all the time history results; and (2) compare the tabulated deflections to the corresponding deflections obtained from the equivalent static acceleration analyses, and explain any significant differences.

In its response dated January 29, 2007, the applicant stated that the deflections given in Tables 6.3-1 to 6.3-3 are the envelope of maximum relative deflections from all of the time history results for the soil and HR cases. Displacements at different nodes for the soil cases have been obtained relative to the translation of a reference node at the bottom of the foundation and near the center of the basemat. Deflections for the HR case are relative to the fixed base at foundation level.

The applicant further stated that the deflections given in these tables have been revised to remove drift, by adding a small constant acceleration to the response acceleration at every time step for the first 0.05 seconds of the time history. If baseline correction is not performed, a residual drift in displacement time histories will be obtained at the end of the seismic excitation. The applicant provided Tables RAI-TR03-022-1 to RAI-TR03-022-3 in its response, showing the revised relative displacements. The applicant also stated that it is not possible to compare equivalent static displacements to the time history displacements for the soil cases. The time history results include rocking about the base, while the equivalent static analysis has a fixed base.

The staff questioned the approach the applicant had used to eliminate drift and, following discussions of this issue during audits in 2007, and 2008, the applicant submitted a revised

RAI response, in a letter dated August 20, 2008. The applicant revised the approach for eliminating drift. The new approach calculates displacements internally within the SASSI program, based on an analytical complex frequency domain approach that uses inverse fast Fourier transforms to compute relative displacement histories, instead of double numerical integration in the time domain for computing absolute displacement time histories from absolute acceleration time histories. The analytical approach is more accurate than a typical baseline correction (time integration) algorithm. The applicant also submitted a proposed revision to TR-03, Section 6.3, "Seismic Displacement Calculation," adding more detail about the analysis methodology and identifying that the ACS SASSI RELDISP module is used for this calculation.

The applicant also indicated in its response that it had switched to seismic RSA and is not using equivalent static analyses; and consequently the staff's initial request for comparison of dynamic results to equivalent static analysis results is no longer applicable. The applicant also submitted a proposed revision to TR-03, Section 6.3, covering this change.

The staff reviewed the response and found the applicant's revised approach to eliminate drift acceptable, because it is mathematically rigorous. For comparison of displacements, the staff noted that RSA is only applied to the ASB and CIS, not to the SCV. Thus, this issue remained unresolved for the SCV. The staff confirmed that TR-03 had been appropriately revised in Revision 3, resolving the drift issue. The applicant also submitted a detailed comparison of time history results to equivalent static acceleration results for the SCV, in a revised response to RAI-TR03-16, demonstrating the conservatism of the equivalent static analysis for the SCV. As a result, the staff considered the static versus. dynamic issue resolved for the SCV. Therefore, RAI-TR03-22 was resolved.

In a letter dated September 10, 2010, the applicant submitted revised responses to RAI-TR03-22 and related RAI-TR03-37. These responses identified alternate methods that the applicant has used to calculate relative displacements. The applicant identified two methods, in addition to the ACS SASSI RELDISP module, for inclusion in the next revision of the AP1000 DCD and the next revision of TR-03. The proposed AP1000 DCD additions, included in the response to RAI-TR03-37, are as follows:

DCD 3G.4.1 "ANSYS Fixed Base Analysis"

> ANSYS is used to calculate the maximum relative deflection to the nuclear island for the envelop case that considers all of the soil and hard rock site cases. Synthesized displacement time histories are developed using the envelope seismic response spectra from the six site conditions (hard rock, firm rock, soft rock, upper-bound soft-to-medium, soft-to-medium, and soft soil). Seismic response spectra at nine locations are used (4 edge locations, 1 center location, and 4 corner locations). It is not necessary to adjust for drift since deflections relative to the basemat are calculated, and the drift would be subtracted from the results.

DCD 3G.4.2 "3D SASSI Analyses"

> Westinghouse has adopted the approach that calculates displacements internally within the ACS SASSI program based on an analytical complex frequency domain approach that uses inverse Fast-Fourier Transforms (FFT) to compute relative displacement histories instead of double numerical integration in the time

domain that computes absolute displacement time histories from absolute acceleration time histories.

The relative displacement time history is calculated using ACS SASSI RELDISP module. The complex acceleration transfer functions (TF) are computed for reference and all selected output nodes. The relative acceleration transfer function is calculated by subtracting the reference node TF from the output node TF. The relative displacement transfer function is obtained by dividing the circular frequency square (ω^2) for each frequency data point. The relative displacement time history is obtained by taking the inverse FFT.

Relative displacements are calculated between adjacent buildings and the nuclear island using soft springs between the buildings. The spring stiffness is very small so that it does not affect the dynamic response. These calculations are performed using 2-D models and the SASSI 2000 code. The relative deflection is calculated using the maximum compressive spring force and the stiffness value.

The applicant also proposed comparable revisions to TR-03 in the response to RAI-TR03-22. The staff determined that the additional methods used by the applicant to calculate relative displacements are technically correct, and do not require any correction for drift. In subsequent revisions to the AP1000 DCD and TR-03, the applicant made appropriate changes which resolve this issue.

The staff reviewed the comparison of the NI10 and NI20 seismic analysis models, described in TR-03, Appendix C. The staff's review identified the need for a number of clarifications and explanations of the results presented. In RAI-TR03-32, the staff requested that the applicant provide these clarifications and explanations.

The staff and the applicant discussed the issues raised in this RAI at audits in 2007, 2008, and 2009. The applicant submitted several revisions to its RAI response, to address the staff's original and follow-up questions. Following the April 2009 audit, the only remaining technical issue was whether the NI20 model refinement is sufficient to represent vibration modes up to 33 Hz are potentially excited by the CSDRS ground spectrum input. The staff was concerned that, if the dynamic analysis model(s) of the AP1000 do not accurately predict the amplified response of flexible regions, then the ISRS at those locations may be underestimated. The staff initiated an independent comparison of modal properties between the ANSYS NI10 model and the ANSYS NI20 model. Based on the preliminary results of the staff's confirmatory analyses, the staff requested that the applicant demonstrate that all walls, floors, and roof slabs with a fundamental plate vibration frequency less than 33 Hz are adequately represented in the NI20 model, such that an ANSYS NI20 modal analysis will capture these vibration modes. If this is not the case for specific walls, floors, or roof slabs, the staff requested that the applicant develops an approach to generate the ISRS that consider the additional amplification in the middle of the wall, floor, or roof slab.

In TR-03, Revision 4 (March 2010), Section 4.2.4, the applicant stated that the NI05 model was reviewed to identify flexible regions that may produce amplified response spectra. The applicant concluded that the NI20 model was too coarse in some areas to pick up all local vibration modes up to 33 Hz, based on comparison to NI05 modal analysis results.

Consequently, the seismic response in the middle of some wall, floor, and roof panels is underestimated, leading to nonconservative ISRS for subsystem design. To address this, the applicant proposed a method of evaluating these areas using the more detailed NI05 model to evaluate flexible regions. The staff's review of the proposed method found that that there was insufficient description of the proposed method and that an example case (including results) would be helpful in understanding the implementation. This issue was identified as Open Item OI-TR03-32.

In a letter dated July 9, 2010, the applicant submitted a revised response to RAI-TR03-32. The applicant stated the NI05 model had been reviewed for flexible regions where out-of-plane response may occur at frequencies less than 33 Hz. The applicant noted that each of the regions reviewed have a higher mesh refinement than the NI20 model. The regions, which have flexible areas, are evaluated in one of two ways:

1. Flexible areas that were previously identified (TR-03, Revision 4, Table 4.2.4-10) have amplified response spectra developed from the envelope of the time history analysis results for the HR and soil sites.

2. Flexible regions, which require a detailed analysis to obtain the amplified response spectra use input directly from time history analysis. The NI05 finite element model is used to capture out-of-plane flexibilities that, because of mesh refinement, the NI10 and NI20 models could not capture. The resulting nodes have been designated with (NI05) to distinguish that the amplified response spectra come from that model.

This applicant identified proposed revisions to TR-03, to document the methods and results. The staff reviewed the flexible regions identified in Tables RAI-TR03-032-2, RAI-TR03-032-3, and RAI-TR03-032-4 of the RAI response, and the ISRS comparisons (NI05 amplified versus NI10/NI20) shown in Figures RAI-TR03-032-7 to RAI-TR03-032-13 of the RAI response. Based on its review, the staff finds the applicant's method for identifying flexible regions and modifying the ISRS to be acceptable. By using the mesh refinement of the NI05 model, the applicant was able to locate and evaluate flexible regions of the NI structures that were inadequately modeled in the less refined NI20 and NI10 models. RAI-TR03-32 and the associated open item are resolved. In a subsequent revision to TR-03, the applicant made appropriate changes to the report text. RAI-TR03-32 and the associated open item are resolved.

The staff reviewed TR-03, Section 4.2.4, which summarizes the applicant's seismic analysis models and methods used for the AP1000 design. In Table 4.2.4-1 of TR-03, the applicant summarized the type of structural models, analysis methods, and computer codes used in the evaluations to extend the NI seismic analyses to soil sites. In the table, the applicant stated that the 2D finite element lumped-mass stick model of the ASB was analyzed using the SASSI Code, by time history analysis method for the purpose of parametric studies to establish the bounding generic soil conditions. However, during its review of the responses to other RAIs, the staff noted that 2D seismic analyses were apparently used for other purposes also. In RAI-TR03-34, the staff requested that the applicant clarify the information provided in Table 4.2.4-1, and update this table, as needed, to identify all applications of 2D seismic analysis, and how the results were used.

In its response dated July 5, 2007, the applicant stated that Table 4.2.4-1 had been revised to show the additional seismic models and analyses identified. The revision to the table also added the polar crane models and the CV shell model, included in the response to RAI-TR03-20. During the May 2008 audit, the staff verified that TR-03, Revision 1 included the revised Table 4.2.4-1, documenting the use of 2D analysis models. However, additional errors were found in the table. In a letter dated August 20, 2008, the applicant submitted a proposed revision to TR-03 Table 4.2.4-1. In a subsequent revision to TR-03, the applicant made appropriate changes to Table 4.2.4-1, which resolve this issue.

3.7.2.4.2 Nuclear Island Seismic Analysis using HRHF Input Motion

Subsequent to NUREG-1793 for the AP1000 DCD, Revision 15, the applicant added AP1000 DCD Appendix 3I in Revisions 16 and 17, in order to address the adequacy of the AP1000 seismic design for ground response spectra typical of CEUS HR sites, which are "rich in the high frequency range." These sites are referred to as HRHF sites. The applicant's technical basis for AP1000 DCD Appendix 3I is TR-115.

In May 2008, the staff issued ISG-1 on acceptable methods to demonstrate seismic adequacy for HRHF ground spectra. The four key elements of the guidance are:

- Use of the staff-accepted Abrahamson coherency function, to reduce the effects of the high-frequency ground motion.

- Use of a staff-accepted computer code (e.g., ACS SASSI) specifically developed to include the effects of incoherency.

- Use of building structural models sufficiently refined to adequately predict modal response up to 50 Hz.

- Selection of an adequate sampling of SSCs for detailed evaluation of response to the HRHF ground spectra.

The staff reviewed AP1000 DCD Appendix 3I and TR-115 using the elements of the ISG-1, in full consideration that the applicant's submittal represent the industry's first attempt to implement ISG-1.

The staff reviewed the introduction to TR-115, Revision 0, Section 1.0, and noted that the first paragraph stated that the purpose of the report is two-fold: (1) to confirm that high frequency seismic input is not damaging to equipment and structures qualified by analysis for the AP1000 CSDRS; and (2) to demonstrate that normal design practices result in an AP1000 design that is safer and more conservative than that which would result if designed for the high frequency input. The staff found that the above statements, made by the applicant, were too generic in nature, and required a qualification that they apply only to the HRHF spectra actually used in the analyses. The staff also noted that the last paragraph to the introduction section of TR-115 needed to be similarly qualified. In RAI-SRP3.7.1-SEB1-02, the staff requested that the applicant revise the stated purpose of TR-115, accordingly.

In a letter dated April 25, 2008, the applicant proposed changes to the introduction section of TR-115, to satisfy the staff's concern. The staff evaluated the RAI response and the proposed revisions to TR-115, and found them acceptable. The staff subsequently confirmed that TR-115, Revision 1, included the proposed revisions.

Although the applicant clarified the purpose of TR-115, the staff determined that the report contained insufficient information regarding site parameter requirements. The staff requested that the applicant specifically identify in TR-115 the minimum Vs of the underlying medium that must be satisfied in order to reference the results in TR-115, and also provide the technical basis for this determination. The staff noted that the definition of an HR site in the AP1000 DCD is a site with a minimum Vs of 2438.4 m/s (8,000 fps).

In a letter dated September 12, 2008, the applicant responded that the only requirement that COL applicants must demonstrate, to be covered by TR-115, is that their site GMRS is enveloped by the HRHF spectra. The applicant stated that sites with high Vs have higher loads due to a higher frequency than those with lower Vs, and sites that are enveloped by the HRHF input spectra, but have lower Vs, will have lower HRHF seismic loads than those used in the evaluation reported in TR-115.

The staff evaluated the supplemental response, and determined that the applicant's statement, that only a spectrum comparison is necessary, has no established technical basis. Softer material beneath the foundation will shift spectral peaks; whether the results for softer materials are enveloped by the HR results needs to be demonstrated. Based on the above assessment, the staff submitted Supplement 2 to RAI-SRP3.7.1-SEB1-02, requesting the applicant to address the following:

(a) Describe in detail the modeling of underlying media and any side media in the special SASSI analyses of the HRHF GMRS. How many cases were analyzed? Describe each case and the purpose for each case.

(b) What is the Vs associated with each of the media included in the SASSI analyses?

(c) How was the seismic motion at the surface developed for input to the SASSI analyses? Was the HRHF GMRS applied directly as surface motion, or was the surface motion developed from the HRHF GMRS applied at the NI foundation level? If the latter, describe in detail the method used to calculate the surface motion.

(d) Define numerically the range of Vs of the underlying media for which the special SASSI analyses are valid. Provide a detailed technical basis for this determination (e.g., results from parametric studies, previous documented studies, documented test results, "expert" judgment, etc.).

(e) For all COL applications that reference AP1000 DCD Appendix 3I and/or TR-115, are the site characteristics enveloped by the range of Vs defined in (d) above?

In a letter dated February 19, 2009, the applicant responded to RAI-SRP3.7.1-SEB1-02 (Supplement 2). The applicant presented a table of Vs versus depth for the single HRHF analysis conducted, but also restated its contention that only a spectral comparison is required. The staff found the applicant's response to Supplement 2 did not resolve the issue, and discussed this with the applicant in a teleconference on March 5, 2009. The applicant agreed that it is necessary for a specific site to satisfy both the response spectra criteria and also the Vs profile, in order to be covered by the analysis reported in TR-115.

In a letter dated April 14, 2009, the applicant revised its response to RAI-SRP3.7.1-SEB1-02 (Supplement 2), stating that either both requirements must be met, or a site-specific evaluation is needed. The applicant also identified a proposed revision to AP1000 DCD Sections 2.5.2.1 and 2.6, to incorporate this information. On the basis that the applicant has identified both essential requirements, the response to RAI-SRP3.7.1-SEB1-02 is acceptable. In a revised response dated July 9, 2010, the applicant indicated that a statement will be added to TR-115 that a comparison of the site-specific Vs profile to the generic HRHF Vs profile is needed in addition to the comparison of the site-specific spectra to the generic HRHF spectra. In subsequent revisions to the AP1000 DCD and to TR-115, the applicant made appropriate changes to the DCD and report text, which resolve this issue.

In a revised response dated July 9, 2010, the applicant indicated that a statement will be added to TR-115 to indicate that a comparison of the site-specific Vs profile to the generic HRHF Vs profile is needed in addition to the comparison of the site-specific spectra to the generic HRHF spectra. In a subsequent revision to the AP1000 DCD and TR-115, the applicant made appropriate changes to the DCD and report text, which resolve this issue.

The staff reviewed the description of ”Evaluation Methodology” in TR-115, Section 3.0, and noted that the methodology is consistent with the presentation made by the applicant during the April 2007 audit. However, TR-115, Section 3.0, does not include any of the quantitative information presented at the audit to demonstrate the implementation of the approach. In RAI-SRP3.7.1-SEB1-03, the staff requested that the applicant make available for audit, a detailed report of numerical results that demonstrate the implementation specifically for the AP1000. During the May 2008 audit, the staff reviewed the applicant’s report, which documents the implementation of the methodology, and concluded that it is consistent with the presentation made to the staff during the April 2007 audit and the staff’s ISG on incoherency. Initially, the staff considered RAI-SRP3.7.1-SEB1-03 to be resolved. However, the applicant subsequently revised the ACS-ANSYS NI20 model used for the HRHF analysis, in order to correct modeling errors identified by the staff during its confirmatory analysis effort. The staff identified the review of the revised analysis results as Open Item OI-SRP3.7.1-SEB1-03 in the SER with open items. During the June 14-18, 2010 audit, the staff reviewed the revised NI20 [ ] model (in calculation report, [ ]) to ensure that modeling corrections had been addressed. The staff verified that the SASSI model properly represented the actual AP1000 NI structural features. The staff also confirmed that seismic motion incoherency was implemented in accordance with the staff’s ISG. Based on the staff’s audit of [ ], RAI-SRP3.7.1-SEB1-03 and the associated open item are resolved.

The staff reviewed the details of the “Screening Criteria” in Section 4.0 of TR-115. The applicant lists four screening criteria used to select SSCs for detailed evaluation. Based on the screening criteria, it was not clear to the staff why the containment structure is not identified for detailed comparison of the CSDRS and the HRHF responses. In RAI-SRP3.7.1-SEB1-04, the staff requested that the applicant either include a detailed comparison for the containment structure in Section 6.1, or describe in detail its technical basis for excluding the containment structure.

In its response dated April 25, 2008, the applicant stated that the steel containment structure was not chosen for evaluation since it does not meet the criterion of significant modal response within the region of high frequency amplification. The applicant stated that the dominant frequencies for horizontal response are below 10 Hz, and the dominant mode in the vertical direction is below 20 Hz, which are not in the region where the HRHF spectra exceed the AP1000 CSDRS; and that over 75 percent of the containment structure mass participates in modes below the frequency where the HRHF spectra exceed the CSDRS. The staff evaluated the above response and initially concluded that the basis for excluding the containment shell was adequately described. However, the staff subsequently noted that AP1000 DCD Revisions 16 and 17, Section 3G.2.1.3, identifies high frequency modes (20-30 Hz) in the upper closure dome of the steel containment. Since high frequency modes in the upper closure dome were not addressed in TR-115, or in the initial RAI response, the staff requested that the applicant submit a supplemental RAI response justifying why these modes in the upper closure dome would not be excited by the HRHF ground spectra.

In its supplemental response dated September 12, 2008, the applicant stated that the seismic response spectra in the vicinity of the polar crane (~68 m (~224 ft) El.) are representative of the seismic response of the upper closure dome, and that the CSDRS spectra envelope exceeds the HRHF FRS at this location. Therefore, the applicant concluded that the closure dome will have lower response due to HRHF excitation than due to CSDRS excitation. The staff found this response to be inadequate because the results being compared are based on the stick model of the containment structure, which does not include the flexibility of the upper closure dome. The staff requested that the applicant provide information pertinent to addressing the staff's concern.

In its revised response dated May 14, 2009, the applicant stated that the NI20 ACS SASSI analysis for the HRHF ground motion input produced ISRS at the base of the SCV that are completely enveloped by the comparable ISRS produced by the CSDRS ground motion input, across the entire frequency range. The staff reviewed the comparison plots provided in the response, and noted that in this case the HRHF input would not excite the vibration modes in the SCV dome. The staff noted, however, that the applicant needed to confirm this after the HRHF reanalysis was completed. Pending the staff's evaluation of the applicant's revised incoherency analysis results (discussed under RAI-SRP3.7.1-SEB1-03, RAI-SRP3.7.1-SEB1-09, RAI-SRP3.7.1-SEB1-10, and RAI-SRP3.7.1-SEB1-11), this was designated as Open Item OI-SRP3.7.1-SEB1-04 in the SER with open items.

In its revised response dated July 9, 2010, the applicant provided updates to RAI response Figures RAI-SRP3.7.1-SEB-04-1, RAI-SRP3.7.1-SEB-04-2, RAI-SRP3.7.1-SEB-04-3, and RAI-SRP3.7.1-SEB-04-10 that show the corrected spectra comparisons. The staff noted that the CSDRS ISRS still envelope the HRHF ISRS, except for a very minor local exceedance in the Y direction ISRS. Since the input at the base of the SCV is more severe for the CSDRS than for the HRHF spectra, the staff accepts the applicant's decision to screen out the SCV from the HRHF detailed evaluation sample. RAI-SRP3.7.1-SEB1-04, and the associated open item, are resolved.

The staff's reviewed the analytical models described in TR-115, Section 5.0, and noted that the applicant had not adequately justified the applicability of the NI20 model to accurately predict high frequency modes potentially excited by the HRHF ground motion input. In RAI-SRP3.7.1-SEB1-06, the staff requested that the applicant include in Section 5.1 of TR-115 a comparison of frequencies and mode shapes between the more refined NI10 model and the NI20 model, to demonstrate the adequacy of the NI20 model to accurately predict high frequency modes.

In its response dated April 25, 2008, the applicant stated that at the December 20, 2007, meeting between the staff and industry related to the high frequency seismic events, it was agreed that a maximum analysis frequency of 50 Hz would be sufficient to transmit the high frequency response through the model. The applicant further stated that using the NI20 model (mesh size of 6.1 m (20 ft), and the shortest wavelength of 42.1 m (138 ft), there are close to 7 nodes per wavelength, to transmit the high frequency through the finite elements; and stated that it is not necessary to include in Section 5.1 a comparison of frequencies and mode shapes between the NI10 and NI20 models.

During the May 2008 audit, the staff noted that NUREG-0800 Section 3.7.2 (Revision 3, March 2007) identifies the staff's expectations for demonstrating adequacy of the element refinement to accurately simulate behavior at the highest frequency of interest, and requested that the applicant submit additional information to demonstrate the adequacy of the NI20 model. The applicant submitted supplemental responses in September 2008, January 2009, and June 2009. The staff reviewed these supplemental responses and concluded that none of the information submitted directly addressed the staff's initial RAI question.

As a result of the inadequate responses from the applicant, the staff initiated an independent confirmatory analysis effort in June 2009, to study the modal properties of both the NI10 and NI20 models and compare the two models up to 50 Hz. Based on this effort, the staff concluded that the overall building response is adequately represented in the NI20 model, up to 50 Hz. However, local panel vibration modes of walls, floors, and ceilings, up to 50 Hz, are not necessarily modeled with sufficient refinement in the NI20 model. The staff's concern is that, if the NI20 model cannot accurately predict the amplified response of flexible regions up to 50 Hz, then any HRHF high frequency exceedances of the design ISRS (based on the CSDRS) cannot be accurately predicted. Therefore, the staff requested that the applicant review the NI20 model to determine which wall, floor, and ceiling panels are not modeled with sufficient refinement, and to address how this affects the structural design loads and the ISRS, for the HRHF ground spectra input. This was identified as Open Item OI-SRP3.7.1-SEB1-06 in the SER with open items.

In its revised response dated July 27, 2010, the applicant stated that the procedure for addressing the out-of-plane response of flexible regions was the same as that described in its revised response (July 9, 2010) to RAI-TR03-032. The applicant used the NI05 model to identify flexible regions where the out-of-plane response may occur at frequencies less than 50 Hz. The staff's review of the applicant's July 9, 2010 response RAI-TR03-032 is in Section 3.7.2.4.1 of this SER. Based on its review, the staff finds the applicant's method for identifying flexible regions (below 50 Hz) and modifying the ISRS to be acceptable. By using the mesh refinement of the NI05 model, the applicant was able to locate and evaluate flexible regions of the NI structures that were inadequately modeled in the less refined NI20 model. The applicant identified proposed changes to TR-115 to document the new procedure. Therefore, RAI-SRP3.7.1-SEB1-06 and the associated open item are resolved. In a subsequent revision to TR-115, the applicant made appropriate changes to the report text, which resolves this issue.

In its review of the NI10 and NI20 spectral comparisons in Section 5.1, the staff noted that the locations presented showed no significant amplification in the high frequency range. In RAI-SRP3.7.1-SEB1-08, the staff requested that the applicant include in Section 5.1, NI10 versus NI20 comparisons at locations and in directions where there is significant amplification at high frequency.

In its response dated September 12, 2008, the applicant stated that Figures 5.1-4 and 5.1-5 would be added to Section 5.1 of TR-115 to show the locations and response spectra at additional locations. The staff reviewed the supplemental response and found that the two added locations exhibit more significant response in the high frequency region than the three original locations. Significant spectral amplification in X and Y is generally in the 10-20 Hz range, with one Y-direction peak in the 20-30 Hz range. Significant spectral amplification in Z-direction is generally in the 20-30 Hz range.

The staff noted, however, that the comparisons presented did not demonstrate any consistent pattern of correlation among the three models (ANSYS NI10, ANSYS NI20, and SASSI NI20).

In two of the horizontal comparisons, there are significant differences in the 7-8 Hz range, where excellent correlation would be expected. The staff concluded that although the applicant's response addressed the information request, there was no discussion of the anomalies in the comparisons. The staff was concerned that the applicant had not conducted a sufficient assessment of these results before submitting them. Therefore, the staff issued RAI-SRP3.7.1-SEB1-08, Supplement 1, describing the anomalies and requesting the applicant to review and comment on them.

In it supplemental response dated February 24, 2009, the applicant stated that the results presented were obtained from different models (NI10 and NI20) and different technologies (ANSYS - time domain solution, and SASSI - frequency domain solution), and that this can result in the differences identified. The applicant stated that the response spectra show:

- In general the shapes of the response spectra are similar.
- The NI20 model has higher response than the NI10 model.
- SASSI analyses are conservative.

The staff determined that the applicant had not addressed the specific questions posed by the staff, and discussed this with the applicant during the April 2009 audit. The applicant agreed to provide additional information to explain the inconsistencies noted by the staff.

In a letter dated June 3, 2009, the applicant submitted a supplemental response to this RAI, explaining that the inconsistent results reported in the Z direction between nodes 2247 and 2078 was due to modeling differences between the NI10 and NI20 models. The staff reviewed the additional information, and concluded that the explanation is plausible, but not conclusive. The staff determined that resolution of this RAI would need to be deferred until the staff had completed its independent confirmatory analysis program. This was identified as Open Item OI-SRP3.7.1-SEB1-08 in the SER with open items.

The results of the staff's confirmatory analysis of the NI20 SASSI model are described under OI-SRP3.7.1-SEB1-09, OI-SRP3.7.1-SEB1-10, and OI-SRP3.7.1-SEB1-11. The staff identified errors in the applicant's NI20 SASSI model, which required the applicant to perform a reanalysis of all SASSI runs. During the June 14-18, 2010 audit, the staff reviewed the revised NI20 SASSI model and results (in calculation report, [ ]). The staff verified that the revised SASSI model properly represented the actual AP1000 NI structural features.

In its revised response dated July 9, 2010, the applicant indicated that the differences in response between the southeast and northeast corners of the auxiliary building, as depicted in corrected TR-115 Figures 5.1-7 and 5.1-8, are due to local differences in geometry between the NI10 and NI20 models, and also due to differences in the seismic ISRS at the base of the auxiliary building, between SASSI and ANSYS. The applicant also identified a proposed revision to TR-115. The staff determined that the applicant's response is acceptable, on the basis that these results are not design-basis results, but are only intended to demonstrate dynamic similarity between the three models (ANSYS NI10, ANSYS NI20, and SASSI NI20). Also, as discussed under RAI-SRP3.7.1-SEB1-06, there are local regions where NI20 does not possess the necessary model refinement to represent modal behavior up to 50 Hz. In these areas, the applicant is relying on the more refined NI05 model to develop HRHF ISRS. Therefore, the staff considers RAI-SRP3.7.1-SEB1-08, and the associated open item to be resolved. In a subsequent revision to TR-115, the applicant made appropriate changes to the report text, which resolves this issue.

The staff reviewed the HRHF ISRS presented in TR-115, Section 5, and issued three related RAIs. RAI-SRP3.7.1-SEB1-09, RAI-SRP3.7.1-SEB1-10, and RAI-SRP3.7.1-SEB1-11 requested that the applicant provide clarification and explanation of in-structure response reductions and apparent inconsistencies in the presented results. The significant issues raised by the staff and the applicant's responses follow.

(1) The staff noted that the spectral acceleration ratio of coherent motion to incoherent motion is as high as 3, and a ratio of 2 is fairly common. The staff requested that the applicant provide the detailed technical basis for concluding that the calculated reductions are reasonable, and consistent with the ISG on this subject; and also to identify whether any independent peer review of this result had been performed, considering it is a first-time application of this technology.

(2) The staff noted that spectral acceleration reductions are indicated at frequencies as low as 6-10 Hz. The staff requested that the applicant provide the detailed technical basis for concluding that the calculated reductions at a low frequency are reasonable, and consistent with the ISG on this subject; and also to identify whether any independent peer review of this result had been performed, considering it is a first-time application of this technology.

(3) The staff noted that even when the beneficial effects of incoherency are included, there are high frequency exceedances at a number of the sample locations evaluated. However, the applicant apparently has concluded that the worst-case exceedances have been determined, without expanding the sample size and evaluating additional locations. The staff requested that the applicant provide a detailed technical basis for concluding that the seismic response of AP1000 SSCs to the defined HRHF ground spectra input is enveloped by the response at the selected sample locations.

(4) The staff reviewed the ISRS for the containment operating floor, east side, El. 40.9 m (134.25 ft) (Node 2136), and for the containment operating floor, west side, El. 40.9 m (134.25 ft) (Node 2170), in TR-115, Revision 1, Figure 5.2-2. The staff observed that the east side and west side Y-direction spectra are very similar. However, the east side and west side X-direction spectra and the east side and west side Z-direction spectra are very different, for both the HRHF-coherent and HRHF-incoherent cases.

Location	Direction	HRHF-coherent	HRHF-incoherent
East Side	X	1.6g (20 Hz)	1.05g (20 Hz)
West Side	X	3.5g (13 Hz)	2.8g (13 Hz)
East Side	Y	3.5g (16 Hz)	1.95g (16 Hz)
West Side	Y	3.7g (16 Hz)	2.05g (16 Hz)
East Side	Z	1.9g (40-50 Hz)	0.65g (40-50 Hz)
West Side	Z	3.2g (30 Hz)	1.7g (30 Hz)

The staff could not determine a rational explanation for this behavior, and requested that the applicant provide a detailed technical explanation for these apparently inconsistent results.

In a letter dated February 4, 2009, the applicant provided the following response:

(1) SASSI-Simulation incoherency approach used to generate the seismic response spectra is in accordance with Section 4, Section 1.0 of "Interim staff Guidance (ISG) on Seismic Issues Associated with High Frequency Ground Motion in Design Certification and Combine License Applications," supplements to Section 3.7.1, "Seismic Design Parameters," of NUREG-0800. In generating the seismic response spectra, the applicant made no changes to the accepted industry methodology. The technical basis for incoherence is discussed in EPRI Report 1012966, "Effect of Seismic Wave Incoherence on Foundation and Building Response," December 2005. Similar results were shown in Figure 6-1 to 6-11 of EPRI Report 1012966. Figure 6-12 showed 5-fold reduction at 50 Hz.

(2) See (1) above. Figure 6-6 of EPRI Report 1012966 showed the similar reduction at 10 Hz.

(3) The applicant had agreed to evaluate a representative sample of SSCs located in areas that are subject to high frequency response, and have frequency content in the high frequency region, to confirm that high frequency seismic input is not damaging, and to demonstrate that normal design practices using the CSDRS result in an AP1000 design that is safer and more conservative. This evaluation is reported in TR-115. The SSCs selected based on the screening criteria are sufficient to demonstrate that high frequency seismic events are not damaging. There may be spectra that have higher exceedances; however, safety-related equipment may not be located in these locations, SSCs located in these areas may not have high frequency response, and further the evaluation performed demonstrates that the HRHF seismic event is not damaging and there is margin between the CSDRS and HRHF response. The applicant's evaluation approach is in compliance with Section 4, Subsections 3.0 and 4.0 of the "Interim Staff Guidance on Seismic Issues Associated with High Frequency Ground Motion in Design Certification and Combined License Applications."

(4) Figure RAI-SRP3.7.1-09-C (in the response) shows the location of nodes 2136 and 2170. Node 2170 is surrounded by a large semi-circle IRWST water tank while node 2136 is surrounded by concrete structure floor and steam generator compartment wall. Node 2136 showed more interaction in X and Z direction between the CISs. The responses of both nodes in Y direction are similar because of less structure interaction between the steam generator compartment wall and other concrete structure. The differences between coherent and incoherent responses are justified in (1) and (2) above.

The staff reviewed the applicant's responses to the supplemental information request, and determined that the responses to (1) and (2) were unacceptable, because the applicant referenced an EPRI report that is not referenced in ISG-1. The applicant needed to confirm that it used the specific reports referenced in the ISG, dated May 19, 2008. If this is not the case, then the applicant would need to perform new analyses that are consistent with the ISG approved methods. Also, the applicant had to confirm that the results questioned by the staff in (1) and (2) are consistent with results presented in TRs that the staff has accepted.

The staff discussed this RAI response with the applicant during the April 2009 audit. The staff determined that the best course of action to resolve the remaining staff concerns on Items (3) and (4) was to conduct independent confirmatory analyses. To support this effort, the applicant agreed to submit the SASSI NI20 model used in its incoherency analyses to the staff. The staff also requested that the applicant conduct several parametric analyses, using a simplified AP1000 model from the EPRI studies and varying the basemat dimensions and properties of the foundation media.

Confirmatory Analysis

To support the staff's review of the applicant's responses to RAI-SRP3.7.1-SEB1-09, RAI-SRP3.7.1-SEB1-10, and RAI-SRP3.7.1-SEB1-11, the staff initiated a confirmatory analysis effort in May 2009. The applicant provided the staff with the seismic analysis models (ANSYS NI20 and SASSI NI20), so that an independent check of modeling assumptions could be performed. In the confirmatory analysis effort, the staff identified several key findings:

1. The staff identified several modeling errors in the applicant's SASSI NI20 model. The errors related to the end-release assumptions for certain beam elements and their effect on over-constraining the global SASSI model. In addition, there were several foundation nodes on the NI basemat that were not identified as SASSI interface nodes. It was not clear to what extent these modeling errors might affect ISRS as well as the ZPA values used for structural design. The staff informed the applicant, during the August 2009, audit in Cranberry, Pennsylvania, of these errors and that the errors are likely to affect the results presented in TR-115 and TR-03. The applicant agreed to submit revised results for all prior SASSI analyses reported in TR-115 and TR-03.

2. The staff studied the adequacy of the NI20 model refinement to reasonably predict all vibration modes up to 50 Hz, as specified in the ISG. The conclusion is that there are local regions (i.e., floor, wall, and roof slabs) where the refinement is not sufficient to pick up a local 50 Hz vibration mode. Therefore, the ISRS may not be accurate in these areas. In RAI-TR03-032 and RAI-SRP3.7.1-SEB1-06, the staff requested that the applicant review the NI20 model, locate all such local areas, determine whether there are mounted systems and components in these areas, and describe how the appropriate ISRS will be developed for these areas.

3. The staff compared results between ACS SASSI and the latest version of SASSI 2000, for the AP1000 NI20 model and HRHF ground motion, with and without incoherency effects. There are significant reductions in the low frequency region of the ISRS when incoherency effects are included. The staff found that the low frequency reductions were not consistent with EPRI calculations referenced in ISG-1. The staff's review of the applicant's use of incoherency is discussed below.

Use of Incoherency

The staff focused its review of the applicant's use of spatial incoherency by requesting the applicant (RAI-SRP3.7.1-SEB1-10) to provide comparisons of ISRS using both coherent and incoherent input motion. In response to RAI-SRP3.7.1-SEB1-10, the applicant provided response spectra comparisons at several locations on the NI:

A. Top of the shield building (El. 99.8 m (327.4 ft))
B. East side of the containment operating floor (El. 40.9 m (134.25 ft))
C. West side of the containment operating floor (El. 40.9 m (134.25 ft))
D. Shield building, northeast corner (El. 40.9 m (134.5 ft))

E. Shield building, at fuel building roof (El. 54.7 m (179.6 ft))
F. Reactor coolant pump (RCP) (El. 30.2 m (99.0 ft))

For the purpose of comparing the applicant's results to previous EPRI calculations, the staff reviewed the response spectra comparisons, and developed approximate ratios of incoherent to coherent motion in the low and high frequency ranges. These comparisons are provided in SER Table 3.7-1. The applicant also stated that the Abrahamson Hard-Rock Coherency Model (2007), as incorporated into ACS- SASSI, was used to perform SSI calculations. The staff finds that the applicant's use of the 2007 Abrahamson Hard-Rock coherency model is consistent with staff guidance (i.e., ISG-1).

Table 3.7-1. Incoherent Versus Coherent Response (Approximate)

Building Location	Direction	Incoherent/Coherent Response Ratio	
		0-10 Hz	10-50 Hz
Top of the shield building	X	0.90	0.75
	Y	0.95	0.85
	Z	0.65	0.90
East side of the containment operating floor	X	0.90	0.75
	Y	0.90	0.70
	Z	0.90	0.55
West side of the containment operating floor	X	0.90	0.85
	Y	0.85	0.75
	Z	0.90	0.50
Shield building, Northeast corner	X	0.85	0.70
	Y	0.95	0.75
	Z	0.80	0.65
Shield building, at fuel building roof	X	0.85	0.75
	Y	0.80	0.75
	Z	0.80	0.60
Reactor coolant pump	X	0.90	0.90
	Y	0.80	0.95
	Z	0.75	0.85

The results shown in SER Table 3.7-1 indicate that low frequency reductions range from 5-35 percent. The locations of the most significant response reductions are at the top of the shield building and at the RCP, with approximately 25-35 percent reductions in the 0-10 Hz range.

High-frequency response reductions range from 5-50 percent. The locations of the most significant high-frequency reductions are at the east and west sides of the containment operating floor, in the vertical direction, and the shield building (at fuel building roof), in the Y direction. Approximate reduction of 45-50 percent in the 10-50 Hz range was observed at these locations.

The staff also reviewed spectral response comparisons for several nodes on the basemat. These basemat nodes exhibited similar reductions in response both in the low and high frequency ranges. The staff finds that the high-frequency response predictions are reasonable based on comparisons with similar calculations performed by EPRI (TR-1015111, 2007) using more simplified structural models. However, the staff finds that the applicant's low-frequency response reductions, in excess of 30 percent, to be unsupported by the EPRI calculations. To address this concern, in RAI-SRP3.7.1-SEB1-11, the staff requested that the applicant provide justification for the significant reductions in a low frequency response.

In its response, the applicant stated that the low frequency reductions were due to the use of the 2007, HR coherency function itself, which can have a 50 percent reduction at 50 m (164 ft) in the 2-5 Hz range. The staff found the applicant's justification inadequate because the applicant referenced EPRI calculations (TR-1015111, 2007, Chapter 5), which are based on a soil coherency model that is not applicable to HR sites. The staff notes that Appendix B of the same EPRI report includes results using the approved 2007 coherency function and serves as the staff's basis for comparison.

The staff investigated the applicant's low-frequency response predictions. With the intent of reducing computational effort, the staff developed a simplified FEM of the AP1000 NI. This reduced model was then used for SSI analysis using the ACS- SASSI and SASSI -square root of the sum of the square (SRSS) codes. The simplified SSI model had dynamic response characteristics similar to those of the applicant's more detailed NI model, for frequencies below about 15 Hz. The dynamic response of the simplified model was confirmed by comparing fixed-base TFs at several locations to the more detailed AP1000 NI model. A transfer function is defined as a frequency-dependent function of SSI amplification due to a unit input motion. Further, for incoherent analysis using both analytic formulations recognized by the ISG, the confirmatory analyses used the same 2007 Abrahamson coherency function that the applicant referenced, as well as the applicant's HRHF input motion.

The staff performed SSI analyses using the simplified model for both coherent and incoherent motion. The goal of this analysis was to determine if the low frequency reductions of ISRS seen in the applicant's analysis could be duplicated with SASSI-SRSS. This analysis also used the same HR site and HRHF input motion provided by the applicant.

The SSI analysis results using SASSI -SRSS for the simple NI model, as well as the full NI20 FEM with HRHF input, indicate negligible reductions in ISRS in the low frequency range due to incoherency effects. SSI TFs of the simplified model from both SASSI -SRSS and ACS- SASSI show negligible reductions in the low frequency range (below 10 Hz). In addition, 5 percent damped ISRS from SASSI -SRSS analysis of the NI20 model exhibit only negligible reductions at low frequency.

Based on the review of the applicant's results and the staff's independent confirmatory analysis efforts, the staff concluded that the applicant's predictions of in-structure response in the low frequency range were not consistent with EPRI's calculations and the staff's confirmatory calculations. The staff also noted that the applicant's high-frequency incoherent results cannot be considered acceptable if low frequency results cannot be validated. These issues are identified as Open Items OI-SRP3.7.1-SEB1-09, OI-SRP3.7.1-SEB1-10, and OI-SRP3.7.1-SEB1-11.

During the June 14-18, 2010 audit, staff reviewed the revised NI20 SASSI model (in calculation report, [ ]) to ensure that modeling corrections had been addressed. The staff verified that the SASSI model was properly transferring bending moments at the beam (or shell) connections with solid elements. In a letter dated July 9, 2010, the applicant submitted a revised response to RAI-SRP3.7.1-SEB1-11. The applicant indicated that [ ] modeling corrections (e.g., beam element and shell element connections to solid elements) had been addressed and the reanalysis had been performed.

The applicant provided ACS SASSI results for the corrected NI20 model. Using the incoherency option in ACS SASSI, the applicant developed ISRS results for 25 simulations (with and without phase adjustment) for the AP1000 NI six key locations (shown in Figures RAI-SRP3.7.1-SEB1-11-50 through RAI-SRP3.7.1-SEB1-11-67 of the response). The staff reviewed these comparisons and finds that while there are some differences between the original HRHF results and the corrected results (with phase adjustment), the original HRHF results are generally conservative.

The applicant also provided ISRS comparisons (coherent and incoherent) at the four corners and center of the NI basemat (shown in Figures RAI-SRP3.7.1-SEB1-11-68 through RAI-SRP3.7.1-SEB1-11-82 of the response). The applicant stated that these analyses incorporate a phasing correction, which no longer results in significant low-frequency reductions. The staff reviewed these comparisons and finds that there are minimal (<10 percent) ISRS reductions below 10 Hz for the locations presented.

Based on review of the applicant's corrected NI20 SASSI model and the new HRHF results, the staff finds that the applicant has properly implemented modeling corrections, and the ISRS show negligible reductions due to incoherency below 10 Hz. On the basis of these findings, RAI-SRP3.7.1-SEB1-11 and associated open item are resolved.

In a letter dated July 9, 2010, the applicant submitted a revised response to RAI-SRP3.7.1-SEB1-09. In response to a request from the staff, the applicant identified the following proposed addition to TR-115, Section 5.2:

> The exceedances of CSDRS-based ISRS by HRHF-based ISRS are addressed as part of the sampling evaluation documented in this report to confirm that high frequency input has marginal effect on equivalent piping, and structures qualified by analysis for the AP1000 CSDRS.

The applicant had previously addressed issue (4) described above in its February 9, 2009, response, by providing Figure RAI-SRP3.7.1-09-C in the response, which shows the location of nodes 2136 and 2170, and stated that node 2170 is surrounded by a large semi-circular IRWST water tank, while node 2136 is surrounded by concrete structure floor and steam generator compartment wall. The applicant noted that node 2136 showed more interaction in X and Z direction between the CISs. The responses of both nodes in Y direction are similar because of less structure interaction between the steam generator compartment wall and other concrete structure. Prior to the staff's confirmatory analysis, and the applicant's reanalysis after correction of modeling errors, the staff had reserved judgment on the applicant's explanation. With the resolution of RAI-SRP3.7.1-SEB1-10 and RAI-SRP3.7.1-SEB1-11, the staff has concluded that the applicant's explanation for the differences is viable. Therefore, RAI-SRP3.7.1-SEB1-09, and the associated open item, are resolved. In a subsequent revision to TR-115, the applicant made appropriate changes to the report text, which resolves this issue.

Acceptability of ISRS Reductions

In a letter dated July 9, 2010, the applicant submitted a revised response to RAI-SRP3.7.1-SEB1-10, which provided the reanalysis for seismic response, using the corrected NI20 model. In Figures RAI-SRP3.7.1-SEB1-10-1 to RAI-SRP3.7.1-SEB1-10-21 of the response, the applicant provided incoherent and coherent ISRS comparisons. The applicant stated that some ratios of incoherent-to-coherent response are shown to be less than 0.5. To justify this level of reduction, the applicant used the EPRI AP1000 stick model to compare ISRS reductions to the 3D AP1000 model. Three cases were analyzed: EPRI stick model with EPRI soil profile and EPRI time history; EPRI stick model with EPRI soil profile and HRHF time history; EPRI stick model with HRHF soil profile; and HRHF time history input. The results of these analyses are shown in Figures RAI-SRP3.7.1-SEB1-10-22 to RAI-SRP3.7.1-SEB1-10-33 of the response. The results showed that a larger foundation will have a larger reduction in response due to incoherency effects. The results for the top-of-CIS show reductions of the magnitude seen in the NI20 results (approximately 50 percent reduction). The top of the SCV and top the shield building also show similar results. Figures RAI-SRP3.7.1-SEB1-10-34 and RAI-SRP3.7.1-SEB1-10-35 of the response show a comparison of the basemat response of the NI20 model and the EPRI stick models. The comparison shows that the reductions due to incoherency are similar in magnitude.

The staff reviewed the applicant’s comparison of incoherent and coherent results and finds the results similar to those developed independently (SER Table 3.7-1). Based on the similar ISRS reductions of the AP1000 to the EPRI calculations (which are referenced in the ISG), the staff finds the applicant’s reductions due to the use of incoherency to be acceptable. Therefore, RAI-SRP3.7.1-SEB1-10, and the associated open item are resolved.

Evaluation of Structures for HRHF Loading

During the April 2007 audit, the applicant presented structural response comparisons between CSDRS loading and HRHF loading. The staff obtained clarification from the applicant that the HRHF results assumed coherent motion. However, the staff noted that TR-115, Section 6.1, did not identify whether the structural response comparisons in Tables 6.1-1 through 6.1-6, between CSDRS loading and HRHF loading, assumed coherent motion or incoherent motion. In RAI-SRP3.7.1-SEB1-12, the staff requested that the applicant clearly define how it calculated the HRHF structural loads presented in TR-115, Tables 6.1-1 through 6.1-6.

In a letter dated April 25, 2008, the applicant stated that the HRHF member forces provided in Tables 6.1-1 through 6.1-6 are based on incoherency. The incoherent member forces are averaged from 25 independent Monte Carlo runs done with [ ] and multiplied by the element thickness to form the member forces presented.

The staff also requested, in RAI-SRP3.7.1-SEB1-13, that the applicant provide additional comparison results in Tables 6.1-1 through 6.1-6, based on use of the HRHF ground motion without considering reduction for incoherency, similar to the results presented in April 2007. In a letter dated April 25, 2008, the applicant provided the requested comparisons between the coherent and incoherent results in a set of tables designated RAI-SRP3.7.1-SEB1-13-01 to RAI-SRP3.7.1-SEB1-13-01-6. The applicant also noted that it had identified inconsistencies in the HRHF incoherent results tabulated in TR-115, and referred to its response to RAI-SRP3.7.1-SEB1-14.

During review of TR-115, Tables 6.1-1 through 6.1-6, the staff had noted several erratic patterns of differences between the CSDRS results and the HRHF results. In RAI-SRP3.7.1-SEB1-14, the staff requested that the applicant review the tabulated results in Tables 6.1-1 through 6.1-6, and provide a technical explanation for all patterns of differences that the applicant determined to be in need of further review.

In a letter dated April 25, 2008, the applicant stated that it had reviewed the tabulated results in Tables 6.1-1 through 6.1-6 and concluded that there were inconsistencies in the tabulated results. These inconsistencies were corrected; the revised tables were included in the RAI response, and also identified for inclusion in TR-115, Revision 1. The applicant stated that the conclusions in Section 6.1 remain unchanged. During the May 2008, audit, the staff discussed these three RAI responses with the applicant. The expanded and corrected results included in the response to RAI-SRP3.7.1-SEB1-13 show that the HRHF coherent results are enveloped by the CSDRS results. Therefore, the staff concluded that structures designed to the CSDRS input are also adequately designed for the HRHF input. The staff also confirmed that the corrected tables were included in TR-115, Revision 1. On this basis, RAI-SRP3.7.1-SEB1-12, RAI-SRP3.7.1-SEB1-13, and RAI-SRP3.7.1-SEB1-14 are resolved.

3.7.2.5 Development of Floor Response Spectra

In AP1000 DCD, Revision 19, Section 3.7.2.5, the applicant stated that design FRS are generated according to RG 1.122, “Development of Floor Design Response Spectra for Seismic Design of Floor-Supported Equipment or Components,” Revision 1. The seismic FRS is computed using time-history responses determined from the NI seismic analyses. The time-history responses for the HR condition are determined from a mode superposition time history analysis using computer program [ ]. The time-history responses for the FR and soil conditions are determined from a complex frequency response analysis using the computer program, [ ]. FRS for damping values equal to 2, 3, 4, 5, 7, 10, and 20 percent of critical damping are computed at the required locations.

The applicant stated that FRS for the design of subsystems and components are generated by broadening the enveloped nodal response spectra determined for the HR site and soil sites. The spectral peaks are broadened by ±15 percent to account for the variation in the structural frequencies, due to the uncertainties in parameters, such as material and mass properties of the structure and soil, damping values, seismic analysis technique, and the seismic modeling technique. Figure 3.7.2-14 shows the broadening procedure used to generate the design FRS.

The applicant further stated that spectral peaks at frequencies associated with fundamental SSI frequencies are reviewed. If there is a “valley” between peaks due to different soil profiles and not the building modal response, then this valley is filled by extending the broadening of the lower peak horizontally until it meets the broadened upper peak. The SSE FRS for 5 percent damping, at representative locations of the coupled ASBs, the SCV, and the CIS, are presented in AP1000 DCD, Revision 19, Appendix 3G.

Based on its review of AP1000 DCD, Revision 19, Section 3.7.2.5, and the related information in Appendix 3G, the staff concluded that the applicant’s approach for enveloping the multiple site responses, and filling any “valley” in the envelope attributable to soil response, is consistent with current staff guidance, and is acceptable.

3.7.2.6 Three Components of Earthquake Motion

In AP1000 DCD Section 3.7.2.6, the applicant stated that seismic system analyses are performed considering the simultaneous occurrences of the two horizontal and the vertical components of earthquake. In mode superposition time-history analyses using the computer program, ANSYS, the three components of earthquakes motions are applied either simultaneously or separately. In the ANSYS analyses with three component earthquake motion applied simultaneously, the effect of the three components of earthquake motion is included within the analytical procedure so that further combination is not necessary. In analyses where the earthquake components are applied separately, the three components of earthquake motion are combined using one of the following methods:

- For seismic analyses with the statistically independent earthquake components applied separately, the time-history responses from the three earthquake components are combined algebraically at each time step to obtain the combined response time-history. This method is used in the SASSI analyses.

- The peak responses due to the three earthquake components from the response spectrum and equivalent static analyses are combined using the SRSS method.

- The peak responses due to the three earthquake components are combined directly, using the assumption that when the peak response from one component occurs, the responses from the other two components are 40 percent of the peak (100 percent-40 percent-40 percent method). Combinations of seismic responses from the three earthquake components, together with variations in sign (plus or minus), are considered. This method is used in the NI basemat analyses, the CV analyses and the shield building roof analyses.

The applicant further stated that the CV is analyzed using axisymmetric FEMs. These axisymmetric building structures are analyzed for one horizontal seismic input from any horizontal direction and one vertical earthquake component. Responses are combined by either the SRSS method or by a modified 100 percent-40 percent-40 percent method in which one component is taken at 100 percent of its maximum value and the other is taken at 40 percent of its maximum value.

The applicant stated that a summary of the dynamic analyses performed and the combination techniques used is presented in AP1000 DCD Appendix 3G. In Appendix 3G.4.3.1, the applicant indicated that for RSA, the SRSS method is used to combine the spatial components, in accordance with Section 2.1 of RG 1.92, “Combining Modal Responses and Spatial Components in Seismic Response Analysis,” Revision 2.

The staff reviewed the update to AP1000 DCD Section 3.7.2.6, and related information in Appendix 3G, and concluded that: (1) algebraic combination at each time step is consistent with standard practice and the staff guidance for time history analyses using three statistically independent inputs, including SSI analyses using ANSYS, and is acceptable; and (2) use of the SRSS combination is consistent with standard practice and the staff guidance for RSA, equivalent static analysis, and time history analysis when the three inputs are not statistically independent, and is acceptable.

In NUREG-1793 for the AP1000 DCD, Revision 15, the staff had accepted the use of the 100-40-40 method for combining the responses due to the three components of earthquake motion, when the equivalent static acceleration method is used. In July 2006, the staff issued RG 1.92, Revision 2, which included guidance on implementation of the 100-40-40 method. After the submittal of the AP1000 DCD, Revision 17, the applicant identified significant design changes to the roof of the shield building, which is analyzed for seismic response using equivalent static analysis and the 100-40-40 combination method. In addition, equivalent static analysis and the 100-40-40 combination method are used for seismic evaluation of the containment structure and the basemat. Therefore, the staff inquired whether the applicant had implemented the 100-40-40 method in accordance with the guidance provided in RG 1.92, Revision 2. The staff's safety concern was that improper implementation of the 100-40-40 combination method may result in unconservative estimates of seismic demands. This issue was addressed by Open Item OI-TR85-SEB1-27. This open item has been resolved, and the staff has accepted the applicant's implementation of the 100-40-40 method, based on comparison of the applicant's results to results using the SRSS combination method. See Section 3.8.4.1.1.3.4 of this report for the staff's detailed assessment.

3.7.2.7 Combination of Modal Responses

In AP1000 DCD, Revision 17, Section 3.7.2.7, the applicant stated that the modal responses in a RSA are combined using the grouping method shown in Section C of RG 1.92, Revision 1, and when high frequency effects are significant, they are included using the procedure given in Appendix A to NUREG-0800 Section 3.7.2. The applicant further stated that in the fixed base mode superposition time history analysis of the HR site, the total seismic response is obtained by superposing the modal responses within the analytical procedure so that further combination is not necessary. This is unchanged from the AP1000 DCD, Revision 15.

A summary of the dynamic analyses performed and the combination methods used are presented in AP1000 DCD, Revision 17, Appendix 3G. In paragraph 3G.4.3.1, the applicant indicated that the RSA is conducted in accordance with Sections 1.1.3, 1.3.2, 1.4.2, and 1.5.2 of RG 1.92, Revision 2. The staff noted that the applicant's use of the guidance in RG 1.92, Revision 2, for combination of modal responses in RSA, is acceptable because it is consistent with the latest staff guidance on this subject.

However, the staff could not determine whether the applicant's mode superposition time history analyses adequately account for the residual rigid response associated with natural vibration modes with frequencies higher than the input spectrum ZPA frequency. RG 1.92, Revision 2, incorporates more recent research findings with respect to modal response combination methods and the treatment of residual rigid response. It is important to accurately account for the residual rigid response if a nuclear power plant SSC has significant natural vibration modes with frequencies higher than the input spectrum ZPA frequency. Ignoring the residual rigid response in these cases may result in significant underestimation of SSC element forces and moments in the vicinity of supports, as well as underestimation of support forces and moments. In RAI-SRP3.7.1-SEB1-17, part (d), the staff requested that the applicant identify whether the method employed is consistent with or different from the RG 1.92, Revision 2, approach, and to provide the technical basis for the adequacy of any method used that differs from the current staff guidance. The applicant's initial response to the staff's RAI was unsatisfactory. This was identified as Open Item OI-SRP3.7.1-SEB1-17 in the SER with open items.

In its revised response to RAI-SRP3.7.1-SEB1-17, part (d), dated July 27, 2010, the applicant stated that modal superposition time history analysis provides sufficient solution accuracy, without including the residual rigid response, because the modes, which respond beyond the ZPA frequency of the input have no significant contribution to the amplified ISRS. In order to verify the accuracy of the analyses conducted, the applicant performed time history analysis using the NI10 model, with a cutoff frequency of 44 Hz, and an identical time history analysis with additional modes up to 64 Hz for the ASB, and additional modes up to 100 Hz for the CIS. The ISRS comparisons at 5 percent damping are documented in the RAI response at key locations of the ASB and CIS. The applicant provided similar comparisons for key locations in the ASB NI05 model, for 40 Hz and 85 Hz cutoff frequencies. The staff reviewed the comparisons of the ISRS, which showed negligible differences in results between the 2 selected cutoff frequencies. These results support the applicant's position; therefore, the staff concluded that the applicant's implementation of the mode superposition time history analysis method produced sufficiently accurate results, even though it does not formally account for the residual rigid response above the cutoff frequency, as specified in RG 1.92, Revision 2. Therefore, RAI-SRP3.7.1-SEB1-17, part (d), and the associated open item are resolved.

3.7.2.8 Interaction of Noncategory I Structures With Seismic Category I Structures

In AP1000 DCD, Revision 17, Section 3.7.2.8, the applicant described the approach for evaluating the effects of interactions of noncategory I structures with seismic Category I SSCs, and components. The approach identified in the AP1000 DCD, Revision 15, remains unchanged. The evaluation must satisfy one of the following three criteria: (1) collapse of the noncategory I structure will not cause an impact with any seismic Category I SSC; (2) collapse of the noncategory I structure will not impair the intended function of any seismic Category I SSC; or (3) the noncategory I structure is classified as seismic Category II and is analyzed and designed to prevent its collapse under the SSE. The applicant identified three structures adjacent to the AP1000 NI: the annex building, the radwaste building, and the turbine building. There is no change between the AP1000 DCD, Revisions 15 and 17 for the radwaste building. The applicant's evaluation for the radwaste building was previously accepted by the staff.

In the AP1000 DCD, Revision 17, the applicant revised the seismic classification of the annex building. In AP1000 DCD, Revision 15, the entire annex building was classified as seismic Category II. In AP1000 DCD, Revision 17, Section 3.7.2.8.1, the applicant stated that only the portion of the annex building adjacent to the NI is classified as seismic Category II. The applicant stated that the annex building is analyzed for the SSE for the six soil profiles described in AP1000 DCD Section 3.7.1.4 and that for the HR site, a range of soil properties was assumed for the layer above rock at the level of the NI foundation. In RAI-SRP3.7.1-SEB1-15, part (b), the staff requested that the applicant clarify the seismic classification of the remainder of the annex building and confirm that for analysis purposes, the entire annex building has been treated as seismic Category II.

In its initial response dated February 6, 2009, the applicant stated that as shown in AP1000 DCD Table 3.2-2, the annex building area outlined by columns E-I.1 and 2-13 is classified as seismic Category II. The annex building area outlined by columns A-D and 8-13, as well as column A-G and 13-16 is classified as nonseismic. For design purposes, only the portion identified as seismic Category II is designed following the seismic Category I structures acceptance criteria. The applicant stated that the portions of the annex building classified as nonseismic are not adjacent to the NI, and their collapse will not cause the nonseismic structure to strike a seismic Category I SSC, nor will their collapse impair the integrity of seismic Category I SSCs. The applicant further stated that the nonseismic portion of the annex building is only one story, with roof elevations below 36.7 m (120 ft). If this portion of the annex building failed, it would not cause any failure to the seismic Category II portion that could impair the integrity of the seismic Category I structures.

The staff reviewed the response and determined that additional information was needed about the seismic model used for evaluation of the seismic Category II portion of the annex building; specifically, how the nonseismic portion is incorporated in the model. During the April 2009 audit, the applicant presented pictures of the annex building, showing the seismic Category II and nonseismic portions. The applicant confirmed to the staff that failure of the nonseismic portion is not a safety concern. The applicant stated that the small, single story nonseismic section will be included in the Category I-equivalent seismic analysis of the annex building. The applicant agreed to submit a revision to its earlier response. In a letter dated August 11, 2009, the applicant submitted its revised response, providing the clarifications requested by the staff. Therefore, RAI-SRP3.7.1-SEB1-15, part (b) was resolved.

AP1000 DCD, Revision 17, Section 3.7.2.8.3, describes the design of the turbine building. The applicant revised the description of the turbine building to state that the south end of the turbine building is separated from the rest of the turbine building by a 0.61 m (2 ft) thick RC wall that provides a robust structure around the first bay. This wall isolates the first bay of the turbine building from the general area of the turbine building and from the adjacent yard area. The applicant defined the seismic classification of the turbine building as nonseismic. The staff noted an inconsistency in the turbine building description. AP1000 DCD, Revision 15, Section 3.7.2.8.3, stated "…the major structure of the turbine building is separated from the nuclear island by approximately 18 feet." However, in AP1000 DCD, Revision 17, Section 3.7.2.8.3, this statement and additional descriptive information about the turbine building were deleted. Based on the information in Revision 17, the staff could not determine whether the original classification of the turbine building as nonseismic is still valid.

In RAI-SRP3.7.1-SEB1-15, part (c), the staff requested that the applicant provide the technical basis for not classifying the turbine building as seismic Category II, considering its proximity to the NI and the infeasibility of demonstrating the acceptability of a collapse.

In its initial response dated February 6, 2009, the applicant stated that during the HR certification of the AP1000, the NRC reviewed the classification of the turbine building as a nonseismic structure. The NRC concluded from this review (NUREG-1793) "that the method and criteria used for the design of the turbine building will prevent, during a SSE event, the turbine building to jeopardize the safety function of the NI structure, and was therefore acceptable." This conclusion was reached after the applicant agreed to modify the analysis and design requirements to:

- Upgrade the UBC seismic design from Zone 2A, importance Factor of 1.25, to Zone 3 with an Importance Factor of 1.0 in order to provide margin against collapse during the SSE.

- To use eccentrically braced steel frame structures meeting the requirements given in AP1000 DCD Section 3.7.2.8.3.

The applicant further stated that the turbine building is designed as an eccentrically braced frame structure under the guidance of the UBC and is, by the principle of the code, therefore, designed to deform during the design seismic event rather than collapse. The methods and criteria that were agreed to with the NRC have not changed and are given in AP1000 DCD Section 3.7.2.8.3, Revision 17.

The staff reviewed the response and determined that the applicant had not addressed the significance of the change in the description of the turbine building from Revision 15 to

Revision 17. During the April 2009 audit, the applicant presented pictures of the turbine building, showing: (1) the recent addition of a new seismic Category II portion, which is in close proximity to the NI; and (2) the existing nonseismic portion, which is at a sufficient distance from the NI that failure is not a safety concern.

The applicant stated that any effects of the nonseismic sections of the turbine building on the Category II section of the turbine building will be included in the Category I-equivalent seismic analysis. The applicant agreed to submit a revision to its earlier response. In a letter dated August 11, 2009, the applicant submitted its revised response, providing the clarifications requested by the staff. Therefore, RAI-SRP3.7.1-SEB1-15, part (c), is resolved. In a subsequent revision to the AP1000 DCD, the applicant identified the new seismic Category II portion of the turbine building, which resolves this issue.

During the April 2009 audit, the staff and the applicant also discussed a related issue, concerning the effects of structure-soil-structure interaction (SSSI)I between the NI and the adjacent Category II structures. These adjacent Category II structures could rest on compacted backfill, with Vs significantly below 1000 fps. The applicant formally submitted its approach in a revised response to RAI-SRP3.7.1-SEB1-15, dated August 11, 2009, which included a discussion of how 2D analysis results will be scaled to simulate 3D behavior in the SSSI response. The staff reviewed the applicant's approach for performing SSSI analyses of buildings adjacent to the NI, and finds the approach acceptable. However, no analysis results were included in the RAI response. This was identified as Open Item OI-SRP3.7.1-SEB1-15 in the SER with open items.

In a follow-up response submitted July 28, 2010, the applicant provided results of the assessment of SSSI for buildings adjacent to the AP1000 NI. The seismic analyses were performed primarily using 2D [ ] models, as shown in Figures RAI-SRP3.7.1- SEB1-15-3 and RAI-SRP3.7.1-SEB1-15-4, included in the response, but the results were corrected by using a 3D-2D effect factor, which was developed using 3D [ ] models of the buildings on rigid foundations, as shown in Figure RAI-SRP3.7.1-SEB1-15-5, included in the response. Three soil cases were analyzed: UBSM, SM, and SS.

The applicant stated that the seismic Category II buildings are designed using the envelope of foundation input response spectra (FIRS) from the AP1000 design basis HR and soil cases, as well as the AP1000 HRHF spectra. The HRHF plant-grade spectra are generated using backfill soil profiles corresponding to Vs of 152.4 m/s (500 fps), 213.36 m/s (700 fps), and 304.8 m/s (1000 fps) at plant grade. The backfill Vs profiles extend from basemat El. 18.4 m (60.5 ft) to grade El. 30.5 m (100 ft). The applicant made a comparison of the resulting forces (axial and shear) and moments and showed, in Figures RAI-SRP3.7.1-SEB1-15-13 and RAI-SRP3.7.1-SEB1-15-14 of the response, that the forces and moments are controlled by the CSDRS demand rather than the HRHF demand. Also in the July 28, 2010, letter response, the applicant proposed to revise AP1000 DCD Section 3.7.2.8.4 to provide screening criteria for the COL applicant for determining whether site-specific analysis is required. If the criteria below are not met, then the COL applicant can perform site-specific analyses to demonstrate that its site-specific seismic Category II foundation seismic response spectra are less than the AP1000 annex building and turbine building first bay generic design envelope foundation spectra. The screening criteria are:

1. The site meets Section 2.5.4.5 AP1000 DCD soil uniformity requirements.

2. For soil sites, the site GMRS is enveloped by the AP1000 CSDRS with soil profiles SS, SM, UBSM, SR, FR, and HR.

3. For HRHF sites, the site GMRS is enveloped by the AP1000 HRHF response spectra with a minimum backfill surface Vs of 500 fps, and a minimum lateral extent of the backfill corresponding to a line extending down from the surface at a one horizontal to one vertical (1H:1V) slope from the outside footprint limit of the seismic Category II structure.

4. The bearing capacity with appropriate factor of safety is greater than or equal to the bearing demand.

Based on the applicant's SSSI analysis results, and the applicant's criteria for requiring site-specific analysis, the staff finds that the applicant's approach to developing seismic demands on seismic Category II structures is acceptable. Consequently, RAI-SRP3.7.1-SEB1-15 and the associated open item are resolved. In a subsequent revision to AP1000 DCD Section 3.7.2.8.4, the applicant described the screening criteria for site-specific analysis, which resolves this issue.

3.7.2.9 Conclusion

The staff concludes that Revision 19 to the AP1000 DCD continues to support the seismic system analysis for Category I SSCs to meet the applicable NRC regulations for the AP1000 DC.

The revision to the AP1000 DCD provides sufficient information to satisfy the applicable requirements of 10 CFR Part 50, Appendix A, GDC 2; 10 CFR Part 50, Appendix S; and 10 CFR Part 100, Appendix A, for the seismic design and analysis aspects for Category I SSCs to be used in the AP1000 reactor.

The changes to the DCD implementing the revised AP1000 design meet the standards of Criterion vii of 10 CFR 52.63(a)(1) in that they contribute to increased standardization; without these DCD changes each COL applicant would have to address these issues individually.

3.7.3 Seismic Subsystem Analysis

NUREG-0800 Section 3.7.3, "Seismic Subsystem Analysis," provides guidelines for the staff to use in reviewing issues related to seismic design/analysis of subsystems. This review focused on such subsystems as the miscellaneous steel platforms, steel frame structures, tanks, cable trays and supports, HVAC ductwork and supports, and conduit and supports. Section 3.7.3, "Seismic Subsystem Analysis" of the AP1000 DCD Revision 15, was accepted in the staff's safety evaluation for the HR site DC, as documented in NUREG-1793. The AP1000 DCD, Revisions 16 through 19, made no changes to AP1000 DCD Section 3.7.3. The staff considers that its previous safety evaluation of AP1000 DCD Section 3.7.3 remains valid.

AP1000 DCD Section 3.7.2 describes the applicant's seismic analysis methods for large atmospheric storage tanks, such as the PCCWST. The PCCWST is located on the top of the shield building and is an integral part of the shield building. The applicant described the modeling and analysis approach for the PCCWST in AP1000 DCD Appendix 3G and TR-03. The staff's review identified the need for additional information. The assessment of this issue is in Section 3.7.2.3 of this SER.

3.7.4 Seismic Instrumentation

This section of NUREG-1793 is unchanged by the AP1000 DCD amendment.

3.7.5 Combined License Action Items

In AP1000 DCD Revision 18, Section 3.7.5.2 "Post-Earthquake Procedures," the applicant added the following commitment to resolve an issue related to the new and spent fuel racks seismic response evaluation:

> An activity of the procedures will be to address measurement of the post-seismic event gaps between the new fuel rack and the walls of the new fuel storage pit and between the individual spent fuel racks and from the spent fuel racks to the spent fuel pool walls and to take appropriate corrective action if needed (such as repositioning the racks or analysis of the as-found condition).

The staff assessments are in Sections 9.1.1 (new fuel rack) and 9.1.2 (spent fuel racks) of this report.

3.7.6 Seismic Design Conclusions

The staff concludes that the proposed amendment to the AP1000 DC, related to the seismic design of Category I SSCs, as described in the evaluation above, is acceptable because it satisfies the applicable requirements of 10 CFR Part 50, Appendix A, GDC 1; 10 CFR Part 50, Appendix S; and 10 CFR Part 100, Appendix A.

Revision 19 to the AP1000 DCD provides sufficient information to satisfy the applicable requirements of 10 CFR Part 50, Appendix A, GDC 1; 10 CFR Part 50, Appendix S; and 10 CFR Part 100, Appendix A for the seismic design and analysis aspects for Category I SSCs to be used in the AP1000 reactor.

The applicant proposed changes to the AP1000 DCD that provide the seismic design and supporting analysis for a range of soil conditions representative of expected applicants for a COL referencing the AP1000 design. As a result, the certified design can be used at more sites without the need for departures to provide site-specific analyses or design changes, resulting in a more uniform analysis and seismic design for all the AP1000 plants. Providing the information that demonstrates the adequacy of the seismic design for a wider range of soil conditions increases the standardization of this aspect of the design. In addition, these changes reduce the need for COL applicants to seek departures from the current AP1000 design since most sites do not conform to the currently-approved hard rock sites. Therefore, the change increases standardization and meets the finality criterion for changes in 10 CFR 52.63(a)(1)(vii).

3.8 Design of Category I Structures

The staff has reviewed the adequacy of the design of Category I structures of the applicant's AP1000 DCD, Revisions 16 and 17 for the standard plant using the guidance provided in Sections 3.8.1, 3.8.2, 3.8.3, 3.8.4 and 3.8.5 of NUREG-0800.

The NRC issued NUREG-1793 in September 2004 for AP1000 DCD, Revision 15. Subsequent to the issuance of NUREG-1793, the applicant submitted Revisions 16 and 17 of the AP1000 DCD. Additionally, the following TRs were reviewed:

(1) TR-09, "Containment Vessel Design Adjacent to Large Penetrations," APP-GW-GLR-005

(2) TR-57, "Nuclear Island: Evaluation of Critical Sections," APP-GW-GLR-045

(3) TR-44, "New Fuel Rack Design & Structural Analysis," APP-GW-GLR-026

(4) TR-54, "Spent Fuel Storage Rack Structure/Seismic Analysis," APP-GW-GLR-033

(5) APP-1200-S3R-003, "Design for the AP1000 Enhanced Shield Building"

(6) TR-85, "Nuclear Island Basemat and Foundation," APP-GW-GLR-044

(7) TR-113, "AP1000 Containment Vessel Shell Material Specification," APP-GW-GLN-113

With these revisions, the applicant is seeking to make changes in the following areas: (1) steel containment; (2) concrete and steel internal structures of steel containment; (3) other seismic Category I structures; and (4) foundations. The specific changes in each area are evaluated by the staff using the NUREG-0800 sections identified above.

3.8.1 Concrete Containment

This section is not applicable to the AP1000 design since the AP1000 uses a steel containment.

3.8.2 Steel Containment

Using the regulatory guidance in NUREG-0800 Section 3.8.2, "Steel Containment," the staff reviewed areas relating to steel containments or to other Class MC steel portions of steel/concrete containments. The specific areas of review provided in NUREG-0800 Section 3.8.2 are as follows: (1) description of the containment; (2) applicable codes, standards, and specifications; (3) loads and loading combinations; (4) design and analysis procedures; (5) structural acceptance criteria; (6) materials, quality control, and special construction techniques; (7) testing and inservice surveillance program; (8) ITAAC; and (9) COL action items and certification requirements and restrictions. Not all of these areas were applicable to the review of the proposed changes to AP1000 Section 3.8.2 and the following SER sections provide the staff's evaluation for the relevant areas.

In its previous evaluations of AP1000 DCD, Section 3.8.2, the staff identified acceptance criteria based on the design meeting relevant requirements in 10 CFR Part 50, Appendix A, GDC 1; in GDC 16, "Containment Design"; in GDC 51, "Fracture Prevention of Containment Pressure Boundary"; and in GDC 53, "Provisions for Containment Testing and Inspection." The staff found that the AP1000 containment design was in compliance with these requirements, as referenced in NUREG-0800, Section 3.8.2, and determined that the design of the AP1000 containment, as documented in the AP1000 DCD, Revision 15, was acceptable because the design conformed to all applicable acceptance criteria. In its previous evaluations of AP1000 DCD Section 3.8.2, the staff also concluded that satisfaction of the relevant requirements of GDC 2; GDC 4; and GDC 50, "Containment Design Basis," will be demonstrated upon completion of the ASME design report by the COL applicant.

In AP1000 DCD, Revisions 16 and 17, the applicant made the following changes to Section 3.8.2 of the certified design:

1. As a result of the extension of the AP1000 design from hard rock sites to sites ranging from soft soils to hard rock, various seismic re-analyses of the Nuclear Island (NI) structures (containment, auxiliary, and shield buildings) were performed. The design of the steel containment structure for seismic loading relies upon the use of the equivalent static method, in which the acceleration profile calculated from the dynamic seismic analysis of a stick model representation of the steel containment is applied as a static load (mass times acceleration). The dynamic seismic re-analyses of the AP1000 NI, to extend the seismic design basis to soil sites, includes the same stick model representation of the steel containment. In TR-09, the applicant compared the corresponding acceleration profiles obtained from the soil-structure interaction analyses for the various soil sites to the original hard rock acceleration profile used to design the steel containment. On the basis of this comparison, the applicant concluded that the steel containment design is adequate for the range of soil sites considered.

2. The applicant eliminated the COL information item for design of the containment vessel adjacent to large penetrations. The basis for this change is documented in TR-09. The applicant indicated that the applicable changes have been incorporated into the DCD. Therefore, the combined license application (COLA) applicants are no longer required to address this item.

3. Section 3.8.2.7 of DCD Revision 16 was revised to remove the requirement that the in-service inspection of the containment vessel will be performed in accordance with the American Society of Mechanical Engineers (ASME) Code, Section XI, Subsection IWE, and that this is the responsibility of the COL applicant. This requirement was replaced by the statement that the in-service inspection of the containment vessel will be performed.

4. The applicant undertook efforts, based on feedback from the staff transmitted in an NRC letter dated October 15, 2009, to redesign the shield building. The applicant revised the design of the shield building and submitted the details of this redesign in a separate shield building report which accounts for the revised NI model subjected to seismic and other applicable loads.

The staff has performed a confirmatory seismic analysis of the NI and discovered errors in the applicant's model used in the SSI seismic analyses. These errors occurred during the conversion of the [ ] NI20 model to the [ ] NI20 model used in the SSI analyses. The applicant indicated that it would correct the model and rerun the seismic SSI analyses. The new seismic SSI analysis was submitted on March 22, 2010, as APP-GW-S2R-010, Revision 4 (TR-03). The staff finds that both seismic loads (member forces) for structures and the design-basis ISRS have changed at some locations. The applicant's reanalysis results and RAIs, discussed in Sections 3.8.2 through 3.8.5 of the SER and the shield building SER, reflect the results of the reanalysis.

3.8.2.1 Description of the Containment

During the review of the AP1000 DCD Tier 2, Revision 16, the staff identified that Figure 3.8.2-4, Sheet 6 of 6, which presents a typical containment electrical penetration, has been revised in TR-134, Revision 0. In RAI-SRP3.8.2-SEB1-06, the staff requested that the applicant explain why wedge supports on the outside of containment are used for this penetration. If they provide support to the containment penetration in the vertical and/or horizontal directions, the staff asked how the containment deformation is due to thermal and other loads accommodated or considered in the analysis. The applicant was also requested to address this item for other penetrations where this issue is applicable.

In a letter dated February 19, 2009, the applicant stated that in Figure 3.8.2-4 of the AP1000 DCD, Revision 17, the typical containment electrical penetration design was replaced with a design that does not include wedge supports at the shield building end. AP1000 DCD, Revision 17, Sections 3.8.2.1.6 and 3.8.2.4.2.5, also include revisions to information on the electrical penetrations. The staff reviewed the AP1000 DCD, Revision 17 and verified that Figure 3.8.2-4 for the typical containment electrical penetration design does not include wedge supports, and, thus, eliminates an undue constraint on the penetration. Therefore, the staff finds that RAI-SRP3.8.2-SEB1-06 is resolved.

3.8.2.2 Applicable Codes, Standards, and Specifications

During the review of the AP1000 DCD Tier 2, Revision 16, the staff identified that Section 3.8.2.2, as well as other sections of the DCD related to structures; refer to AP1000 DCD Section 1.9 for discussion of conformance with RGs. The staff finds that for RG 1.7," Control of Combustible Gas Concentrations in Containment," and RG 1.57," Design Limits and Loading Combinations for Metal Primary Reactor Containment System Components," the AP1000 DCD is in accordance with earlier revisions of the RGs. The AP1000 DCD indicates that RG 1.160, "Monitoring the Effectiveness of Maintenance at Nuclear Power Plants," is not applicable to the AP1000 DC and that Section 17.5 of the AP1000 DCD defines the responsibility for a plant maintenance program. RG 1.199, "Anchoring Components and Structural Supports in Concrete," which is identified as another applicable guide in NUREG-0800 Section 3.8, is not described at all in Section 1.9 of the AP1000 DCD.

In RAI-SRP3.8.2-SEB1-02, the staff requested that the applicant indicate whether the design, construction, and inspection of the AP1000 plant are in accordance with the current RGs and whether RG 1.199 was used to meet the NRC's regulatory guidance for the design, evaluation, and QA of anchors (steel embedments).

In a letter dated April 17, 2009, the applicant provided its response to this RAI. The staff's assessment of the response for each RG is discussed below:

<u>RG 1.7</u>

The applicant's response indicated that the current AP1000 certified design is consistent with Revision 3 of RG 1.7 (issued in March 2007). The AP1000 containment design is a passive system, using convective mixing. Design features promote free circulation of the containment atmosphere. NUREG-1793 documents an analysis of the effectiveness of the passive mixing.

The staff found that the applicant did not discuss whether the hydrogen generated loads were evaluated in accordance with RG 1.7 for the containment acceptance criteria and RG 1.57 for the applicable load combinations.

<u>RG 1.57</u>

The applicant's response indicated that RG 1.57, Revision 1 (issued in March 2007) endorses ASME Boiler and Pressure Vessel Code (B&PV), Section III, "Rules for Construction of Nuclear Facility Components," Division 1, Subsection NE, "Class MC Components," 2001 Edition with 2003 Addenda and Section XI, "Rules for Inservice Inspection of Nuclear Power Plant Components," 2001 Edition with 2003 Addenda.

The applicant's response also indicated that the CV is designed to meet the requirements of ASME B&PV Code, Section III, 2001 Edition including the 2002 Addenda. The 2003 Addenda did not include any requirements that impact the design of the CV described in the AP1000 DCD. There are only two changes (which are in Subsection NE-5000, "Examination") and they are related to the examination of the welds and do not impact the design. Therefore, the applicant concluded that the CV design is in conformance with this RG.

Since the response did not discuss the regulatory positions in RG 1.57, the applicant was requested to specifically confirm whether all of the regulatory positions presented in RG 1.57, Revision 1, have been satisfied for the AP1000 plant.

<u>RG 1.199</u>

The response indicated that RG 1.199, Revision 0, was issued in November 2003, to provide guidance to licensees and applicants on methods acceptable to the staff for complying with the NRC's regulations in the design, evaluation, and QA of anchors (steel embedments) used for component and structural supports on concrete structures. As a result of studies and tests performed, questions were raised regarding the design methodology used in Appendix B to American Concrete Institute (ACI)-349-80, "Code Requirements for Nuclear Safety-Related Concrete Structures and Commentary," 1980. After an extensive review of available test data, the ACI 349 Code committee issued a revision to ACI 349, Appendix B in February 2001.

RG 1.199 generally endorses Appendix B to ACI 349-01, with exceptions in the area of load combinations.

– The AP1000 NI concrete structures are designed to meet the requirements of the ACI 349-01 Code, including Appendix B on the design of anchors in concrete.

– Following the release of this RG, the load combinations used in the design of NI concrete structures were reviewed and approved by the NRC in the AP1000 DC for the HR sites.

The attached table to the RAI response provided itemized conformance with the regulatory positions of this RG.

In the RAI response above, the applicant did not provide any information on the provisions in RG 1.160 (10 CFR 50.65, "Maintenance Rule").

In the audit conducted during the week of May 4, 2009, the staff discussed with the applicant all the missing information associated with the above key RGs. In a letter dated September 29, 2009, the applicant transmitted a revised RAI response, which provided additional information. The staff reviewed the response and determined that it did not fully address all of the concerns related to the RGs. Therefore, the applicant was requested to address the following remaining items:

1. Explain whether the regulatory positions in RG 1.7, Revision 3 and RG 1.57, Revision 1, related to containment structural integrity under the hydrogen generated pressure loads, were satisfied or provide justification for the use of alternate methods.

2. Explain whether the regulatory positions in RG 1.57, Revision 1, related to the design limits and load combinations, were met.

3. Document in the AP1000 DCD the testing and inservice surveillance programs for plant structures. Monitoring and maintenance criteria are identified in NUREG-0800 Sections 3.8.1 through 3.8.5. With the exception of containments, each of these sections identifies that RG 1.160 is applicable. Therefore, confirm that RG 1.160 is applicable for the maintenance of structures at the plant and confirm that it will be followed when implementing 10 CFR 50.65. Also, revise the AP1000 DCD to reflect the applicability of RG 1.160, Revision 2. The performance of inservice inspection of containment is required by 10 CFR 50.55a, “Codes and standards,” and ASME B&PV Code, Section XI, “Rules for Inservice Inspection of Nuclear Power Plant Components.

4. Revise the AP1000 DCD to indicate that RG 1.199 (2003) is applicable for anchoring components and structural supports in concrete for the AP1000 plant.

In response to the above requests, the applicant’s letters dated July 2, and August 25, 2010, indicate that the AP1000 CV design is consistent with the guidance of RG 1.7, Revision 3, and RG 1.57, Revision 1. Details of the methods used to address the hydrogen generated loads, load combinations, and design limits for containment design are presented in the response to RAI-SRP3.8.2-SEB1-03. Since the design of the CV is consistent with these two RGs, the staff finds that Items 1 and 2 identified above have been adequately addressed.

To address the inservice inspection of plant structures, the applicant proposed to revise the text in AP1000 DCD Sections 3.8.3, 3.8.4, 3.8.5 and 3.8.6, and in AP1000 DCD Tables 1.8-2 and 1.9-1, to indicate that the COL applicant is responsible for establishing a structures inspection program consistent with the maintenance rule in 10 CFR 50.65 and the guidance provided in RG 1.160. This addresses the inservice testing, inspection, or special maintenance requirements for the seismic Category I and seismic Category II structures. Since the AP1000 DCD will be revised to identify the requirements for the COL applicants to develop the inservice inspection and maintenance program for structures, the staff concludes that Item 3 has been adequately addressed. The staff’s evaluation of the inservice inspection requirements for containment is discussed later in Section 3.8.2.6 of this SER.

To address Item 4, the applicant proposed to revise the text in AP1000 DCD Sections 3.8.3, 3.8.4 and 3.8.5, and in AP1000 DCD Table 1.9-1, to indicate that the design of anchorage to concrete is in accordance with ACI 349-01, Appendix B, and is in conformance with RG 1.199, Revision 0. Since the AP1000 DCD will be revised to require that concrete anchors will be designed in accordance with RG 1.199, Revision 0, the staff concludes that Item 4 has been adequately addressed. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue. The staff's evaluation of the inservice inspection requirements for containment is discussed later in Section 3.8.2.6 of this report.

In a subsequent revision to the AP1000 DCD, the applicant made appropriate changes to the DCD text, which resolves the above issues.

3.8.2.3 Loads and Load Combinations

During the review of AP1000 DCD Tier 2, Revision 16, the staff identified in RAI-SRP3.8.2-SEB1-03 a concern that Table 3.8.2-1 does not include several load combinations that are applicable to the CV design. These missing load combinations are described in 10 CFR 50.44, "Combustible gas control for nuclear power reactors"; RG 1.57; RG 1.7; and NUREG-0800 Section 3.8.2.II, Acceptance Criteria 3.B.iii. In a letter dated February 19, 2009, the applicant provided a response to this RAI. The response provided the technical basis for not considering the load combination for post flooding condition and also explained how the loading combination for external pressure due to inadvertent actuation of the fan coolers was considered. Further, the load combination with OBE for fatigue consideration was not required because the conditions specified in the ASME B&PV Code, Section III, Division 1, Subsection NE were satisfied. However, the staff determined that insufficient information was provided to explain the remaining missing load combinations and the external pressure loading imposed on the containment.

In a letter dated February 17, 2010, the applicant provided a revised response to address the remaining questions on the missing load combinations and the question on the correct external pressure to be used for the containment design. Based on the staff's review of this RAI response and the related response to RAI-TR09-08, Revision 4, the staff determined that several items still needed to be addressed. Therefore, in a follow-up RAI, the staff requested that the applicant explain why the load combinations that combine wind load with design pressure load and combine tornado wind load plus external pressure load do not appear in the proposed revision of AP1000 DCD Table 3.8.2-1. Also, the AP1000 DCD table should identify the values for the different pressures and the corresponding temperatures inside and outside containment that are used in each of these load combinations. In addition, the applicant was requested to clarify the response given regarding the hydrogen generated load evaluations for containment. These clarifications are needed to ensure that the applicable loads and load combinations described in 10 CFR 50.44; RGs 1.57 and 1.7; and NUREG-0800 Section 3.8.2, were considered.

In response to the above requests, the applicant's letters dated July 2, and August 25, 2010, indicate that the design wind load is small, within the operating pressure of the containment, which ranges from -1.38 to 6.89 kPag (-0.2 to 1.0 pounds per square inch gauge (psig)). This occurs because the shield building, which surrounds the containment, has limited openings in the vent area at the top of the cylindrical shield building wall. Therefore, the load combination that combines design wind load plus internal design pressure of 406.8 kPag (59 psig) is not included in Table 3.8.2-1. For the load combination of tornado wind load plus external pressure, the RAI response indicates that the effects of the tornado wind load for the AP1000 containment reduces the external pressure. Therefore, there is no need to consider this load combination. The staff finds that the RAI response for these two load combinations is acceptable because the effect of the wind load is considered to be negligible and the tornado load reduces the effect of the containment external pressure load.

For the definitions of the different pressures and corresponding temperatures inside and outside containment that are used in the load combinations presented in AP1000 DCD Table 3.8.2-1, the RAI response indicates that they are presented in the response to RAI-TR09-08, Revision 5. The staff confirmed that the four different pressures and temperatures are defined in the response to RAI-TR09-08. The adequacy of these pressure and temperatures is evaluated separately under the staff's assessment of RAI-TR09-08.

The RAI response provided clarifications and also proposed to make revisions in the AP1000 DCD to explain how the hydrogen generated pressure and hydrogen burn loadings were considered in accordance with 10 CFR 50.44. In addition, as noted in the staff's evaluation of RAI-SRP3.8.2-SEB1-02 above, the design of the AP1000 CV for hydrogen generated loadings is consistent with the guidance of RG 1.7, Revision 3, and RG 1.57, Revision 1. The staff finds that the information provided and the proposed changes to the AP1000 DCD are acceptable because the design is performed in accordance with 10 CFR 50.44, applicable RGs, and is consistent with NUREG-0800 Section 3.8.2. In a subsequent revision to the AP1000 DCD, the applicant made appropriate changes to the DCD text and tables, which resolve this issue.

3.8.2.4 Design and Analysis Procedures

During the review of AP1000 DCD Tier 2, Revision 16, the staff identified that Section 3.8.2.4.1.2, which describes the local analyses for the penetrations of the steel containment, has been revised from its previous revision. The revision relies on the use of a new 3D finite element model of the entire containment, which includes the penetrations rather than using separate localized models of the penetrations. In RAI-SRP3.8.2-SEB1-04, the staff requested that the applicant provide a more detailed explanation of: (1) the new 3D finite element model of the entire containment described in Section 3.8.2.4.1.2 used for the local evaluation near penetrations; and (2) the axisymmetric model described in Section 3.8.2.4.1.1 and Appendix 3G, which is used for the analysis of the containment in regions away from penetrations. This information is needed to ensure that the revised model of the entire containment, developed for local analysis of penetrations, is adequate to capture the containment response.

In a letter dated April 29, 2009, and in a subsequent letter dated July 7, 2009, the applicant provided information to address this RAI. The staff reviewed this response and concluded that the applicant has provided a description of the 3D finite element model of the entire containment, and a description of the finite element model of the containment used for the local evaluation near large penetrations. The response indicated that more detailed information is presented in TR-09. The staff's evaluation of TR-09 is presented below. The staff reviewed the RAI response and concluded that the analysis approach is consistent with industry methods and guidance presented in NUREG-0800 Sections 3.7 and 3.8. In the July 7, 2009, RAI response, the applicant proposed several changes to be included in a future revision of the AP1000 DCD. In a subsequent revision to the AP1000 DCD, the applicant made appropriate changes to the DCD text, which resolves this issue.

Containment Penetrations Technical Report TR-09

The applicant submitted TR-09 (current version is Revision 5, March 2011) to summarize the design of CV reinforcement adjacent to large penetrations. The design of the penetrations in the TR-09 report also considers the results of the seismic evaluations conducted to extend the applicability of the AP1000 CV design to soil sites.

The applicant completed the design and analyses of the CV reinforcement for the large penetrations (two equipment hatches and two airlocks), and submitted the evaluation to the NRC as TR-09, Revision 0 in May 2006. However, the main steam and feedwater penetrations were not addressed in TR-09, Revision 0. In RAI-TR09-01, the staff requested that the applicant include the design and analysis details for the main steam and feedwater penetrations in TR-09.

In a letter dated September 5, 2007, the applicant indicated that Section 2.6 had been added to Revision 1 of TR-09, describing the design of the main steam and feedwater penetration reinforcement, and that the penetration assemblies are connected to the vessel by expansion bellows, thus preventing significant cyclic thermal and mechanical loading in the SCV.

Subsequently, during the October 2007 audit, the applicant provided report number APP-MV50-S2C-012, Revision 2, "Design of Containment Vessel Penetration Reinforcement," which included the detailed design calculations for the main steam and feedwater penetration reinforcement. The staff later reviewed this report and found that it adequately described the design of penetration reinforcement for the main steam, feedwater, and the start-up feedwater penetrations. During the October 2007 audit, the staff raised a concern that TR-09, Revision 1, did not address the fuel transfer tube penetration. The staff requested that the applicant provide information related to the design of the fuel transfer tube penetration comparable to the level of detail provided for the main steam and feedwater penetrations.

In a letter dated June 4, 2009, the applicant transmitted TR-09, Revision 3, which included the additional section on the design of containment penetration reinforcement for other penetrations, including the fuel transfer tube penetration. The staff reviewed TR-09, Revision 3 and concluded that sufficient information was provided to describe the design procedure for the other mechanical and electrical penetration reinforcements. The staff noted that the design procedure is consistent with accepted analytical methods for design of containment penetration reinforcements and is in accordance with the provisions of the ASME B&PV Code, Section III, Subsection NE, for metal containments.

On the basis that the applicant completed and documented the design of the major containment penetrations and documented the design procedure for the other containment penetrations, in accordance with the provisions of the ASME B&PV Code, Section III, Subsection NE, for metal containments, the staff considers RAI-TR09-01 resolved.

In TR-09, Revision 0, the applicant attempted to justify the use of seismic loading derived from the initial HR site condition for the design/analysis of containment penetrations for soil sites. However, the information provided was insufficient for the staff to conduct its review for the extension of the evaluation for soil sites. Therefore, in RAI-TR09-02, the staff requested that the applicant provide the necessary quantitative information in TR-09 to specifically demonstrate the design adequacy of containment penetrations for all soil conditions.

In its response dated September 5, 2007, the applicant indicated that with the exception of the large penetrations (equipment hatches and personnel airlocks), the CV design was completed for the HR site condition and was reviewed by the NRC during the HR DC, and that this design has not changed. The applicant referenced comparisons included in TR-09, Revision 1, demonstrating that the HR design forces are still applicable. The staff reviewed Figure 2-10 of TR-09, Revision 1, which compares member force and moment results from the dynamic analyses for all soil cases, to the certified HR design member forces and moments. The HR design values envelop the corresponding values for all soil sites. On this basis, the staff concluded that the overall design of the CV, based on the HR site, is also acceptable for the range of soil sites evaluated by the applicant. Therefore, RAI-TR09-02 is resolved.

Since design details for the penetrations included in TR-09, Revision 0, were not provided, the staff requested in RAI-TR09-03 that the applicant include appropriate design information (geometry, material and material properties, dimensions and wall thicknesses) for each penetration in TR-09, and specify the ASME B&PV Code, Class MC jurisdictional boundaries for each penetration.

In a letter dated September 5, 2007, the applicant indicated that typical design information for the penetrations is provided in the AP1000 DCD. This material has now been included in Appendix A of the TR-09 report. Penetration assemblies, such as those shown in the upper figure on AP1000 DCD Figure 3.8.2-4 (Sheet 4 of 6), are ASME B&PV Code Class 2. Expansion bellows and guard pipes are ASME B&PV Code Class 2 or Class MC. The penetration assemblies are welded to sleeves that are ASME B&PV Code Class MC. Process piping welded directly to the vessel, such as shown in the lower figure in AP1000 DCD Figure 3.8.2-4 (Sheet 4 of 6), is ASME B&PV Code Class 2.

The material of construction is SA738 Grade B for the vessel shell, insert plates and nozzle necks of penetrations with inside diameters greater than 60.96 cm (24 in). For penetrations less than 60.96 cm (24 in) inside diameter and greater than 5.08 cm (2 in) nominal diameter, forgings of SA350 LF2 material are used for the nozzle neck.

Other design requirements for the mechanical penetrations, as stated in the applicant's letter dated September 5, 2007, are as follows:

- Design and construction of the process piping follow the ASME B&PV Code, Section III, Subsection NC. Design and construction of the remaining portions follow the ASME B&PV Code, Section III, Subsection NE. The boundary of jurisdiction is according to the ASME B&PV Code, Section III, Subsection NE.

- Penetrations are designed to maintain containment integrity under design basis accident conditions, including pressure, temperature, and radiation.

- Guard pipe assemblies for high-energy piping in the containment annulus region between the containment shell and shield building that are part of the containment boundary are designed according to the rules of Class MC, Subsection NE, of the ASME B&PV Code.

- Bellows are stainless steel or nickel alloy and are designed to accommodate axial and lateral displacements between the piping and the CV. These displacements include thermal growth of the main steam and feedwater piping during plant operation, relative seismic movements, and containment accident and testing conditions. Cover plates are provided to protect the bellows from foreign objects during construction and operation. These cover plates are removable to permit inservice inspection.

The staff finds that the applicant provided design details sufficient to enable the staff to proceed with its review of the penetrations; therefore, RAI-TR09-03 is resolved.

Based on the review of TR-09, Revision 0, the staff noted that there was insufficient description of the load cases analyzed. Therefore, in RAI-TR09-05, the staff requested that the applicant describe the loads analyzed and how they were combined, and whether the containment post-loss-of-coolant accident (post-LOCA) flooding load was included in the load combinations.

In a letter dated September 5, 2007, the applicant indicated that Section 2.3 of TR-09 had been revised to describe the individual loads and their combinations; and that the post-LOCA flooding event is not considered in the load combination because it is enveloped by other design load combinations. During the October 2007 audit, the staff found that the load combinations in the AP1000 DCD and in the Containment Vessel Design Report (APP-MV50-S3R-003) are the same, but the load combinations listed in TR-09 are different. The staff requested that the applicant explain the differences or demonstrate that they are all consistent.

The adequacy of the containment load combinations is also addressed under RAI-SRP3.8.2-SEB1-03, which is evaluated in Section 3.8.2.3 of this SER. In a subsequent revision to TR-09, the applicant incorporated appropriate changes to the report text and table, which resolve the issues.

There were no results presented in TR-09, Revision 0, for buckling analyses of the containment. Therefore, in RAI-TR09-07, the staff requested that the applicant include in TR-09, Revision 0, a detailed description of buckling analysis and results.

In a letter dated September 5, 2007, the applicant indicated that Section 2.4.2.2 had been added to TR-09, Revision 1, to provide the requested information. During the May 19-23, 2008 audit, the staff reviewed calculation APP-MV50-S2C-010, Revision 0, “3D Model - Analysis of Large Penetrations,” and concluded that the buckling analyses were appropriately considered and that the calculated stresses were less than the acceptance limits. Therefore, RAI-TR09-07 is resolved.

The staff noted that AP1000 DCD, Revision 15, as well as AP1000 DCD, Revisions 16 and 17, indicate that the design external pressure is 2.9 pounds per square inch differential (psid). However, in TR-09, the applicant presented a justification for reducing the design external pressure from 2.9 psid to 0.9 psid, and stated that an estimate of the external pressure was provided in the response to DSER OI 3.8.2.1-1. Therefore, in RAI-TR09-08, the staff requested that the applicant demonstrate the design adequacy of the containment penetrations and the steel CV for a design external pressure of 2.9 psid.

In its Revision 2 response to RAI-SRP6.2.1.1-SPCV-07, dated December 14, 2009, the applicant stated that the design external pressure of 2.9 psid is used in the design load combination and the lower external pressure of 0.9 psid is a more credible external pressure used to define Service Level A and D load combinations. Because the Service Level A load combinations include thermal loads, the applicant evaluated different events at various external temperature conditions to demonstrate that 0.9 psid bounds the external pressure excursions that could occur on a cold day.

In a letter dated February 17, 2010, the applicant provided information to address questions raised regarding the temperature and external pressure loads used for design of the containment. The staff’s review of this information determined that additional information was required. In a follow-up to RAI-TR09-08, the staff requested that the applicant provide the following:

a. In Table 1 of the RAI response, the results show a trend of higher external pressure as the outside temperature increases. However, the analysis is limited to ≤ 19 degrees F, for which the external pressure is 0.98 psi. Provide the technical basis for limiting the analysis to ≤ 19 degrees F for the outside temperature.

b. After reviewing the RAI response and the proposed revision to AP1000 DCD Table 3.8.2-1, it is not clear what temperature gradient/external pressure combination is used in the Service Level A load combination notated by Footnotes 3 and 5. Describe in detail, the pressure and temperature condition used in this Service Level A load combination, and the technical basis for concluding it is the worst case. Include this information in AP1000 DCD Section 3.8.2 and in TR-09. Revise AP1000 DCD Table 3.8.2-1 footnotes to reference AP1000 DCD Section 3.8.2 that describes this loading condition.

c. The staff noted a number of inconsistencies between proposed AP1000 DCD Table 3.8.2-1 and the latest TR-09 Table 2-4, both of which identify the applicable load combinations for design of the containment structure. Revise these tables so that they are consistent, or provide the technical basis for the inconsistencies.

d. The maximum external pressure is no longer listed as 0.9 psi in the proposed revision to AP1000 DCD Table 3.8.2-1. For consistency, ensure that all references to the 0.9 psi external pressure in both the AP1000 DCD and TR-09 are appropriately revised.

Based on the applicant's letter dated July 30, 2010, much of the transient information provided previously was revised because a containment vacuum relief system was added with an actuation point of 5.5 kPa (0.8 psid). Based on the external pressure that the containment vacuum relief system can mitigate, a conservative external design pressure is defined as 11.7 kPa (1.7 psid). This design external pressure is combined with a coincident temperature of -40 °C (-40 °F) outside air temperature, which corresponds to -28 °C (-18.5 °F) for the CV shell region that is not insulated and 21.1 °C (70 °F) for the shell region that is insulated from the cold outside air. Additional information on the appropriate temperatures for this external pressure loading condition is discussed under RAI-SRP3.8.2-CIB1-01 in Section 3.8.2.5 of this SER. The applicant's July 30, 2010, letter provided the proposed changes to AP1000 DCD Section 3.8.2 related to the revised pressures and temperatures for design of the containment. The letter also indicated that TR-09 will be revised to be consistent with the AP1000 DCD changes. The staff's review of the letter concluded that the information provided in the response described the various pressure and temperature loadings to be used for design of the containment, and thus, addressed all of the staff's prior concerns for defining the pressure and temperature loads on the containment. In subsequent revisions to the AP1000 DCD and TR-09, the applicant made appropriate changes to the DCD and the report text and tables, which resolve this issue.

3.8.2.5 Materials, Quality Control, and Special Construction Techniques

In Revision 16 to the AP1000 DCD, the applicant proposed changes to the supplementary requirements of the CV shell material specification. This resulted in changes to the AP1000 DCD in Section 3.8.2.6. In a letter dated May 11, 2007, the applicant submitted TR-113, Revision 0 to provide the technical justification for the proposed changes.

Revision 15 to the AP1000 DCD, Section 3.8.2.6 specified the basic CV material as SA-738, Grade B plate. The procurement specification for this plate material is required to include supplemental requirements S17, "Vacuum Carbon-Deoxidized Steel" and S20 "Maximum

Carbon Equivalent for Weldability." The applicant has investigated the availability of SA-738, Grade B plate material (with S17 supplementary requirement) in the United States as well as in all the large, steel-producing countries in the world. The investigation determined that steel producing mills do not use an S17 process, but, rather, use a supplementary requirement S1 process to get similar high-quality, vacuum-degassed steel.

The applicant proposed to correct the AP1000 DCD in Revision 16 to specify supplementary requirement S1 instead of the currently specified supplementary requirement S17. The applicant provided the following technical justification in support of the proposed change to AP1000 DCD Section 3.8.2.6.

The use of a vacuum carbon-deoxidized (VCD) process in steel production typically applies to certain grades of chromium-molybdenum (Cr-Mo) steels where carbon contents are lower and reduced silicon content is beneficial. The VCD process allows oxygen and carbon to react in the molten steel and evolve as carbon monoxide, which is drawn off by the vacuum. While under vacuum, other gases, such as hydrogen and nitrogen, also tend to be removed from the steel. Reducing the oxygen content by VCD reduces the need for the addition of other deoxidizing additions such as silicon or aluminum. Steels treated by VCD have a specified silicon content of 0.12 percent maximum that is lower than the normally specified range of silicon content. This process is beneficial in Cr-Mo steels that are susceptible to temper embrittlement during elevated-temperature service. Silicon is one of the impurity elements that contribute to the loss of toughness. By reducing the silicon content of the steel the tendency for temper embrittlement is reduced. The use of the VCD process for vacuum degassing of SA-738 plate material was discussed with a metallurgist from a large, domestic-steel plate producer. The steel producers in the United States typically do not use VCD for plate materials like SA-738. For this reason, requiring supplementary requirement S17 to be used for the production of SA-738 plate material is somewhat of an anomaly. Therefore, the supplementary requirement S1, "Vacuum Treatment," is more appropriate for this type of material because S1 requires the steel to be made by a process, which includes vacuum degassing while molten by a suitable practice selected by the steel manufacturer or purchaser.

In addition, Revision 16 to the AP1000 DCD, Section 3.8.2.6 was changed to specify the lowest service temperature of -28 °C (-18.5 °F) instead of -26.1 °C (-15 °F), which was previously stated in Revision 15 of the AP1000 DCD. TR-113 did not specify the change to the service temperature nor provide any justification for this change in service temperature as required by 10 CFR 52.63(a)(1).

The staff reviewed the applicant's request to revise AP1000 DCD, Section 3.8.2.6 concerning the supplementary requirements of the CV shell material specification and found it acceptable because of following reasons.

The SA-738, Grade B plate material was approved for use in metal CV construction in ASME Code Case N-655, Section III, in February 2002. This plate material was also incorporated into Table 1A of Section II, Part D in the 2002 Addenda to the 2001 Edition of the ASME B&PV Code. The NRC conditionally accepted ASME Code Case N-655 in RG 1.84, "Design, Fabrication, and Materials Code Case Acceptability, ASME Section III," Revision 33 in August 2005. The conditions that the NRC placed on the use of SA-738 plate material were to specify the use of supplementary requirements S17 and S20 when using SA-738 material for CV construction. The two conditions were needed to ensure adequate material properties and weldability of the CV material. The ASME Code, Section III, exempts SA-738, Grade B, material up to 4.4 cm (1.75 in) of thickness from post-weld, stress-relief heat treatment.

Because the welds in CV material thickness up to 4.4 cm (1.75 in) thick will not be stress-relieved, higher residual stresses will be present in the welds. Also, the material will likely be procured in the quenched and tempered condition. Welding will reduce the impact properties of the material in the heat affected zone. Requiring the use of vacuum degassed steel will ensure adequate material properties because nonmetallic inclusions, such as oxides and silicates will be minimized as a result of the vacuum degassing of the steel. S17 supplementary requirement was specified to accomplish the vacuum degassing of the steel. Requiring supplementary requirement S20 and a carbon equivalent weldability check will ensure that the steel is readily weldable.

The staff specified the use of S17 for SA-738 material because at the time of the review of ASME Code Case N-655, S17 was the only requirement clearly listed in the specification that would provide for vacuum degassing of steel. Supplementary requirement S1 was also available for SA-738 plate material; however, S1 is listed in SA-20, "General Requirements for Steel Plates for Pressure Vessels," which is referenced in the SA-738 specification. Therefore, in order to impose the S1 requirement in the CV, the designer would have to specify two specifications instead of one. The purpose of the staff's condition was to specify the use of vacuum degassed steel. Imposing an S1 supplementary requirement would accomplish this goal. Furthermore, at the time of approval of ASME Code Case N-655 neither the staff nor the applicant was aware that the steel producers had limited S17 to the production of Cr-Mo steels. Since the discovery of this situation, the ASME Code has approved a revision to the ASME Code Case N-655-1, which correctly specifies the use of S1 and S20 supplementary requirements for the use of SA-738 plate material. On this basis, the staff concludes that the proposed revision to AP1000 DCD, Section 3.8.2.6 to specify supplementary requirement S1 meets the requirements of 10 CFR 50.55a and the ASME Code, Section III, and is acceptable.

In regard to the service temperature of the CV, Tier 2, Section 3.8.2.6 of the AP1000 DCD, describes the materials used to fabricate the CV. The material selected satisfies the lowest service metal temperature requirement, established by analysis for the portion of the vessel exposed to the environment when the ambient air temperature is -40 °C (-40 °F). TR-113, Revision 0, submitted by the applicant in a letter dated May 11, 2007, also revised this section to specify the lowest service temperature of -28.1 °C (-18.5 °F) instead of -26.1 °C (-15 °F), which was previously stated in Revision 15 of the AP1000 DCD. TR-113 did not specify the change to the service temperature nor provide any justification for this change in service temperature as required by 10 CFR 52.63(a)(1). In NUREG-1793, Section 3.8.2.6, the staff approved -26.1 °C (-15 °F) as the lowest service temperature based on the staff's review of the applicant's calculation APP-PCS-M3C-002, Revision 1, "AP1000 Containment Shell Minimum Service Temperature." Therefore, the staff requested that the applicant provide its reason and justification for the change in minimum service temperature of the CV in accordance with 10 CFR 52.63(a)(1), along with the analysis that supports the new service temperature proposed in Revision 16 of the AP1000 DCD. This was previously addressed in RAI-SRP3.8.2-CIB1-01.

In a letter dated July 22, 2008, the applicant stated that an additional scenario was postulated for the CV shell analysis, which determined that the CV will be subjected to a service metal temperature of -28.1 °C (-18.5 °F). This evaluation postulated that an SSE event occurred in conjunction with -40 °C (-40 °F) outside temperature and inadvertent actuation of active containment cooling. APP-GW-GLR-005 (TR-09) only described the analysis, and inadvertently did not include the corresponding service metal temperature.

Since TR-09 did not include the analysis or the service metal temperature, the staff could not confirm that -28.1 °C (-18.5 °F) was the lowest service metal temperature of the CV shell, which is fabricated from SA-738 Grade B material. This material must meet the requirements of NE-2000 for fracture toughness (Charpy V-notch test) in the as-welded condition for thicknesses up to and including 4.4 cm (1.75 in), and in the post-weld heat treated condition for thicknesses greater than 4.4 cm (1.75 in). The minimum service temperature is used to determine the testing temperature for the Charpy V-notch tests required by the ASME Code, Section III, Subsections NE 2300 and NE-4300. Previously, the applicant stated in its letter dated April 22, 2003, that the SA-738, Grade B plate material will be procured using the service metal temperature of -26.1 °C (-15 °F) (i.e., -48.3 °C (-55 °F) Charpy V-notch test temperature as required by the ASME Code, Section III, Subsections NE-4335.2(b)(2) and Tables NE-4622.7(b)-1, note (2)(b)(1)) in order to account for degradation during welding of the heat affected zone in the base material. In addition, the applicant stated in a letter dated March 13, 2003, that the previous analysis added a -13.3 °C (8 °F) conservative factor to obtain a minimum service metal temperature of -26.1 °C (-15 °F).

Therefore, the staff required additional information to verify the minimum service metal temperature including the details of the analysis (e.g., calculation methodology, assumptions made, similarities/differences from previous analysis, etc.) to confirm that -28.1 °C (-18.5 °F) is the lowest service metal temperature to ensure that the material will be tested to have adequate toughness for the design and environment the containment shell will experience. The staff also requested clarification of whether the conservative factors described in the applicant's letter dated March 13, 2003, were used in this analysis or provide justification for not including these conservative factors.

In a letter dated May 7, 2009, the applicant stated that the additional information was provided in APP-MV50-Z0C-020, Revision 0. However, the staff requested that the assumptions made along with the similarities/differences from the previous analysis (for Revision 15 of the AP1000 DCD) be addressed. In response to Revision 2 of RAI-SRP3.8.2-CIB1-01, the applicant provided in a letter dated September 17, 2009, the assumptions and differences between the analyses. The applicant stated that the original analysis for -26.1 °C (-15 °F) minimum service metal temperature in Revision 15 of the AP1000 DCD was performed by a hand calculation using a simple radial heat balance model, and then added an -13.3 °C (8 °F) conservatism factor. The minimum service metal temperature of -28.1 °C (-18.5 °F) was determined by a WGOTHIC computer code, using a free/forced convection model. This model calculated a higher heat transfer coefficient; thereby, resulting in a lower minimum service metal temperature (-28.1 °C (-18.5 °F) versus -26.1 °C (-15 °F)). The staff notes that WGOTHIC is currently used in other pressure and temperature determinations for operating reactors. In addition, WGOTHIC has its own inherent conservatisms within the computer code. Therefore, the staff determined that the use of WGOTHIC computer code is valid in determining the minimum service metal temperature for the steel containment.

In a letter dated February 17, 2010, the applicant performed a new WGOTHIC analysis documented in APP-MV50-Z0C-039, Revision 0, which used an outside temperature at -40 °C (-40 °F) and -34.4 °C (-30 °F). However, the staff notes that this analysis was not a bounding case, since it used different assumptions for the wind speeds at these two temperatures based on Duluth, Minnesota, meteorological data. The Duluth data documented the wind speed at -34.4 °C (-30 °F) to be faster than at -40 °C (-40 °F). Using these temperatures and wind speeds, the -34.4 °C (-30 °F) case resulted in a higher velocity through the annulus between the containment and air baffle, and thereby, a greater heat transfer coefficient. Therefore, based on the Duluth, Minnesota, weather records, the applicant's analysis determined that the -34.4 °C

(-30 °F) outside temperature condition resulted in minimum service metal temperature of -8.1 °C (-0.61 °F) versus a minimum service metal temperature of -13.8 °C (7.18 °F) for an outside temperature of -40 °C (-40 °F). Since the analysis in APP-MV50-Z0C-039, Revision 0 was not a bounding case, the staff requested that a bounding analysis be performed using an outside temperature of -40 °C (-40 °F) and a maximum wind speed of 77 km/h (48 mph), used in previous calculations, or provide justification for the validity of the Duluth temperature/wind speed data along with a sensitivity study.

In a letter dated May 10, 2010, the applicant provided an analysis for the loss of alternating current (ac) power (LOAC) transient using an outside temperature of -40 °C (-40 °F) with a corresponding wind speed of 48 mph, which produced a minimum service metal temperature of -27.2 °C (-16.91 °F), which is bounded by the -28.1 °C (-18.5 °F) minimum service metal temperature in the AP1000 DCD. The staff notes that the -8.4 °C (16.91 °F) temperature included a factor to compensate for any temperature uncertainty in the calculation near the air baffle plate. The bounding case used the LOAC transient in Case 11 of APP-MV50-ZOC-039, Revision 0, by adjusting the wind speed to 77 km/h (48 mph). Based on the June 18, 2010, letter, the applicant stated that the LOAC transient was the limiting event since the inadvertent activation of the containment fan cooler event is no longer credible because the fan coolers are operational. Therefore, the staff considers this to be a bounding condition in determining the minimum service metal temperature and that the -28.1 °C (-18.5 °F) temperature in the AP1000 DCD is supported by an appropriate analysis. The staff notes that in the letter dated May 10, 2010, the applicant provided a bounding calculation in lieu of justifying the current data in APP-MV50-ZOC-039, Revision 0. However, the applicant did not revise APP-MV50-ZOC-039, Revision 0, to reflect this bounding calculation, and assumes that the results depicted in APP-MV50-ZOC-039, Revision 0, are the result of record for the AP1000 DCD. The staff requests that the applicant revise APP-MV50-ZOC-039, Revision 0, to reference this bounding calculation, since the bounding case was provided in lieu of justifying the current data in APP-MV50-ZOC-039, Revision 0. The staff identifies this as Open Item OI-SRP3.8.2-CIB1-01.

In a letter dated July 9, 2010, the applicant stated that the bounding case provided in the letter dated May 10, 2010, would be incorporated into APP-MV50-ZOC-039. In addition, the applicant stated in letters dated July 30, 2010, and August 16, 2010, that the addition of a vacuum relief system does not invalidate APP-MV50-ZOC-039 for the determination of the minimum service metal temperature. The staff agrees that the bounding calculation for the minimum service metal temperature in APP-MV50-ZOC-039, as modified by letter dated July 9, 2010, is still applicable, since it is calculates the lowest possible service metal temperature corresponding with an outside temperature of -40 °C (-40 °F). This resolves Open Item OI-SRP3.8.2-CIB1-01.

However, the staff notes that Revision 17 inadvertently revised Section 3.8.2.6 of the AP1000 DCD to specify a minimum service metal temperature of -26.1 °C (-15 °F). In a letter dated June 18, 2010, the applicant proposed to change the minimum service metal temperature back to -28.1 °C (-18.5 °F), which is supported by the bounding analysis. Therefore, the staff finds this proposed change acceptable. In a subsequent revision to the AP1000 DCD, the applicant made appropriate changes to the DCD text, which resolves this issue.

3.8.2.6 Testing and Inservice Inspection Requirements

During the review of AP1000 DCD Tier 2, Revision 16, the staff identified that Section 3.8.2.7 had been revised to remove the requirement that the inservice inspection of the CV would be performed in accordance with the ASME Code, Section XI, Subsection IWE, and that this is the responsibility of the COL applicant. In accordance with the guidance presented in NUREG-0800 Section 3.8.2, this information should be provided by the applicant for review by the staff. Therefore, the staff requested, in RAI-SRP3.8.2-SEB1-05, that the applicant include in the AP1000 DCD information that describes how the AP1000 containment complies with the 10 CFR 50.55a requirements and the ASME Code, Section XI for the preservice and inservice examination of the containment.

In a letter dated February 27, 2009, the applicant indicated that Section 3.8.2.7 of the AP1000 DCD would be revised to reference Section 6.6, which identifies that the COL applicant will perform inservice inspection of the containment according to the ASME Code, Section XI. Section 6.6.9.1 includes a COL information item for the COL applicant to prepare preservice and inservice inspection programs for the ASME Code systems and components.

Section 6.6 was revised in the AP1000 DCD, Revision 17 to specifically include ASME Code Class MC components. The applicant indicated that Sections 6.6.9.1 and 6.6.9.2 will be revised to also specifically include Class MC systems and components.

The staff concludes that the RAI response is acceptable because: (1) the applicant will revise AP1000 DCD Section 3.8.2.7 to reference Section 6.6, which indicates that inspection of the containment is performed in accordance with the ASME Code, Section XI and 10 CFR 50.55a; (2) AP1000 DCD Section 6.6 indicates that COL applicants will prepare the inspection program for the containment; and (3) the applicant will revise AP1000 DCD Sections 6.6.9.1 and 6.6.9.2 to require the preparation of an inspection program for Class MC (containment) systems and components. In a subsequent revision to the AP1000 DCD, the applicant made appropriate changes to the DCD text, which resolves this issue.

3.8.2.7 Conclusion

In NUREG-1793 and its Supplement 1, the staff documented its conclusions that the AP1000 design and the DCD (up to and including Revision 15 of the AP1000 DCD) were acceptable and that the applicant's application for the DC met the requirements of Subpart B to 10 CFR Part 52 that are applicable and technically relevant to the AP1000 standard plant design.

The staff reviewed the applicant's proposed changes to the AP1000 containment as documented in AP1000 DCD, Revision 19, against the relevant acceptance criteria as listed above and in NUREG-0800 Section 3.8.2.

The staff concludes that the AP1000 DCD Section 3.8.2.5 revisions proposed by the applicant meet the requirements of 10 CFR 50.55a and the ASME Code, Section III, applicable RGs, and NUREG-0800 Section 3.8.2 and, therefore, are acceptable.

The staff concludes that design of the containment continues to meet all applicable acceptance criteria. In summary, based on the above discussions, the staff finds that the design of the AP1000 containment is acceptable.

The changes to the DCD implementing the revised AP1000 design meet the standards of Criterion vii of 10 CFR 52.63(a)(1) in that they contribute to increased standardization; without these DCD changes each applicant would have to address these issues individually.

3.8.3 Concrete and Steel Containment Internal Structures

Using the regulatory guidance in NUREG-0800 Section 3.8.3, "Concrete and Steel Internal Structures of Steel or Concrete Containments," the staff reviewed: (1) description of the internal structures; (2) applicable codes, standards, and specifications; (3) loads and loading combinations; (4) design and analysis procedures; (5) structural acceptance criteria; (6) materials, quality control, and special construction techniques; (7) testing and inservice surveillance programs; (8) ITAAC; and (9) COL action items and certification requirements and restrictions. Not all of these areas were applicable to the review of the proposed changes to AP1000 Section 3.8.3 and the following SER sections provide the staff's evaluation for the relevant areas.

In its previous evaluations of AP1000 DCD, Section 3.8.3, the staff identified acceptance criteria based on the design meeting the relevant requirements in 10 CFR 50.55a; 10 CFR Part 50, Appendix A, GDC 1, GDC 2, GDC 4, and GDC 50. The staff found that the design of the AP1000 CISs was in compliance with these requirements, as referenced in NUREG-0800 Section 3.8.3 and determined that the design of the AP1000 CISs, as documented in AP1000 DCD, Revision 15, was acceptable because the design conformed to all applicable acceptance criteria.

In AP1000 DCD, Revisions 16 and 17, the applicant made the following changes to Section 3.8.3 of the certified design:

1. As a result of the extension of the AP1000 design from just hard rock sites to sites ranging from soft soils to hard rock, various seismic re-analyses of the NI structures were performed. Whereas the original design relied upon the equivalent static method of analysis for seismic loading, the re-analyses included the additional use of response spectrum and time history methods of analysis. In DCD Revision 16, Table 3.8.3-2 was revised to include the use of the response spectrum analysis for the seismic analysis of the containment internal structures. Time history analyses were used to determine maximum soil bearing pressures under the NI and, subsequent to the submittal of DCD Revision 17, to perform an updated NI stability evaluation.

2. In DCD Revision 16, the applicant removed Section 3.8.3.4.1.2 - Stiffness Assumptions for Global Seismic Analyses in the previous certified DCD. This section discussed the stiffness properties used in the seismic analyses of the containment internal structures and the auxiliary building modules. Reference was made to DCD Table 3.8.3-1, which contained the various stiffness cases for the concrete filled steel modules used for structures inside containment and the auxiliary building. This deletion of the prior text in Section 3.8.3.4.1.2 shifted the text in the sections that followed Section 3.8.3.4.1.2 (i.e., prior Section 3.8.3.4.1.3 became Section 3.8.3.4.1.2 and prior Section 3.8.3.4.1.4 became 3.8.3.4.1.3).

3. In DCD Revision 16, the applicant revised Section 3.8.3.5.7 - Design Summary Report. DCD Revision 15 indicated that the results of the evaluation would be documented in an as-built report by the Combined License applicant. In DCD Revision 16, this was revised to state that, "The results of the evaluation will be documented in an as-built summary report." Thus the phrase "by the Combined License applicant" was removed.

4. In DCD Revision 16, the applicant revised Section 3.8.3.5.8 - Design Summary of Critical Sections, in several subsections which describe the design of different

specific critical sections. This set of revisions included changes in the text portion, revisions in a number of the DCD tables, and removal of some Tier 2* information. Some of these revisions referred to Appendix H of the DCD, which is discussed below in item 5.

5. Based on the changes discussed above for DCD Section 3.8.3.5.8, the referenced DCD Appendix 3H - Auxiliary and Shield Building Critical Sections, in both DCD Revisions 16 and 17, had substantial revisions in the text, tables, and figures.

6. In DCD Revisions 16 and 17, the applicant revised Section 3.8.3.6 - Materials, Quality Control, and Special Construction Techniques. The revisions relate to the change in material for the structural modules from Nitronic 33 to Duplex 2101, and relate to the change in the industry standard from NQA-2 to NQA-1 for packaging, shipping, receiving, storage and handling of the structural modules in accordance with industry specification AISC N690.

7. In DCD Revision 17, the applicant revised Section 3.8.3.6.3 - Concrete Placement, regarding how concrete will be placed in the CA01 module inside the containment. The previous phrase in DCD Revision 15, which stated that the concrete is placed in each wall continuously from the bottom to the top was removed, and the description of the concrete placement was revised to state that concrete will be placed either through multiple delivery trunks located along the top of the wall or through windows in the module walls or pumping ports built into the module wall.

8. A new 59.5 m^3 (2100 ft^3) pressurizer is used. It has a smaller length from the outside surface of the lower head to the outside surface of the upper head. This change was made to reduce the seismic response of the pressurizer compartment.

3.8.3.1 Applicable Codes, Standards, and Specifications

During the review of AP1000 DCD Tier 2, Revision 16, the staff noted that Sections 3.8.3.2 and 3.8.4.2 describe the codes, standards, and specifications used for structural components of the AP1000. In view of the extension of the AP1000 design to soil sites, reanalysis for updated seismic spectra, design changes made to structures, and to ensure that the AP1000 meets the safety requirements in current regulatory positions, the staff, in RAI-SRP3.8.3-SEB1-01, requested that the applicant identify whether the AP1000 plant meets industry standard American National Standards Institute/American Institute of Steel Construction (ANSI/AISC)-N690-1994, Supplement 2 (2004) and the more recent versions of the applicable American Welding Society (AWS) standards than are currently listed in AP1000 DCD, Revision 16. These references are cited in the current NUREG-0800, Section 3.8, which was issued subsequent to the license application for the AP1000 DCD, Revision 16.

In the applicant's letters dated April 3, 2009, and October 22, 2009, the applicant stated that the references to AISC-N690-1994 and the other applicable codes, standards and specifications in AP1000 DCD Sections 3.8.3.2 and 3.8.4.2 have not changed from AP1000 DCD, Revision 15 to Revision 17. The applicant indicated that the staff previously accepted the technical basis for concluding that the standards listed in AP1000 DCD Section 3.8, Revision 15 provide sufficient conservatism or equivalent levels of safety. Therefore, the applicant does not intend to evaluate conformance to later editions and revisions of these codes and standards.

Since the staff previously accepted the use of the ANSI/AISC-N690-1994 and AWS standards in the certified design as described in AP1000 DCD, Revision 15 and these standards were considered to be acceptable, subject to certain supplementary requirements as stated in AP1000 DCD Section 3.8, the staff finds that these standards are also acceptable for use in the current design of the AP1000. Therefore, RAI-SRP3.8.3-SEB1-01 is resolved.

3.8.3.2 Analysis Procedures

During the review of the AP1000 DCD Tier 2, Revision 16, the staff noted that the entire Section 3.8.3.4.1.2, "Stiffness Assumptions for Global Seismic Analyses," of the AP1000 DCD, Revision 15 had been deleted. Therefore, in RAI-SRP3.8.3-SEB1-03, the staff requested that the applicant provide a description of the CIS model, the stiffness assumptions used, and the basis for the selection of the stiffness for the CIS and auxiliary building modules.

In a letter dated February 24, 2009, the applicant provided a response, which explained that the description for the model development and analysis for the CIS are provided in AP1000 DCD Section 3.7 and TR-03. As a result of the staff's review of the RAI response, several questions were identified and these items were discussed with the applicant in a conference call on May 12, 2009. The applicant was requested to clarify the information presented in the first three rows of AP1000 DCD Table 3.8-2, regarding the specific models used. In addition, the staff requested that the applicant explain whether the models were local or global and where these analyses were described in the AP1000 DCD, and the basis for selecting the module concrete stiffness values used. During the conference call, the applicant indicated that it would provide a revised RAI response to address these items.

In a letter dated October 19, 2009, the applicant provided some information regarding the stiffness values used; however, the staff determined that further justification was needed regarding the proper stiffness utilization for the modules of the CIS and for the other RC structures. The RAI response indicates that the NI model of concrete structures is based on the gross concrete section stiffness reduced by a factor of 0.8 for the consideration of the effect of concrete cracking as recommended in Table 6-5 of FEMA 356. The staff finds that Table 6-5 of FEMA 356 indicates that the factor of 0.8 is only applicable to flexural rigidity for concrete walls that are uncracked when inspected. For walls that are cracked, the stiffness reduction factor for flexure is 0.5. For shear rigidity, the FEMA table indicates that the stiffness reduction factor is 0.4 for walls that are uncracked and cracked. Therefore, it is not appropriate to reference the FEMA standard as justification for the use of the 0.8 factor. In a follow-up RAI, the applicant was requested to justify the stiffness reduction factor used in the analysis and design of RC structures and the concrete-filled steel members used for the CIS and other structures.

To demonstrate the adequacy of using the 0.8 stiffness reduction factor for the RC and concrete-filled steel members in the seismic analysis of the NI structures, the applicant performed a study. In a letter dated July 30, 2010, the applicant updated its responses to RAI-SRP3.7.1-SEB1-19 and RAI-SRP3.8.3-SEB1-03, and provided comparisons of the [ ] linear and [ ] nonlinear analysis results. The [ ] linear analysis used the [ ] stiffness reduction factor and the [ ] nonlinear analysis used a concrete cracking model, which reflected the concrete stiffness based on the degree of cracking in the finite elements. Both analyses were time-history analyses based on the envelope of the soil and rock profiles. Comparisons were made at the shield building roof elevation, shield building West wall (at grade elevation) and at four other locations in the auxiliary building. The response spectra at these six locations showed a comparison close enough to allow for a conclusion that the [ ] stiffness reduction factor is acceptable.

However, the applicant did not provide [ ] comparisons for the same locations. Since [ ] is the AP1000 design basis code, the staff believes that the [ ] to [ ] comparisons are required to validate model similarity. In an updated response to RAI-SRP3.8.3-SEB1-03, dated September 3, 2010, the applicant provided the requested comparisons between the [ ] and [ ] linear analysis results. This comparison demonstrated similarity between the [ ] and [ ] models. The applicant also provided additional information on the [ ] RC to SC connection modeling approach. This information showed that the response of this [ ] RC/SC connection compared closely with the detailed FEM representation of the RC to SC connection, which included the tie bars, reinforcement, steel plates, and concrete. The RAI response also provided markups to DCD Section 3.8.3 to incorporate the concrete stiffness reduction factor used for the CIS.

On the basis of the results of the studies discussed above, the staff concluded that the approach for addressing concrete cracking is acceptable. The applicant's study using [ ], supported by the correlation of linear results between [ ] and [ ], indicate that a reduced concrete modulus of [ ] is justified for the design-basis analysis of the concrete filled steel modules and RC sections and, therefore, is acceptable. The staff further concluded that the RC/SC connection simulation in the [ ] nonlinear analysis model provides a reasonable representation of the effect of the connection on the overall seismic response and its use is acceptable. In a subsequent revision to the AP1000 DCD, the applicant made appropriate changes to the DCD text and table, which resolve this issue.

3.8.3.3 Design Procedures and Acceptance Criteria

The staff requested, in RAI-SRP3.8.3-SEB1-04, that the applicant address concerns with the design details of the structural module connections to the RC basemat. Section 3.8.3.5.3 of the AP1000 DCD indicates that the steel plate modules are anchored to the RC basemat by mechanical connections welded to the steel plate or by lap splices. Typical details of these two options are shown on AP1000 DCD Figure 3.8.3-8, Sheets 1 and 2.

In a letter dated February 27, 2009, the applicant provided clarification of the details of the structural module connection to the basemat concrete. Correction of the connection detail on the left side of Figure 3.8.3-8, Sheet 2, and a new alternate connection detail will be included in the next update to the AP1000 DCD. Regarding the connection detail on the right hand side of Figure 3.8.3-8, Sheet 2, the staff's understanding is that this type of connection detail is not addressed by ACI 349 Code and does not provide for a direct transfer of load from the concrete to the steel module plates as do the other two alternates. Therefore, the applicant was requested to explain why the connection detail on the right side of Figure 3.8.3-8 was not removed or to provide a technical basis to demonstrate its structural adequacy. The information provided in the RAI response simply made reference to recommendations and test data given in a paper presented in a conference. In a conference call on May 12, 2009, the staff discussed the above items with the applicant, and the applicant agreed to provide a revised RAI response to address the staff's concerns.

In a letter dated March 12, 2010, a partial response was provided; however, the information still did not demonstrate the adequacy of the connection of the structural modules to the base concrete. Therefore, in a follow-up RAI, the staff indicated that, since the type of connection shown in the right side of AP1000 DCD Figure 3.8.3-8, Sheet 2, is not covered by ACI 349, the applicant should describe how the loads from the module could be properly transferred from the module to the embedded bars in the base concrete and explain how the design is performed. Also, the applicant was requested to explain why the design of the connection does not rely on the other existing option of transferring loads directly from the faceplates to the base concrete using vertical bars and mechanical connectors.

In response to the above requests, the applicant's letters dated July 30, 2010 and August 25, 2010, deleted the connection detail that does not have a direct load transfer path from the structural modules to the base concrete. In addition, a representative connection detail relying only on a direct load transfer path was proposed to be shown in AP1000 DCD Figure 3.8.3-8, Sheet 2, and all other connection alternatives would be deleted from the figure. Because the connection detail provided is identified as representative and the final design may differ to account for items such as accessibility for inspection or ease of fabrication and construction, the applicant proposed to include another note, which states that any changes to the mechanical connection detail shall maintain a direct load path to transfer loads from both sides of the module surface plates to the vertical dowel bars in the base concrete through the use of intervening plates, mechanical connectors and welds. The staff found the RAI responses are acceptable because the representative design details proposed will provide a direct load path to transfer loads from both sides of the module surface plates to the vertical dowel bars in the base concrete. In a subsequent revision to the AP1000 DCD, the applicant made appropriate changes to the DCD text and figure, which resolve this issue.

During the review of the AP1000 DCD Tier 2, Revision 16, the staff identified that AP1000 DCD, Revision 16, Tables 3.8.3-3 through 3.8.3-7 had been revised removing their identification as Tier 2*. The revised tables removed information that provided the required plate thicknesses and stress results that permit comparison to the plate thicknesses provided and allowable stress limits. In RAI-SRP3.8.3-SEB1-07, the staff requested that the applicant provide the information in the AP1000 DCD, Revision 16, for these tables equivalent to that provided in Revision 15. Also, AP1000 DCD, Revision 16, Table 3.8.3-7 replaced specific AISC interaction ratio values in Revision 15 with a notation that it is now less than 1.0 at all entries of the table. Therefore, the staff requested that the applicant present the actual interaction ratios as was done in the prior version of the AP1000 DCD.

In a letter dated March 2, 2009, the applicant provided an explanation as to why the Tier 2* information was revised in Revision 16 of the AP1000 DCD. One explanation was that these changes were communicated to the NRC in APP-GW-GLR-045 (TR-57), Revision 1, dated November 21, 2007, Chapter 5.0, "DCD Mark Up" (November 2007), and these changes were also discussed in an audit meeting in Pittsburgh. The RAI response did not provide the requested stress results and the AISC interaction ratio values. The staff reviewed the RAI response and concluded that it did not justify the elimination of the Tier 2* designation of the design information for the critical sections. The AP1000 DCD must provide a complete design for the AP1000 plant and some of this information may be identified as Tier 2* information. In a conference call on May 12, 2009, the staff discussed these issues with the applicant, which agreed to provide a revised RAI response to address the staff's concern.

In a letter dated March 15, 2010, the applicant indicated that all of the information in Table 3.8.3-7 comparable to the data presented in the same table in the AP1000 DCD, Revision 15, would be provided in the proposed mark-ups to the AP1000 DCD amendment application. The changes to the other AP1000 DCD tables were provided in the response to RAI-SRP3.8.3-SEB1-05. The staff's review of the mark-ups for Table 3.8.3-7 concluded that the information provided is comparable to the table in the AP1000 DCD, Revision 15, and that the tabulated results for the steel wall of the IRWST show the interaction ratios are all less than 1.0 in accordance with the AISC and the ASME Code stress limits. The staff met with the applicant on October 14, 2010, to discuss the applicant's proposed identification of Tier 2* items in the proposed DCD. As a result, the applicant stated it is revising the DCD to include revised Tier 2* items in Revision 2 to the response to RAI-SRP3.8.3-SEB1-07, dated October 21, 2010. In a subsequent revision to the AP1000 DCD, the applicant made appropriate changes to the DCD text and tables, which resolve this issue.

During the review of the AP1000 DCD Tier 2, Revision 16, the staff identified several items, described in AP1000 DCD Section 3.8.3.5.8, related to the design summary of critical sections for the CIS to be addressed. These items affect Section 3.8.3.5.8.1, "Structural Wall Modules"; Section 3.8.3.5.8.2, "IRWST Steel Wall"; and Section 3.8.3.5.8.3, "Column Supporting Operating Floor." In RAI-SRP3.8.3-SEB1-05, the staff requested that the applicant explain: (1) why certain Tier 2* information and criteria were removed from the AP1000 DCD; (2) why references for CIS are made to Appendix 3H, which is applicable to auxiliary and shield building critical sections; and (3) whether the existing results in Sections 3.8.1 through 3.8.5, and associated appendices reflect the latest set of updated analyses for the revised seismic loads and other loadings.

In a letter dated March 15, 2010, the applicant addressed most of the concerns identified in this RAI. The staff's review of the response noted that most of the Tier 2* information including descriptions, criteria, member forces, required plate thicknesses and stress results, removed from Section 3.8.3.5.8 of the AP1000 DCD, Revision 17, would be restored in AP1000 DCD Sections 3.8.3.5.8.1 to 3.8.3.5.8.3 and Tables 3.8.3-4 through 3.8.3-6. Therefore, in a follow-up RAI, the staff requested that the applicant include the required plate thicknesses, which were provided in the same table in the certified design presented in the AP1000 DCD, Revision 15, and to correct the designation of the Tier 2* information in AP1000 DCD Section 3.8.3.5.8.1.

In response to RAI-SRP3.8.3-SEB1-05, the applicant's letters dated July 2, and August 25, 2010, provided proposed mark-ups to AP1000 DCD Section 3.8.3.5.8, and the corresponding tables, where the required plate thicknesses were added. The staff reviewed the proposed mark-ups to the AP1000 DCD and concluded that they were acceptable because corrections were made to include the required plate thicknesses and to correct the improper designation of the Tier 2* information.

In addition, the applicant-proposed mark-ups included new criteria, which are tolerances on certain values designated as Tier 2*, intended to explain when changes in the values presented in the critical section Tier 2* tables must be reported to the NRC. The two new criteria presented are as follows:

(1) if a change increases or decreases the design parameters (e.g., reinforcement provided, concrete strength, or steel section size), then the change must be reported to the NRC; and

(2) if changes in the values of the loads, moments, and forces in the critical section tables that are designated as Tier 2* result in a required reinforcement (or plate thickness for the containment internal structures) increase greater than 10 percent of the provided reinforcement (or plate thickness for the containment internal structures) then the increase must be reported to the NRC.

Tier 2* information is part of the DCD that cannot be changed by a license holder without prior approval. However, the criteria, proposed by the applicant for identifying when changes in values presented in the critical section Tier 2* tables identified some Tier 2* changes that would not have to be approved by the NRC; these proposed criteria are not in compliance with the regulatory requirements of 10 CFR Part 52, Appendix D, “Design Certification Rule for the AP1000 Design,” Section VIII.6.a. It should be noted that the proposed criteria for Tier 2* would also apply to AP1000 DCD Section 3.8.5.4.4, Table 3.8.5-3, and AP1000 DCD Appendix 3H, for which the applicant also planned to use its proposed criteria. The staff met with the applicant on October 14, 2010, to provide this feedback. As a result, by letter dated October 21, 2010, the applicant stated it would withdraw TR-57, and revise the DCD to include revised Tier 2* information in Revision 4 to the response to RAI-SRP3.8.3-SEB1-05, dated October 21, 2010. In a subsequent revision to the AP1000 DCD, the applicant made appropriate changes to the DCD text and tables, which resolve this issue.

3.8.3.4 Materials, Quality Control, and Special Construction Techniques

During the review of the AP1000 DCD Tier 2, Revision 16, the staff identified that AP1000 DCD Section 3.8.3.6 was revised regarding the use of different steel materials for CIS structural modules from the previously certified AP1000 design. In RAI-SRP3.8.3-SEB1-06, the staff requested that the applicant discuss the revision of materials: (1) from [ ] grade steel plates and shapes for the modules to allow the use of other grade carbon steel plates and shapes; and (2) from [ ], stainless steel plates for the modules to [ ] stainless steel plates. The applicant was requested to explain why these materials were revised, how the new material properties compared to those of previous materials, and demonstrate that the new material properties are equivalent to, or better than, the properties used in the original analysis and design of the AP1000 CIS structures.

In letters, dated February 27, 2009 and July 2, 2009, the applicant identified the use of [ ] as acceptable carbon steel materials for use in the structural modules because these two materials are considered to have equivalent specifications commonly used for rolled shapes. The applicant also explained that the reason for replacing [ ], [ ] stainless steel plates [ ], [ ], for the modules is that [ ] material is not available in the required plate sizes. The staff found that [ ] have substantially different yield strengths, and that the two stainless materials also have different yield strengths. In addition, it is not clear which material was used in the various designs for qualifying the modules. Therefore, in a follow-up RAI, the applicant was requested to demonstrate that the alternative materials are equivalent to, or better than, those used in the original analysis and design of the modules.

In a letter dated August 31, 2009, the applicant provided information that demonstrated that the alternative materials for the structural modules are equivalent to, or better than, those used in the analysis and design. This was demonstrated for both the carbon steel and stainless steel materials, and, therefore, the staff concluded that the proposed use of these new materials is acceptable. The RAI response also provided some markups to reflect this change in the AP1000 DCD. In a subsequent revision to the AP1000 DCD, the applicant made appropriate changes to the DCD text and table, which resolve this issue.

3.8.3.5 Design Summary Report

In the AP1000 DCD, Revision 16, the applicant revised Section 3.8.3.5.7, "Design Summary Report." The AP1000 DCD, Revision 15 indicated that the results of the evaluation would be documented in an as-built report by the COL applicant. In the AP1000 DCD, Revision 16, this was revised to state that "The results of the evaluation will be documented in an as-built summary report." Thus, the phrase "by the Combined License applicant" was removed. The need to prepare the as-built summary report is being addressed by the applicant as an ITAAC. The staff's evaluation of the need to prepare the as-built report under an ITAAC is discussed in Section 3.8.6, "Combined License Information," in this report.

3.8.3.6 Conclusion

In NUREG-1793 and its Supplement 1, the staff documented its conclusions that the AP1000 design and the DCD (up to and including Revision 15 of the AP1000 DCD) were acceptable and that the applicant's application for the DC met the requirements of Subpart B to 10 CFR Part 52 that are applicable and technically relevant to the AP1000 standard plant design.

The staff reviewed the applicant's proposed changes to the AP1000 CISs as documented in the AP1000 DCD Revision 19, against the relevant acceptance criteria as listed above and in NUREG-0800 Section 3.8.3.

Based on confirmatory review of the subsequent revision to the AP1000 DCD, the staff finds that the design of the CISs continues to meet all applicable acceptance criteria. In summary, based on the above discussions, the staff finds that the design of the AP1000 CIS is acceptable.

The changes to the DCD implementing the revised AP1000 design meet the standards of Criterion vii of 10 CFR 52.63(a)(1) in that they contribute to increased standardization; without these DCD changes each COL applicant would have to address these issues individually.

3.8.4 Other Seismic Category I Structures

Using the regulatory guidance in NUREG-0800 Section 3.8.4, "Other Seismic Category I Structures," the staff reviewed areas related to all seismic Category I structures and other safety-related structures that may not be classified as seismic Category I, other than the containment and its internal structures. The specific areas of review provided in NUREG-0800 Section 3.8.4 are as follows: (1) description of the structures; (2) applicable codes, standards, and specifications; (3) loads and loading combinations; (4) design and analysis procedures; (5) structural acceptance criteria; (6) materials, quality control, special construction techniques, and QA; (7) testing and inservice surveillance programs; (8) ITAAC; and (9) COL action items and certification requirements and restrictions. Not all of these areas were applicable to the review of the proposed changes to AP1000 Section 3.8.4 and the following SER sections provide the staff's evaluation for the relevant areas. The AP1000 DCD amendment incorporates substantial changes to the shield building design, as well as additional analyses to confirm the adequacy of the design. As a result, this evaluation of the shield building replaces the evaluation in Section 3.8.4.1.1 of NUREG-1793 in its entirety, as well as changes to other portions of Section 3.8.4 relevant to the shield building.

In its previous evaluations of AP1000 DCD Section 3.8.4, the staff identified acceptance criteria based on the design meeting the relevant requirements in 10 CFR 50.55a; 10 CFR Part 50, Appendix A, GDC 1; GDC 2; and GDC 4. The staff found that the design of the AP1000 other seismic Category I structures was in compliance with these requirements, as referenced in NUREG-0800 Section 3.8.4 and determined that the design of the AP1000's other seismic

Category I structures, as documented in the AP1000 DCD, Revision 15, was acceptable because the design conformed to all applicable acceptance criteria.

In the AP1000 DCD, Revisions 16 and 17, the applicant made the following changes to Section 3.8.4 of the certified design:

1. As a result of the extension of the AP1000 design from just hard rock sites to sites ranging from soft soils to hard rock, various seismic re-analyses of the NI structures were performed. Whereas the original design relied upon the equivalent static method of analysis for seismic loading, the re-analyses included the additional use of response spectrum and time history methods of analysis. Appendix G of DCD Revision 17 indicates that the response spectrum analysis was used for the 3D refined finite element model of the NI and for the analysis of the PCS valve room and miscellaneous - steel frame structures, flexible walls, and floors. Time history analyses were used to determine maximum soil bearing pressures under the NI and, subsequent to the submittal of DCD Revision 17, to perform an updated NI stability evaluation.

2. In DCD Revisions 16 and 17, the applicant revised the design and analysis procedures under Section 3.8.4.4.1 - Seismic Category I Structures. In particular, this section was revised significantly to reflect the change in the design of the shield building.

3. In DCD Revision 16, the applicant revised Section 3.8.4.5.3 - Design Summary Report. DCD Revision 15 indicated that the results of the evaluation will be documented in an as-built summary report by the Combined License applicant. In DCD Revision 16, this was revised to state that “The results of the evaluation will be documented in an as-built summary report.” Thus the phrase “by the Combined License applicant” was removed.

4. In DCD Revision 16 and 17, the applicant revised Section 3.8.4.6.1.1 - Concrete, regarding the concrete material. For the shield building structure, the compressive strength of concrete was increased from 4,000 to 6,000 psi.

3.8.4.1 Description of Other Seismic Category I Structures

During the review of the AP1000 DCD Tier 2, Revision 16, the staff identified that several revisions were made to AP1000 DCD Section 3.8.4.4.1 and Appendix 3H, some of which are Tier 2* information. In RAI-SRP3.8.4-SEB1-03, the staff requested that the applicant explain why these revisions have been made, demonstrate the design adequacy of these changes, and justify the removal of design information from the AP1000 DCD.

In a letter dated May 4, 2009, the applicant provided explanations of why changes were made in AP1000 DCD Section 3.8.4.4.1 and Appendix 3H. The applicant indicated that these are due to design changes to address the, “enhanced shield building design” features and these changes were already communicated to the NRC in APP-GW-GLR-045, Revision 1, which was later revised again to Revision 2. In a letter dated March 5, 2010, the applicant provided mark-ups to Appendix 3H of the AP1000 DCD, which restore some of the design information that was previously removed. The staff found that the restored information was not complete regarding identification of the required reinforcement for concrete sections, reduction in the number of critical sections evaluated, why certain loads do not appear in the load combinations, and apparent inconsistency in the allowable stress values. Therefore, in a follow-up RAI, the applicant was requested to address these items. In addition, there were a number of issues still outstanding with the changes related to the enhanced shield building design and the removal of Tier 2* information.

In response to the above requests, the applicant's letters dated July 26, 2010, and August 30, 2010, provided proposed mark-ups to AP1000 DCD, Appendix 3H, which: (1) add to the corresponding tables the required reinforcement for concrete sections and an appropriate number of critical sections evaluated; (2) present a revised table that incorporates the design changes related to the enhanced shield building design; and (3) propose two new criteria, the same as presented in the evaluation for the response to RAI-SRP3.8.3-SEB1-05 in this SER, for identifying when changes in the values presented in the critical section Tier 2* tables must be reported to the NRC. In addition, the responses also explained that certain loads in some load combinations were excluded because the loads were not applicable to that load combination or that load combination did not govern the design. The differences in some of the tabulated allowable stress values are due to differences in the stress limit coefficients for tension and compression. The staff's review of the responses concluded that they are acceptable, in part, because: (1) corrections were made to include the required reinforcement for concrete sections and an adequate number of critical sections were evaluated; (2) the critical section table was updated to reflect the design changes related to the enhanced shield building design; and (3) explanations were provided to justify why certain loads do not need to be considered.

Tier 2* information is part of the safety analysis report that cannot be changed by a license holder without prior approval. However, the criteria for identifying when changes in values presented in the critical section Tier 2* tables do not have to be reported to the NRC are not in compliance with the regulatory requirements of 10 CFR 52, Appendix D, Section VIII.6.a, because: (1) any changes made to the Tier 2* italicized or bracketed and asterisked text require prior NRC approval; and (2) a generic criterion whereby changes in the loads or member forces that result in an increase in the required reinforcement (or plate thickness for modules) greater than 10 percent also need to be reported. The key is that the required reinforcement or plate thickness cannot change because if the Tier 2* information changes then criterion number (1) applies and it must receive prior approval from the NRC. It should be noted that the proposed criteria for Tier 2* also apply to AP1000 DCD Section 3.8.5.4.4, Table 3.8.5-3, and AP1000 DCD Appendix 3H, for which the applicant also plans to use the new criteria. The staff met with the applicant on October 14, 2010, to provide this feedback. As a result, the applicant stated it was withdrawing TR-57 by letter dated October 21, 2010, and revising the DCD to include revised Tier 2* information in Revision 4 to the response to RAI-SRP3.8.4-SEB1-03, dated October 21, 2010. In this response, the applicant included new criteria on Tier 2* items in Subsection 3H.1 to be consistent with American Society for Testing and Materials (ASTM)-6, "Standard Specification for General Requirements for Rolled Structural Steel Bars, Plates, Shapes, and Steel Piling," and ASTM-A480, "Standard Specification for General Requirements for Flat-rolled Stainless and Heat-Resisting Steel Plate, Sheet, and Strip." In a subsequent revision to the AP1000 DCD, the applicant made appropriate changes to the DCD text and tables, which resolve this issue.

<u>Nuclear Island Evaluation of Critical Sections Under Technical Report TR-57 and Report APP-1200-S3R-003</u>

The applicant submitted versions of TR-57 on November 21, 2007, and July 1, 2008, to summarize the structural design and analysis of structures identified as "Critical Sections" in the CIS, auxiliary building, and enhanced shield building. The design of the critical sections for the

CIS is summarized in AP1000 DCD Section 3.8.3. The design of the critical sections for the auxiliary and shield building is described in AP1000 DCD Appendix 3H, Section 3H.5. Two of the critical sections identified in Section 3H.5 are not included in Revision 0 of TR-57. According to TR-57, Revision 0, the information on the evaluation of these two sections will be provided in an update to TR-57 when the security-related assessment is more complete. Further, the information in TR-57, Revision 0, represents the results of detailed calculations and analyses. According to the TR-57, Revision 0, the results will change slightly during the design finalization due to anticipated spectra changes resulting from resolution of the high frequency issues and plant security issues. TR-57, Revision 0, also states that small changes in modeling and updates to software may also have a minor effect on the results.

Subsequently, the applicant made further revisions to the shield building design and analyses, and submitted Revision 1 to the report. This report was later revised and completed in Revision 2, transmitted to the NRC in a letter dated July 1, 2008. TR-57, Revision 2, provides the design of five critical sections for the CIS and 12 critical sections for the auxiliary building. A brief description of the design of two critical sections associated with the enhanced shield building design is also presented. For comparison, the AP1000 DCD, Revision 17, as well as the certified design in the AP1000 DCD, Revision 15, also identifies the same critical sections for the CIS and auxiliary buildings.

In addition to TR-57, the applicant also submitted for the staff's review APP-1200-S3R-003, Revision 0, "Design for the AP1000 Enhanced Shield Building," dated August 31, 2009. The purpose of this document was to provide a separate report, which specifically describes the enhanced shield building design methodology, testing, constructability, and inspection. The enhanced shield building report includes the design of three regions/locations: shield building cylinder; shield building roof, exterior wall of the PCS water storage tank; and shield building roof, tension ring, and air inlets.

The NRC sent a letter, dated October 15, 2009, to the applicant on the results of its review of the applicant's August 31, 2009 design methodology report for the AP1000 shield building. The letter stated:

> By letter dated August 31, 2009, the applicant submitted its design methodology report for the AP1000 shield building. The U.S NRC has completed its review of that report. Based on that report and the body of technical information reviewed to date, the NRC has determined that the proposed design of the shield building will require modifications in some specific areas to ensure its ability to perform its safety function under design basis loading conditions and to support a finding that it will meet applicable regulations (i.e., 10 CFR 50.55a and 10 CFR Part 50, Appendix A (GDC 1 and 2)).
>
> Specifically, the design of the steel and concrete composite structural module (SC module) must demonstrate the ability to function as a unit during design basis events; the design of the connection of the SC module to the reinforced concrete wall sections of the shield building must demonstrate the ability to function during design basis events; the design of the shield building tension ring girder, which anchors the shield building roof to the wall, must be supported by either a confirmation test or a validated (or benchmarked) analysis method.

During the review of the August 31, 2009 report, the staff identified a potential error in the applicant's computer code, which had been used to proportion the cross-sectional strength of members involving concrete materials (basemat, CIS, auxiliary building, and the shield building). The staff informed the applicant about this concern and the staff's evaluation of the resolution for this issue is described in Section 3.8.5 of this report, regarding the basemat, where this item is identified in RAI-TR85-SEB1-29.

In a meeting held on November 18, 2009, with the applicant to discuss its new proposal on the design of its shield building, the staff indicated that the applicant did not appear to have implemented the 100-40-40 method for combination of the three direction seismic loading in accordance with RG 1.92, Revision 2, or the ASCE 4-98 method. The implementation of the 100-40-40 combination method is also discussed in Section 3.8.5 of this report, regarding the basemat, where this item is identified in RAI-TR85-SEB1-27.

To address the various issues related to the use of the SC module in the shield building and the design of the connection of the SC module to the RC sections, the applicant performed additional analyses and testing and submitted a revised shield building report to the staff for review. Revision 3 to the shield building report was submitted by letter dated September 20, 2010.

The staff's evaluation and acceptance of the design of the critical sections in TR-57, as provided under the AP1000 DCD, Revision 15, was presented in NUREG-1793. However, because of changes in the design of the shield building, the number of critical sections has increased. The staff's review of the additional critical sections associated with the shield building is provided in Section 3.8.4.1.1 of this report. In a letter dated October 21, 2010, the applicant clarified the design basis for the proposed facility by deleting TR-57 and removing references to TR-57 from the DCD.

New Fuel Racks and Spent Fuel Racks - Technical Reports: TR-44 and TR-54

The applicant submitted TR-44, Revision 0, to summarize the structural/seismic analysis of the AP1000 new fuel storage racks. In addition, the applicant submitted TR-54, Revision 0, to summarize the structural/seismic analysis of the AP1000 spent fuel storage racks. Subsequently, additional revisions were made to these TRs to incorporate changes made in response to RAIs regarding the structural analysis and design of the new and spent fuel racks for various loads and in response to related discussions held during several past design audits.

Section 3.8.4 of AP1000 DCD, Revisions 16 and 17 indicates that the new fuel and spent fuel storage racks are described in Section 9.1 of the AP1000 DCD. Therefore, a description of the technical information presented in the TRs and the staff's evaluation of the information in these reports are presented in Section 9.1 of this report. The description; applicable codes, standards, and specifications; loads and load combinations; analysis and design approach; acceptance criteria; and construction of the fuel racks are evaluated in Section 9.1 of this report, in accordance with the requirements of NUREG-0800 Section 3.8.4, Revision 2, Appendix D. Some of the key outstanding issues that were identified by the staff and evaluated in Section 9.1 of this SER include acceptable methods for evaluation of the horizontal impact forces at the top of the racks and evaluation of buckling at the bottom of the racks during liftoff caused by the seismic loading. In addition, reconciliation of the new seismic loads from the applicant's SSI reanalysis was needed.

Another issue is the evaluation of the spent fuel rack impact forces on the spent fuel pool walls. The concern is that with the reanalysis of the spent fuel racks to incorporate the updated seismic loading and revisions in the design of the racks the maximum impact force from a spent fuel rack onto the pool walls increased substantially. This issue is captured under RAI-SRP9.1.2-SEB1-06. In response to this RAI, the applicant's letter dated August 25, 2010, addressed the remaining questions regarding this issue. This response is also evaluated under Section 9.1.2 of this report.

Design Summary Report

In the AP1000 DCD, Revision 16, the applicant revised Section 3.8.4.5.3, "Design Summary Report." The AP1000 DCD, Revision 15 indicated that the results of the evaluation would be documented in an as-built report by the COL applicant. In the AP1000 DCD, Revision 16, this was revised to state, "The results of the evaluation will be documented in an as-built summary report." Thus, the phrase, "by the Combined License applicant," was removed. Preparation of the as-built summary report is being addressed by the applicant as an ITAAC. The staff's evaluation of the need to prepare the as-built report under an ITAAC is discussed in Section 3.8.6, "Combined License Information," in this report.

3.8.4.1.1 Shield Building

The applicant applied for an amendment to the certified design of the AP1000, an advanced, passive, pressurized-water reactor (PWR) design. The staff has reviewed the revised design of AP1000 seismic Category I structures, including the shield building, as described in Revision 17 of the DCD. The staff applied the guidance provided in Section 3.8.4, "Other Seismic Category I Structures," Revision 3, issued May 2010, of NUREG-0800.

This evaluation of the shield building is based on key design-specific issues. These issues are outlined in NUREG-0800: (1) description of the structures; (2) applicable codes, standards, and specifications; (3) loads and loading combinations; (4) design and analysis procedures; (5) structural acceptance criteria; (6) materials, quality control, special construction techniques, and QA; (7) testing and inservice surveillance programs; (8) ITAAC; and (9) COL action items and certification requirements and restrictions.

The staff issued NUREG-1793 in September 2004 and Supplement 1 in September 2005. Revision 15 of the AP1000 DCD was incorporated into Appendix D to 10 CFR Part 52. Subsequently, the applicant submitted Revisions 16 and 17 to the AP1000 DCD with additional modifications to the TRs that relate to the shield building:

- APP-1200-S3R-003, Revision 2, "Design Report for the AP1000 Enhanced Shield Building," dated May 7, 2010 (Shield Building Report)

- TR-85

- TR-03

With these revisions, the applicant is seeking to make the changes discussed below specific to the design of the shield building.

3.6.1.1.1.1 Safety Function and Description of the Shield Building

The shield building is a safety-related seismic Category I structure that provides structural and radiological shielding for the CV and radioactive systems located in the containment building; protects the containment from external events, including missiles, tornadoes, and seismic events; provides radiation shielding from nuclear materials in containment; supports the PCCWST; and provides for natural air circulation cooling for the CV.

The staff notes that the design of the shield building in the AP1000 is unique in that it is the first shield building design to include the support of the PCCWST at the apex of the building structure. The PCCWST holds 3.039×10^6 kg (6.7 million pounds) of emergency cooling water. This water load accounts for a considerable portion of the load on the roof of the shield building.

The shield building consists of cylindrical walls surrounding, and set at a distance from, the steel containment and a conical roof that supports the PCCWST over the containment. The cylindrical wall of the shield building supports both the roof and the PCCWST. The shield building wall is constructed with both conventional RC and new, first-of-a-kind SC wall modules, which make up about 75 percent of the structure. The SC modules consist of two steel faceplates and have concrete filled in between the faceplates. Shear studs anchor the concrete to the steel faceplates, and tie-bars connect the two outer faceplates together. The shield building roof, an RC structure, is connected to the cylindrical wall by the ring girder/tension ring. The auxiliary building roof and the external walls are connected to the SC cylindrical portion of the shield building. The floor slabs and interior structural walls of the auxiliary building are also structurally connected to the RC cylindrical portion of the shield building. The SC wall is attached to the top and sides of the RC wall with stepped and asymmetrical boundary conditions both in the vertical (meridional) and horizontal (hoop) directions (Shield Building Report, Figure 3.2-2). The SC module steel faceplates are not directly anchored to the RC walls. The SC wall and the RC wall are connected through mechanical connectors (Shield Building Report, Figures 4.1-2, 4.1-3, 4.1-4, and 4.1-5), and the SC wall is also connected to the basemat reinforcement through mechanical splices.

The shield building structure has the following main features:

- a cylindrically shaped wall constructed of SC modules that are stacked vertically, welded together to form a cylinder, and filled with concrete
- an air-inlet region located above the cylindrical wall, designed to allow air flow for containment cooling during certain design basis accidents
- a conical RC roof structure with an integral RC water tank, called the PCCWST. The PCCWST contains approximately 6.7 million pounds of water.
- a ring girder tension ring consisting of a steel box girder filled with concrete, located at the intersection of the conical roof and the air-inlet region
- mechanical connections where the SC wall joins the RC wall

<u>Cylindrical Wall</u>. The executive summary of the Shield Building Report describes the cylindrical SC wall. Figure ES-3 shows the SC wall panel layout, [ ]. The thickness of the SC wall for the air-inlet region varies from [ ].

The free-standing vertical span of the west wall, the height from the top of the basemat to the bottom of the tension ring, is 50.6 m (166 ft, 3 in). The east part of the SC wall connects to the RC wall of the shield building (the part of the 0.9 m (3 ft) thick wall protected by the auxiliary building structure) below the roof of the auxiliary building at El. 44.8 m (146 ft 10 in). The RC floors and walls of the auxiliary building are connected to the RC wall of the shield building and constrain lateral displacement of this wall. The height of the east wall above its SC/RC connection located below the roof of the auxiliary building is 36.4 m (119 ft, 5 in).

Air-Inlet Region. The air-inlet region at the top of the cylindrical wall of the AP1000 shield building has through-wall openings for air flow. These air-inlet openings consist of [ ] steel pipes at a downward inclination [ ] from the vertical. Center-to-center horizontal spacing of these tubes is [ ]. The air-inlet pipes are welded to the steel faceplates. Welded steel studs connect the steel pipes to the concrete.

Roof and PCCWST. The AP1000 shield building roof is a conical RC structure supported by a steel frame consisting of radial steel beams (main roof beams). Metal studs connect a steel plate to the bottom face of the conical RC roof slab. Two vertical, concentric RC walls on the roof, integral with the roof structure, define the boundaries of the PCCWST. At the center of the PCCWST on the roof is an air diffuser, or chimney, that is defined by the inner PCCWST wall.

Tension Ring. The main component of the tension ring is a rectangular, concrete-filled, closed section built of [ ] thick welded steel plates. At the top of the tension ring is a concrete-filled, triangular, closed section of steel plates. The bottom plate of this triangular section is the top plate of the tension ring. The exterior top plate of the triangular section is parallel to the roof slope, while the other top plate is perpendicular to the roof slope to support the roof slab and to anchor some of the roof's reinforcing bars. Attached to the tension ring are interior beam seats that support the radial roof framing girders. Steel plates stiffen the tension ring where these beams are seated.

SC/RC Connections. The SC wall of the shield building connects to the top of the RC basemat (El. 30.5 m (100 ft)) at the bottom of the west wall (for a span of 152.97 degrees). A short portion of the horizontal west wall connection, between azimuths 175.63 degrees and 190.00 degrees, is at El. 33.2 m (109 ft) with a vertical connection at azimuth 190.00 degrees at the transition between El. 30.5 m (100 ft) and El. 33.2 m (109 ft). The east part of the SC wall has a horizontal connection to the RC wall of the shield building below the roof of the auxiliary building at El. 44.8 m (146 ft 10 in), and vertical connections to the sides of this RC wall at azimuth 341.94 degrees, near Wall Q, from El. 30.5 m (100 ft) to El. 44.8 m (146 ft 10 in), and at azimuth 174.60 degrees, near wall N, from El. 33.2 m (109 ft) to El. 44.8 m (146 ft 10 in).

The staff finds that the description of the shield building structure, as provided in the Shield Building Report and as supplemented with design information in the responses to staff questions at the meeting on June 9-11, 2010, provides sufficient information to define the primary structural aspects and elements used by the applicant to design the structure to withstand the design-basis loads.

Using the guidance described in NUREG-0800 Section 3.8.4 and related RGs, the staff reviewed areas related to all seismic Category I structures and other safety-related structures that may not be classified as seismic Category I, other than the containment and its interior structures.

In its previous evaluation of Section 3.8.4 of the AP1000 DCD in NUREG-1793, the staff accepted the design of these structures because it met the following applicable requirements of 10 CFR Part 50:

- 10 CFR 50.55a
- Appendix A
  - GDC 1
  - GDC 2
  - GDC 4

In Revisions 16 and 17 of the AP1000 DCD, the applicant proposed the following changes to Section 3.8.4 of the certified design:

- As a result of the extension of the AP1000 HR design to a design that includes a broader range of soil profiles, the applicant performed various seismic reanalyses of the NI structures. Whereas the original design relied upon the equivalent static method of analysis for seismic loading, the reanalyses included the additional use of response spectrum and time history methods of analysis. Appendix 3G to Chapter 3 of the AP1000 DCD, Revision 17, indicates that the RSA was used for the three-dimensional refined finite element model of the NI and for the analysis of the passive containment cooling water system valve room and miscellaneous steel frame structures, flexible walls, and floors. Time history analyses were used to determine maximum soil bearing pressures under the NI and, subsequent to the submittal of DCD Revision 17, to perform an updated NI stability evaluation.

- In DCD Revisions 16 and 17, the applicant revised the design and analysis procedures in Section 3.8.4.4.1 regarding seismic Category I structures. In particular, the applicant revised this section significantly to reflect the change in the design of the shield building. The shield building design has evolved as described primarily in the Shield Building Report.

- In DCD Revisions 16 and 17, the applicant revised Section 3.8.4.6.1.1, "Concrete." For the shield building structure, the compressive strength of concrete was increased from 27.58 MPa (4,000 psi) design strength in the RC areas to 41.37 MPa (6,000 psi) design strength in the SC structural modules. The applicant revised the test age of concrete from 28 days to 56 days and changed some details about the chemical composition in the Portland cement and the proportioning of the concrete mix.

- In TR-03, the applicant compared the corresponding acceleration profiles obtained from the SSI analyses for the various soil sites to the original HR acceleration profile used in the design of the AP1000. On the basis of this comparison, the applicant concluded that the AP1000 design is adequate for the range of soil sites considered.

- In response to questions from the staff relating to the above issues (discussed below), the applicant redesigned the shield building based on feedback from the staff transmitted in an NRC letter dated October 15, 2009. The Shield Building Report describes these design changes.

Based on its evaluation of the proposed shield building design provided in Revisions 16 and 17 to the AP1000 DCD, the staff issued RAI-SRP3.8.3-SEB1-01 asking the applicant to provide information about the design methodology and to specify which aspects of the shield building design are in accordance with ACI 349, as modified by the additional criteria in RG 1.142, Revision 2, and ANSI/AISC N690. In a letter dated August 31, 2009, the applicant submitted its design methodology report, APP-1200-S3R-003, Revision 0. In a letter dated October 15, 2009, the staff identified modifications that would be required to ensure that the shield building could perform its safety function under design-basis loading conditions and to support a finding that it meets the applicable regulations in 10 CFR 50.55a and GDC 1 and 2 in Appendix A to 10 CFR Part 50.

The letter identified the following key issues:

Detailing, Design, and Analysis

1. The applicant needs to demonstrate the adequacy of the design and detailing of the SC module to function as a fully composite unit as assumed in the applicant's design/analysis. In addition, the applicant needs to demonstrate that the SC module has sufficient ductility to survive severe earthquakes or tornado winds.

2. The SC module wall to RC wall connection is to be designed and detailed for both the RC and SC portion of the connection and supported by a basis for why the connections will carry the shield building design loads.

3. The design and analysis of the shield building tension ring (i.e., ring girder) and the air-inlet region should be supported by a validated design/analysis method (i.e., benchmarked to experimental data), or by confirmatory model tests.

Based on subsequent interactions, including meetings in December 2009 and January and February 2010, as well as telephone conferences between the NRC and the applicant, the applicant submitted APP-1200-S3R-003, Revision 1. Following the March submittal and after several telephone conferences between the NRC and the applicant, the applicant submitted APP-1200-S3R-003, Revision 2 (the Shield Building Report). The staff reviewed the Shield Building Report and held a public meeting with the applicant on June 9-11, 2010. The meeting resulted in 21 items for applicant action, as summarized in an NRC memorandum dated July 19, 2010. The action items required the applicant to address design methods, analyses, and testing issues to help demonstrate the adequacy of the shield building design.

The applicant responded to 18 action items in its June 30, 2010, submittal and responded to the remaining Action Items 4 and 12 on July 23, 2010, and July 31, 2010. The applicant responded to Action Item 21 on September 3, 2010.

The applicant provided the following information in response to the action items:

- analysis methods, results, and justification for the structural demand and capacity of the shield building

- analysis and results, including stress/strain test data, and analysis of test specimens using material models in [   ]

- justification to support global stability in the design of the structure

- design approach and load path for the SC/RC connection, including justification for the shear friction capacity of the connection and any resulting design changes that were made based on the respective evaluations

- justification and qualification and production criteria for the use of mechanical splices in the design of the SC/RC connection

- analysis to support the design of the ring girder and the connection between the ring girder and air-inlet region of the SC wall, including a comparison of the cross-sectional forces between [ ] and [ ] codes to verify shear friction loads

- analysis to support the adequacy of the [ ] used at the transition of the SC wall at the air inlets from 91.4 cm to 137.2 cm (36 in to 54 in) thickness

- evaluation of the effect of concrete cracking on the structural design

The applicant also submitted a supplemental report, “Final Shield Building In-Plane Shear Test Results,” dated June 24, 2010, on the testing of the SC module under cyclic in-plane shear. Section 3.8.4.1.1.3.5 of this report describes the staff’s evaluation of this test.

3.8.4.1.1.2 Regulatory Basis

The AP1000 shield building protects the reactor and containment from exterior missiles generated by tornadoes and, thus, it is subject to impact loads. The AP1000 shield building is classified as a seismic Category I structure because it should remain functional during severe earthquakes. Therefore, the shield building is subject to both seismic and impact loads and is designed and evaluated in accordance with the regulations and guidance as follows:

- 10 CFR Part 50.55a(a)(1) requires, “safety-related structures, systems, and components be designed, fabricated, erected, constructed, tested and inspected to quality standards commensurate with the importance of the safety functions to be performed.”

- GDC 1 states, “Structures, systems and components important to safety shall be designed, fabricated, erected, and tested to quality standards commensurate with the importance of the safety functions to be performed.”

- GDC 2 states, “Structures, systems, and components important to safety shall be designed to withstand the effects of natural phenomena such as earthquakes, tornadoes, hurricanes, floods, tsunami, and seiches without loss of capability to perform their functions.”

- NUREG-0800 Section 3.8.4 refers to RG 1.142 and ACI 349.

- RG 1.142 endorses ACI 349 and sections of ACI 318, “Building Code Requirements for Structural Concrete and Commentary,” issued 2008, as applicable codes for all seismic Category I concrete structures, including concrete shield buildings other than containment structures.

3.8.4.1.1.3 Evaluation

This evaluation is limited to the design basis of the shield building and does not address its ability to protect against a malevolent aircraft crash, which is a beyond-design-basis event evaluated under NUREG-0800 Chapter 19, “Severe Accidents.”

3.8.4.1.1.3.1 Design Methodology and Process for Shield Building Design

In response to staff questions regarding the design methodology and the process for the design of the shield building, the applicant summarized its design process in a matrix in Table 1.2-1 and described it in Chapter 2 of the Shield Building Report. According to this description, the concrete design of the following areas of the AP1000 shield building falls directly within the scope of ACI 349:

- shield building roof
- knuckle region of the roof near the PCCWST wall
- compression ring
- PCCWST

The applicant designed these areas in accordance with the provisions in the established design codes by using linear elastic analysis methods. Specifically, the design for the sections in these areas is based on compliance with the ACI 349 Code, as supplemented with guidance in RG 1.142 for concrete structures. The design of the sections in these areas, which uses established design codes and analysis methods listed in Section 3.8.4 of NUREG-0800, satisfies the regulatory basis listed above and is, therefore, acceptable to the staff.

The following other areas of the shield building structure are considered as special features of the design because the applicant used SC modular wall design:

- SC cylindrical wall
- SC/RC connection
- air-inlet region

Codes and standards for the design of SC modular wall and associated structural components do not exist in the United States. Design guidelines for SC modular construction already exist in Japan, namely Japan Electric Association Code, Guideline 4618, “Technical Guidelines for Aseismic Design of Steel Plate Reinforced Concrete Structures—Buildings and Structures,” issued in 2005. However, these guidelines were not specifically developed for external structures with configurations like those of the AP1000 shield building and have not been approved by the NRC. In the Shield Building Report, the applicant designated the areas of the building that use SC modular construction, which include the SC/RC connections, as special structures under ACI 349, Section 1.4.

The applicant applied the provisions of the established ACI 349 Code to the design of these special structures using linear analysis, nonlinear analysis, and testing. Specifically, the applicant applied the provisions in ACI 349 for the design of RC seismic Category I structures to the design of SC wall modules in the AP1000 shield building design. To validate the use of the code, the applicant performed nonlinear analysis and conducted a testing program to verify the behavior and determine the stiffness, strength, and ductility of proposed SC wall modules under monotonic and cyclic loads. In addition, the applicant reviewed international test data on SC wall modules (Appendix A to the Shield Building Report) to confirm the adequacy of the assumptions used by the integrated design process, such as the assumption that the SC wall modules would function as a composite unit under design-basis loads.

The integrated design process for the SC wall module uses standard methods of analysis to calculate stress demands on the shield building that meet the acceptance criteria in NUREG-0800, namely, linear elastic structural analysis. In addition, the design process uses benchmarked nonlinear analysis to confirm that cracking would not cause significant changes in the design demands; that is, changes that would lead to stresses that would invalidate the design obtained with the extension of the established code provisions.

The applicant's integrated design process also makes use of the design process for structural steel components in certain areas of the shield building. Specifically, it uses ANSI/AISC N690 in designing structural steel components of seismic Category I structures. The applicant used ANSI/AISC N690 in designing the following areas of the shield building:

- the steel roof that supports the concrete roof slab
- tension ring
- SC/RC connection

The design process uses provisions from two different design codes: ACI 349 Code for RC components, which uses an ultimate strength design approach and ANSI/AISC N690 Standard for steel and composite components, which uses an allowable stress design approach. The use of two different codes necessitates that the components or parts of components assessed against each code are clearly distinct and that appropriate load combinations are used for each case. The staff's review of the Shield Building Report concludes that these conditions have been met in an acceptable manner.

Based on the discussion above, the staff accepts the applicant's use of the design methodology provided in ANSI/AISC N690 Standard for structural steel components to design the shield building tension ring and the roof supporting steel beams. In addition, the staff accepts the applicant's approach of using ACI 349 as the basis for the design of the other areas, namely the shield building roof, the knuckle region of the roof near the PCCWST wall, the compression ring in the roof, and the PCCWST and walls.

The staff finds that although ACI 349 is not explicitly applicable to the SC modules, the applicant's design method, which is fundamentally based on ACI 349 and supported by confirmatory analysis and testing to confirm the adequacy of the design, is acceptable.

The staff's evaluation of the technical basis, including testing, confirmatory analysis, and design detailing, that supports this integrated design method appears in subsequent sections of this report.

3.8.4.1.1.3.2 Design of the Shield Building

In the Shield Building Report, the applicant made significant design changes from previous versions of the design by replacing lap splices with mechanical splices at the SC-to-RC connection region between faceplates, increasing the thickness of SC module faceplates from [ ], using more ductile steel, and proposing a testing program to include testing for ductility and behavior under cyclic loads. The applicant also replaced the SC tension ring with a steel box girder, redesigned the air-inlet area with fewer through-wall openings, modified the concrete roof design from an SC module design method to an ACI 349 design method, moved SC/RC connections in the east side of the wall downward and away from the original area where the auxiliary building roof connected to the wall in order to avoid congestion and stress concentrations in the area, reduced the use of self-consolidating concrete, and redesigned the SC/RC connection to provide a direct load path. The applicant also replaced the original high-strength smooth anchor rods between the SC-to-RC basemat with #14 mild steel deformed reinforcing bars, as discussed during the meeting of June 9-11, 2010. The staff considers these changes to be significant improvements in the design of the structure to enable it to function as a unit under design-basis loads.

The staff evaluation of the applicant's analysis for the changes is provided below.

Levels of Analysis

The applicant's approach to developing the design basis involves three levels of analysis as described in the Shield Building Report, Section 2.6, Table 2.6-1. The three levels of analysis, with increasing levels of model refinement, are as follows:

Level 1 is used for determining the load magnitudes (seismic demands) imposed on the structure. Level 2 is used for determining the member forces and deformation demands. Level 3 is used to assess the region with high stresses, strains, and displacements in the shield building, such as the connection regions. Linear elastic models are used at Levels 1 and 2. At Level 3, nonlinear analysis is used to confirm the results at the various levels of analysis.

The applicant used the Level 1 analysis to generate the design-basis ISRS and load magnitudes on the AP1000 NI. The applicant used the [ ] NI20 and [ ] NI10 models to develop ISRS and to design and analyze seismic Category I SSCs. In these analyses, the concrete material modulus of elasticity was reduced to 80 percent of its nominal value to account for minor concrete cracking. The applicant performed confirmatory analysis of the Level 1 analysis using the [ ] finite element analysis code. To accomplish this, the [ ] NI20 model was converted to an [ ] model with the capability to account for concrete cracking. The nonlinear concrete material parameters were benchmarked to SC element tests performed at Purdue University. Chapter 8 of the Shield Building Report describes the results of this confirmatory analysis.

The applicant used the Level 2 analysis to calculate structural design demands for the AP1000 NI. These analyses used the [ ] NI05 building model, which has a characteristic element size of 1.5 m (5 ft). In Section 2.6 of the Shield Building Report, the applicant stated that the accuracy of the NI05 model was validated by comparing the dynamic response to the [ ] NI10 model, which has a characteristic element size of 3 m (10 ft). The applicant performed confirmatory analysis of the Level 2 analysis using the [ ] finite element analysis code. The [ ] model is a highly refined model that explicitly accounts for the steel and concrete materials with separate shell and solid elements. In addition, nonlinear properties are used to characterize the concrete and steel materials. In Section 2.6 of the Shield Building Report, the applicant stated that the [ ] code was benchmarked to the Purdue University testing, as described in Chapter 7 of the Shield Building Report.

The applicant performed the Level 3 analysis to determine stresses, strains, and displacements of the critical high-stress regions in the shield building design using the [ ] finite element code and nonlinear inelastic material modeling. The concrete material parameters were benchmarked against Purdue University test results. The detailed submodels used included elements such as concrete, steel plate, studs, and [ ]. A strain-based failure criterion was selected to ensure acceptable limits under design-basis loads. Results from the Level 2 [ ] analyses are "handed-off" to the Level 3 [ ] analyses by imposing displacements at the boundary of the Level 3 analysis. The applicant described this handoff procedure in Appendix C.3 of the Shield Building Report.

The staff finds the design approach involving the three levels of analysis to determine the load magnitudes (seismic demands), the member forces, and deformation demands and including confirmatory analysis, provides a logical, reasonable, and adequate technical approach to developing the shield building design and, therefore, is acceptable.

The staff accepts the various levels of analysis involving the use of increasingly refined models to better determine element behavior under the design-basis seismic loads (SSE). The models reasonably account for material properties, and the resulting strain and stress data are confirmed under the Level 3 analysis, whereby the results from the standard linear elastic analysis models compare reasonably well with the results from the nonlinear models.

The staff finds that the approach is reasonable in that it enables the applicant to gain a better understanding of the behaviors of the structural elements of the design, particularly in the critical high-stressed regions of the structure such as the SC/RC connection. This SER provides the staff's evaluations of the results of this approach under the subsequent sections.

3.8.4.1.1.3.3 Confirmatory Analysis

In Chapter 8 of the Shield Building Report, the applicant described the approach for its benchmarking analysis methods. It should be noted that the applicant's analysis methods were not benchmarked by updating or "tuning" modeling assumptions to match any particular test. Rather, the applicant provided a confirmatory analysis, whereby it used [ ] and [ ] models to predict the behavior of various elements of the SC module and compared those results to those established using the ACI 349 design methods and SC module tests. The staff reviewed the confirmatory analysis used by the applicant to validate the predicted behavior under design-basis loads, as discussed below.

As previously stated, the applicant's design process for the shield building used standard methods of analysis that meet NUREG-0800 acceptance criteria, namely, linear elastic structural analysis, to calculate stress demands on the building. In addition, the design process uses confirmatory nonlinear analysis to confirm that concrete cracking and steel stresses would not cause significant changes in the design demands.

The applicant also described the approach for its confirmatory analysis methods in the September 3, 2010 supplement to the Shield Building Report. The applicant stated that the goal of the confirmatory process was to develop three-dimensional finite element models for SC structures that can be used to further evaluate the behavior and design of the AP1000 shield building. The applicant used the commercial finite element analysis codes [ ] and [ ] to perform the confirmatory analysis. The critical shield building areas (Section 10.2.2 of the Shield Building Report) designed using ACI 349 were modeled using a detailed Level 3 [ ] analysis for confirmatory purposes. These areas include Wall Q (Section C.6), west wall (Section 10.3 and Section C.5), air inlets (Section C.4), and Wall 5. Section 10.3 of the Shield Building Report summarizes the Level 3 analysis results for these four critical areas. Below is a summary of the applicant's confirmatory analysis methods, including development of the [ ] model, verification of the model predictions with experiments, and performance of the pushout and anchorage tests, followed by the staff's evaluation.

[ ] Model Development

The applicant used the commercial finite element analysis code [ ] to perform confirmatory calculations. Detailed [ ] models of several SC test specimens were developed and included important features of these modules, such as shear studs, [ ], steel plate, and concrete infill.

The steel elements were modeled in [ ] with a reduced integration solid element (C3D8R). The use of this solid element results in faster analysis running times. The nonlinear steel material properties were modeled using a multiaxial plasticity theory with von Mises yield surface, associated flow rule, and isotropic hardening. Table 8.2-1 of the Shield Building Report provides nominal and material parameters for the steel elements for use in the Level 3 analyses. The applicant used measured material properties for the test specimens, described in Chapter 8 of the Shield Building Report.

The applicant modeled the concrete infill using C3D8R elements and a concrete damage plasticity model. This model has isotropic damage rules and can be used for modeling concrete behavior under uniaxial (compression, tension, and shear), cyclic, and multiaxial loading conditions. This model uses a compression yield surface with non-associated flow in compression. In tension, the model uses damaged elasticity concepts to model smeared cracking. The postcracking behavior depends on the tension stiffening modeling used for the concrete. The applicant analyzed three tension-stiffening models: a stress-displacement model (Figure 8.6-3) and two stress-strain models (Figure 8.6-4). As a result of the confirmatory analysis, the applicant selected the stress-strain model in Figure 8.6-4 with the lowest concrete tensile strength for the Level 3 analyses.

The applicant modeled the steel [ ] elements as fully embedded into the concrete infill and verified the approach using pushout tests. Section 8.9 of the Shield Building Report describes the results of these tests. The applicant also conducted finite element mesh sensitivity studies to confirm the adequacy of element size.

In the applicant's supplement to the Shield Building Report dated August 24, 2010, the applicant stated that a limitation of the confirmatory approach is that fracture of steel SC components (e.g., plates, studs, and [ ]) is not explicitly modeled. The applicant chose to establish acceptance criteria (strain limits), based on the guidelines in Nuclear Energy Institute (NEI) 07-13, "Methodology for Performing Aircraft Impact Assessments for New Plant Designs" and the applicant's experimental results, for use in analysis as discussed in Section 10.1 of the Shield Building Report. Once the strains in these components exceeded these limits, the analysis results were judged to be no longer valid. In Section 10.1 of the Shield Building Report, the strain limits for steel studs were set at 5 percent while those for reinforcing bars, including [ ] and steel plates, were set at 2 percent. Subsequently, the applicant revised the strain limits on the [ ] to 1.5 percent, as noted in its August 24, 2010 supplement.

Section 10.1 of the Shield Building Report states that the tensile strain limits for the steel faceplates, 2-percent maximum membrane tensile strain, and for the steel reinforcing bars, 2-percent tensile strain, were taken to be half as large as those in NEI 07-13. Tensile strain limits in NEI 07-13 are already set to be conservatively less than the fracture tensile strain limits for steel materials. For the [ ], the final tensile strain limit chosen by the applicant, 1.5-percent strain, is also less than the [ ] strains at maximum tensile stresses shown in response to Action Item 5. The staff has proposed accepting, through DG-1176, “Guidance for the Assessment of Beyond-Design Basis Aircraft Impacts,” issued July 2009, the ductile material strain limits in Table 3-2 of NEI 07-13 for use in aircraft impact analyses. The staff’s review of the applicant’s material strain limits for steel faceplates (2 percent and [ ] (1.5 percent) finds that these limits are more conservative than those in NEI 07-13 (5 percent for SA 516 plate and 5 percent for Grade 60 reinforcing steel). Based on the conservative use of the failure criteria recommended in NEI 07-13, the staff finds the strain limits chosen by the applicant for the steel faceplates and reinforcing bars to be acceptable for use in confirmatory analysis.

For the shear connectors (studs), the applicant set the strain limit at 5 percent for the ASTM A108 Nelson studs. The staff reviewed the Nelson stud material specifications for similar studs and finds that the specifications require a minimum percentage of elongation (5.1 cm (2 in) gage length) of 20 percent for mild steel and concrete anchors. Therefore, the applicant’s use of a strain limit of 5 percent is conservative, based on a comparison to 20-percent elongation over a 5.1 cm (2 in) gauge length. On the basis of conservative use of a failure strain of 5 percent, the staff finds that a strain limit of 5 percent for A108 Nelson studs is acceptable for use in confirmatory analysis.

<u>Verification with Experiments</u>

In its letter dated August 24, 2010, the applicant stated that the modeling approach would be verified by qualitative and quantitative comparisons with experimental observation and results from large-scale tests conducted by the model developers themselves. The applicant compared the predicted shapes, rotations, and cracking pattern with those observed experimentally. The predictions were also evaluated for behavior by comparing the predicted cracking patterns, steel strains, and particularly the mode of failure with those observed experimentally. The applicant also made quantitative evaluations by comparing the predicted load-deformation responses with those measured experimentally.

As an example, the applicant showed the predicted behavior and failure mode for an out-of-plane shear specimen (a/d=3.5)[1] in Figure 2. The applicant stated that the model predicted the location and orientation of concrete cracks, the formation of concrete compressive struts between cracks, and the tensile stresses and yielding of [ ] at the crack locations.

In Figures 3 and 4, the applicant also compared predicted and measured load with midspan displacement response for two out-of-plane shear critical tests (a/d=3.5 and 2.5). The applicant stated that the model predicted the initial and postcracking stiffness with reasonable accuracy and that overall strength and failure were conservatively predicted. The applicant indicated that the models predict tie-bar plastic strains of 1.5 percent, the strain limit for these bars, at a displacement that approximately corresponds to the displacement in the test when the test specimens failed in a brittle manner. Using the above strain limits, the applicant stated that the finite element models were able to predict the behavior of SC modules in the elastic and postcracked regions of response (typically corresponding to load levels up to and beyond the SSE) with reasonable accuracy.

[1] a/d refers to the length of spans to their depth, also referred to as shear span ratio.

In reviewing the applicant's confirmatory analysis, the staff identified several concerns that were discussed at a June 9-11, 2010, meeting and resulted in action items for the applicant related to the analysis benchmarking and methodology:

- In Action Item 12, the staff asked the applicant to provide a typical load case at the SSE level and compare cross-sectional forces for both the standard [ ] Level 1 analysis and for a linear analysis with the [ ] Level 2 model.
- In Action Item 15, the staff asked the applicant to indicate the locations in the calculated load deflection curves where the 2-percent limiting strains (total strains) would occur.
- In Action Item 16, the staff asked the applicant to provide the benchmarking analysis for the [ ] models.
- In Action Item 17, the staff asked the applicant to describe the handoff procedure from the Level 2 model [ ] to the Level 3 model [ ].

The applicant responded to the above action items in its letter dated August 3, 2010. In response to Action Item 12, the applicant compared forces and moments resulting from linear analysis with the [ ] and [ ] models. Both of the models used linear material properties. Table 12-1 of the response compares the forces and moments generated by the two models based on seismic loading at the same location. Based on its review of the results in Table 12-1, the staff finds that the percentage difference in analysis results between [ ] and [ ] is less than 6 percent for axial tension (F_y) and bending moment (M_z). Therefore, based on the applicant's comparison of the results from linear analysis with [ ] and [ ], which indicates a difference of less than 6 percent for the significant cross-sectional forces, the staff finds the applicant's response to Action Item 12 to be acceptable.

In response to Action Item 15, the applicant provided load-deflection plots in Figures 4.1.1-1 and 4.1.1-2 for out-of-plane test specimens with a/d=3.5 and a/d=2.5, respectively. The plots have markings that show the location in the force-displacement curves where plastic strains of 1.5 percent and 2.0 percent occurred in the analysis with the benchmarked models.

In Figure 3-3 of its September 3, 2010, submittal, the applicant compared the maximum out-of-plane shear demand at the design-basis seismic load (SSE level) with test results (a/d=2.5) and analysis prediction. The staff reviewed the force-deflection plots and finds that comparisons of analysis and testing for the out-of-plane specimens (a/d=3.5 and 2.5) agree reasonably well with respect to stiffness for demands up to the SSE level. Based on this observation, the staff finds the applicant's response to Action Item 15 acceptable.

In response to Action Item 16, the applicant provided additional information on the benchmarking of the [ ] model. For in-plane shear on SC modules, the applicant developed a model with the same characteristics as those used in the shield building wall. The inner and outer steel plates were modeled with 0.9 m (3 ft) elements and had a thickness of 1.9 cm (0.75 in). The applicant used the [ ] Winfrith material model and modeled the steel plate with a piecewise linear plasticity model. The model was loaded in pure shear, and the applicant verified the results against scaled Japanese test data (page 111)[2]. The applicant

[2] Westinghouse Electric Company, "Presentation and Actions for WEC Meeting with NRC June 9 through June 11," June 30, 2010. (ADAMS Accession No. ML101940046)

found that the model prediction of the in-plane shear capacity was in good agreement with the expected value.

For out-of-plane shear, the applicant performed additional [ ] confirmatory analysis. The applicant used models that had the same number of elements through the thickness of the wall as that used in the [ ] Level 2 analyses. Results of these comparisons, shown in Table 3.1 of the response to Action Item 16, indicate that the [ ] models are reasonably accurate for SSE load levels as well as for the range of applicability of the [ ] Level 3 models.

For the Level 2 and 3 local models, the applicant provided an example comparison of analysis predictions for the Wall 5 location. The results appear in Figures 4.1.2-27 through 4.1.2-29. The staff's review of these figures finds that the [ ] Level 2 and [ ] Level 3 models compare well for in-plane shear, out-of-plane shear, and axial tension. Based on the applicant's submittal of the [ ] benchmarking analysis, which presented benchmarking results for in-plane, out-of-plane, and Level 2 versus Level 3 models, the staff finds the applicant's response to Action Item 16 acceptable.

In response to Action Item 17, the applicant provided the steps performed to transfer analysis results from the [ ] Level 2 analysis to the [ ] Level 3 analysis, as well as the benchmarking of that procedure. The Level 2 and 3 integrated analysis includes the following steps:

(A) Identify critical regions in the shield building at the RC/SC interface and air-inlet regions.

(B) Generate the Level 2 model of the NI and shield building for the pushover confirmatory analysis, which includes models for the critical regions.

(C) Create Level 3 models for the same regions using the same cut boundary condition as in the Level 2 model.

(D) Perform the Level 2 analysis ([ ]) and extract the displacements at the cut boundaries of the critical regions.

(E) Apply the Level 2 displacements to the corresponding boundaries of the Level 3 models via shell elements that allow the coarse mesh Level 2 displacements to be interpolated and applied to the Level 3 nodes at the cut boundaries.

(F) Analyze the Level 3 models under the applied displacement boundary conditions in step (E).

To verify the adequacy of using displacements at the cut boundaries to transfer results from the Level 2 analysis to the Level 3 analysis, the applicant organized the benchmarking of this transfer method in two parts. The first part of this confirmatory analysis consisted of the following steps:

(A) Generate separate Level 2 models of the critical regions that match those for the Level 2 pushover analysis.

(B) Create Level 3 models for the same regions using the same cut boundary condition as in the Level 2 model.

(C) Apply unit loads at the boundaries of the Level 3 models to determine the stiffness of the Level 3 models for various loadings.

(D) Apply the same unit loads to the corresponding boundaries of the Level 2 models being benchmarked.

With this confirmatory analysis, the applicant assessed the relative stiffness of the Level 2 and Level 3 models. The range over which the response curves under the applied unit loads calculated with both models approximate each other identifies the range over which the two models have similar stiffness and, therefore, the range of acceptability of the handoff procedure. The applicant provided results from the confirmatory analyses in Figures 4.1.3-27 to 4.1.3-29 for Wall 5 and in Figure 4.1.3-31 for the air-inlet region. Based on the results in these figures, the staff finds that the applicant's handoff is acceptable for loads up to the SSE load level.

For the second part of the confirmatory analysis, the applicant developed an example simple shear wall model. The shear wall was loaded with three different loading cases (tension, in-plane shear, and out-of-plane bending) to verify the handoff procedure in different loading scenarios. Comparisons for axial tension (Figure 4.1.3-10), in-plane shear (Figure 4.1.3-12), and out-of-plane bending (Figure 4.1.3-15) show that the model and submodel compare reasonably well. Based on the review of the applicant's description of steps performed to transfer analysis results from the [ ] model and the verification results, the staff finds the applicant's response to Action Item 17 is acceptable.

<u>Pushout Tests</u>

The applicant performed pushout tests to evaluate the interaction between the [ ] that are welded to the steel plates and embedded in concrete infill. In Section 8.9 of the Shield Building Report, the applicant described the approach to conduct the confirmatory analysis for [ ]. All specimens used a [ ] pitch for stud spacing. Specimen 1 used normal concrete with two studs at [ ] spacing on each face with tie-bars in between the studs, while Specimen 2 used normal weight concrete with [ ] at [ ] spacing. Specimen 3 used self-consolidating concrete with [ ] aggregate and [ ]. Figures 8.9-4, 8.9-9, and 8.9-14 compare the analysis results (load displacement) and testing.

In Section 8.9.4 of the Shield Building Report, the applicant described the approach for modeling the [ ], as well as an evaluation of the mesh refinement. The applicant used the embedded method with [ ] concrete and shear connector elements for its simplicity and ability to capture the primary features of the load-slip displacement behavior.

The staff reviewed the applicant's analysis and testing, which provided results for the interactions between the [ ]. The staff reviewed Figure 8.9-4 and finds the applicant's recommended element size of [ ] to be acceptable for confirmatory analysis because the initial stiffness and strength of the shear connectors have a reasonable correlation to the test results.

Anchorage Test

In the Shield Building Report, the applicant performed a confirmatory analysis of an anchorage test. Although the anchorage test design represented an earlier design concept, described in Revision 1 to APP-1200-S3R-003, the applicant felt that the comparison was still useful for confirmatory purposes. The applicant modeled the full-scale test specimen using [ ] and the concrete damage plasticity model. The mesh size for both the [ ] and the concrete elements was 3.8 cm (1.5 in). In Figure 8.10-2 of the Shield Building Report, the applicant provided a comparison of analysis and test results that shows that the Level 3 models predict reasonably well the strains in the steel faceplates and in the dowels for strains up to about 2 percent. Analysis results in Figure 8.10-6 show the location and orientation of concrete cracks and the formation of compressive struts between cracks, which provide a reasonable explanation for the observed behavior under the monotonic load conditions for the test. The staff reviewed the applicant's comparison of test results and analysis predictions and finds that the analysis results agree reasonably for the entire range of response analyzed and for the monotonic load conditions of the test. The staff notes that although the results reflect the early anchorage design, the comparison between the analysis and the test is acceptable for confirming the strains of the faceplates and the dowels. This finding only applies to the benchmarking of the finite element model for monotonic loading. The assessment of anchorage design may be found in Section 3.8.4 of this evaluation.

Confirmatory Analysis Results

Tables 10.3-2 through 10.3-5 of the Shield Building Report provide the results of the confirmatory analysis for critical areas: the air inlets, west wall, Wall Q, and Wall 5. For SSE load levels, the stress levels in the steel plates, [ ] are below the yield level for each component in the west wall, Wall Q, and Wall 5. In the air-inlet region, there is some predicted yielding of studs with a strain of 0.52 percent. However, this strain is less than the assumed failure strain of 5 percent. The staff finds that these results indicate that while there is some degree of concrete cracking predicted by the nonlinear analysis, as expected, the stresses and strains in the shield building critical areas are below yield, with the exception of some local stud yielding in the air-inlet region.

Conclusion on Confirmatory Analysis

In summary, the staff concludes that the applicant has: (1) performed testing to obtain data on the response and behavior for key failure modes of the SC wall modules; (2) developed confirmatory analysis models; (3) shown that the models predict the observed experimental behavior and response with acceptable accuracy up to the design-basis seismic load level (SSE); and (4) used the confirmatory analysis to predict stresses and strains in critical areas of the shield building for the SSE load level. Further, the staff finds that the applicant has adequately addressed the staff's concerns raised in Action Items 12, 15, 16, and 17, as identified in applicant's June 30, 2010, submittal.

Based on the above findings and the applicant's SSE load level predictions of low stress and strain values in the SC steel plates, [ ] the staff finds the applicant's confirmatory analysis approach to be acceptable. Further, the staff finds the applicant's use of the ACI 349 Code for the design of these critical sections to be acceptable.

3.8.4.1.1.3.4 Seismic Demand and Analysis Methods

Chapter 10 of the Shield Building Report describes the applicant's analyses to determine how the seismic demand that is imposed on the AP1000 NI is implemented in the design of the shield building.

The applicant used three-dimensional finite element models generated with the [ ] and [ ] codes to perform the dynamic analyses. These models comprised shell, beam, and solid elements to represent the structural geometry of the NI. For determining the design-basis FRS and demands used for structural design of the shield building, the applicant used the [ ] NI20 model to perform SSI analyses (for soil sites) and the [ ] NI10 model to analyze the HR site condition. Both models idealized the shield building wall structure with a single shell element representing the SC wall module. The staff reviewed this assumption and found it to be unsubstantiated in both TR-03 and in Revision 1 to APP-1200-S3R-003.

The staff was concerned that a single shell element would not be adequate to analyze the complex through-thickness strain gradients expected near structural discontinuities and to account for concrete cracking. Discussed below is the staff's evaluation of the applicant's method of designing the specific components of the tension ring, air-inlet region, W36 beams, conical roof, and PCCWST.

<u>Determination of Responses to Earthquake Loads</u>

For the design of the shield building, the applicant used response spectrum analyses and the [ ] NI05 model to perform seismic analyses. The applicant validated the [ ] NI05 model, which is a refined version of the [ ] NI10 model, against the NI10 model by comparing the mass participation by frequency of the various response modes of the structure. The NI05 model consists of a combination of shell elements, namely [ ] SHELL 45 for most of the SC wall, solid elements, beam elements, and lumped masses to represent the principal components and structures in the NI. The chosen finite elements for the SC modular wall and the overall refinement of the finite element model are adequate for the calculation of design load demands for the shield building wall for a structure with the proportions of the shield building. The input response spectra at the underside of the basemat were determined from the envelope of the response spectra for all soil cases as well as the HR case. The staff finds that the applicant has correctly applied the input spectra since the spectra envelop the range of soil conditions defined for the AP1000 plant.

For the design of the shield building roof, the applicant used equivalent static analyses with a more refined [ ] finite element model to calculate load demands for the air-inlet region, tension ring, PCS tank wall, and various structural components of the roof. Specifically, the applicant developed a highly detailed linear finite element model of the shield building structure above El. 62.48 m (205 ft). This model, described in Shield Building Report Section 6.2.2, took advantage of the axial symmetry of the shield building above El. 62.48 m (205 ft) to model only a quarter of the building. The applicant used this detailed quarter finite element model because the shield building roof required a more detailed finite element representation to properly capture the demands on each of its structural components. The horizontal input acceleration was an angular acceleration located in the soil beneath the basemat such that the lateral accelerations matched the horizontal accelerations from the SSI analysis. To account for concrete cracking, the stiffness reduction factor of 0.80 times the concrete modulus was utilized in the seismic analysis.

The applicant then combined seismic responses (member forces and deformations) to determine the stresses in some regions of the shield building structure. The Shield Building Report states that the responses of the shield building structure, from the three directions of seismic input, are combined by the square root of the sum of the squares (SRSS) method. However, as clarified in the September 2, 2010 response to RAI-TR85-SEB1-27, and in Shield Building Report, Revision 4, Section 6.2.2, the applicant used the 100-40-40 method for combining the three directions of seismic responses for the shield building roof (tension ring, air-inlet region, W36 beams, conical roof, and PCCWST), the containment, and the basemat. Member forces from the shield building analyses were generated for each element or at critical cross-sections (e.g., the ring girder).

The application of the SSRS method is acceptable to the staff since this method is in accordance with RG 1.92, Revision 2. However, the applicant indicated that use of the 100-40-40 method has reduced the steel reinforcement area by 16 percent when compared to that of the SSRS method (page 3-17 of the Shield Building Report), which the staff believed should not occur when the 100-40-40 method is properly implemented. The applicant addressed this issue for the shield building and the containment in its response to RAI-TR85-SEB1-27 and for the basemat in its response to RAI-TR85-SEB1-32. These two RAIs were addressed and considered resolved. The staff's evaluation of the applicant's response regarding the implementation of the 100-40-40 method is described in Sections 3.8.4.1.1.3.7 and 3.8.5 of the SER.

Design for Concrete Cracking and Steel and Concrete Composite Damping

The applicant stated that its SC wall module is designed in accordance with the strength method in ACI 349. The applicant used a linear elastic analysis finite element computer code, [ ], to quantify the seismic response of member forces in elements for the shield building design. In Section 10.2.1.1 of the Shield Building Report, the applicant stated that for design-basis seismic analysis (Level 1), concrete structures are modeled with linear elastic un-cracked properties with the modulus of elasticity reduced to 80 percent of its value. This reduction is made in order to reduce stiffness and to reflect the observed behavior of concrete when stresses do not result in significant cracking, as recommended in Table 6.5 of FEMA 356.

In Section 3.2.1 of the Shield Building Report, the applicant stated that the SC material damping is assumed to be 5 percent. The staff noted that 5 percent is appropriate for SSE demand and typically invokes a reasonably high response level that includes appreciable concrete cracking. However, the staff was concerned that a reduction factor of 0.8 and 5-percent material damping were incompatible.

In Appendix B to the Shield Building Report, the applicant provided the data on concrete cracking for the shield building (Figures B-18 through B-21) and the auxiliary building (Figures B-48 and B-49) predicted by [ ]. The applicant stated that the predicted concrete cracking for the shield building and auxiliary building was extensive. As a result, the staff could not find the justification for the assumption of a 0.8 reduction factor (for the stiffness ratio) and 5-percent material damping, given the level of cracking indicated in the [ ] analysis. To address this concern, the staff issued RAI-SRP3.7.1-SEB1-19 and requested that the applicant revise its response to RAI-SRP3.8.3-SEB1-03 as appropriate.

In a letter dated July 30, 2010, the applicant updated its responses to RAI-SRP3.7.1-SEB1-19 and RAI-SRP3.8.3-SEB1-03 and provided comparisons of the results of [ ] linear and nonlinear analyses that were time-history analyses based on the envelope of the soil and rock profiles. Comparisons were made at the shield building roof elevation, shield building west wall (at grade elevation), and four other locations in the auxiliary building.

The applicant also provided stress/strain curves for the [ ] linear and nonlinear analyses and showed that cracking was occurring under SSE loading using 5-percent structural damping. The staff reviewed these results and finds the applicant's use of 5-percent structural damping acceptable based on the predictions of seismic demands sufficient to cause concrete cracking.

The staff reviewed the comparisons of ISRS for the analyzed locations and finds only minor differences in response between the [ ] linear and nonlinear models. The small differences in response suggest that the [ ] concrete stiffness reduction factor is a reasonable assumption for SSE loading. However, the applicant did not provide [ ] comparisons for the same locations. Since [ ] is the AP1000 design-basis code, the staff believes that the comparisons of [ ] to [ ] are necessary to validate model similarity.

At the August 18–20, 2010, structural audit, the applicant presented the comparison between the [ ] and [ ] linear analysis results. This comparison sufficiently demonstrated the similarity between the [ ] and [ ] models. In its letter dated September 3, 2010, the applicant updated its response to RAI-SRP3.8.3-SEB1-03 to include the comparisons to [ ].

In conclusion, the staff finds the approach for addressing concrete cracking acceptable. Further, the applicant's studies using [ ], and the correlation of linear results between [ ] and [ ] indicate that a reduced concrete modulus of [ ] and a damping value of 5 percent are justified for the design-basis analysis of the SC wall in the shield building. Therefore, the staff considers these technical issues to be resolved; further discussion appears in Section 3.7.2 (RAI-SRP3.7.1-SEB1-19) and Section 3.8.3 (RAI-SRP3.8.3-SEB1-03) of this report.

In a June 9-11, 2010, meeting, the staff asked the applicant to address concerns about the redistribution of shield building forces resulting from concrete cracking. This item was identified as Action Item 4. To ensure that the dynamic analysis models accounted for the effects of the redistribution of forces caused by shield building concrete cracking, the staff asked the applicant to assess the effects of cracking near the base of the west wall and right above the roof at the auxiliary building. Further, the staff asked the applicant to demonstrate that for SSE-level loading, the maximum in-plane shear stresses remain within the limits allowed by ACI 349.

In its July 30, 2010, letter in response to Action Item 4, the applicant provided the requested comparisons using the [ ] (nonlinear) and [ ] (linear) analysis codes to address the extent of concrete cracking and any needed load redistribution caused by the cracking. The applicant compared concrete shear stress at various locations along the west wall at El. 100′. The results shown in Figures 4-3 through 4-6 of the letter indicate that the in-plane concrete shear stress using [ ] and [ ] remains below 4136 kPa (600 psi) for critical design locations analyzed. The applicant stated that these results demonstrate that the in-plane shear stress is below the allowable shear stress of 4688 kPa (0.85×800 psi = 680 psi) in ACI 349, Section 11.7.5.

The applicant also provided results for in-plane shear distribution at the east wall above the auxiliary building roof. Figure 4-8 provides a comparison of the [ ] and [ ] results and indicates that shear stress is below the ACI 349 allowable limit of 4688 kPa (680 psi).

Based on a review of the applicant's [ ] and [ ] analysis results, the staff finds that the applicant's in-plane concrete shear stresses are below ACI 349 allowable limits at El. 30.4 m (100 ft) and at the east wall above the auxiliary building roof and, thus, finds the results to be acceptable and in accordance with the criteria in NUREG-0800 Section 3.8.4. Therefore, the staff finds the applicant's response to Action Item 4 to be acceptable.

Thermal Loads - Concrete Shrinkage and Thermal Cycling

In both the NRC's letter of October 15, 2009, and Action Items 19 and 20 from the meeting of June 9-11, 2010, the staff raised concerns related to the need for the applicant to consider the effects of concrete shrinkage and thermal cycling loads in the design of the shield building. The staff based its concern, in part, on issues identified in a study by Oliva and Cramer, of the Structures and Materials Test Laboratory at the University of Wisconsin, entitled "Self-Consolidating Concrete: Creep and Shrinkage Characteristics," issued January 2008. The study shows that self-consolidating concrete may exhibit a higher dimension change because of creep and shrinkage than conventional concrete does under shear friction loads. In the Shield Building Report, the applicant predicted extensive vertical cracking because of thermal cycling. As a result, the staff asked the applicant to analyze how the extent of cracking and the load will be redistributed via the design of the shield building to preclude the effects of the cracking on the integrity of the structure.

In response, the applicant reevaluated the thermal shrinkage effect of the in-filled concrete in the SC wall module. After reviewing the parameters used in the thermal shrinkage and thermal cycling analyses, the applicant used a more realistic shrinkage strain value of 200 micrometers per meter (μm/m) ($2x10^{-10}$ inches per inch (in/in)). The applicant stated that the use of the shrinkage strain value indicates that no cracks occurred and the stresses produced on concrete and steel surface plates are extremely low.

The staff believes that the original applicant thermal shrinkage analysis, with the shrinkage strain of 400 μm/m (4×10^{-10} in/in) is conservative because it exceeds the realistic strain value of 200 μm/m (2×10^{-10} in/in). Further, the applicant performed a finite element model analysis using the same three-dimensional finite element model. The finite element model analysis performed was a coupled thermal-mechanical analysis using [ ] 6.9-EF1. This analysis consisted of two approaches—thermal shrinkage and thermal cycling. For thermal shrinkage, an equivalent temperature drop was simulated to produce a uniform thermal contraction in the concrete equal to 200 μm/m (2×10^{-10} in/in). For thermal cycling, a cyclical temperature gradient of 43.33 °C (110 °F) over a 24-hour period was applied. This resulted in a maximum circumferential stress of 2.1 megapascal (MPa) (0.3 ksi) on concrete and -25.8 MPa (-3.74 ksi) on the steel surface plates. The thermal cycling analysis resulted in a maximum circumferential stress of 0.345 MPa (0.05 ksi) on concrete and -2.38 MPa (-2.02 ksi) on the steel surface plates.

The staff reviewed the applicant's reanalysis of thermal cracking and found that the concrete strain of 400 μm/m (4×10^{-10} in/in) is conservative and that vertical cracking is minimal; therefore, the reanalysis is acceptable.

3.8.4.1.1.3.5 Design and Testing for Ductility

In its letter of October 15, 2009, the staff stated that the applicant must demonstrate the adequacy of the design and detailing of the SC wall module to function as a fully composite unit as assumed in the design and analysis. In addition, the staff stated that the applicant must demonstrate that the SC wall module had sufficient ductility to survive earthquakes or tornado winds.

In response to this concern, the applicant made several design changes to the shield building. In the executive summary of the Shield Building Report, the applicant stated that design changes were made to the shield building to improve strength and ductility. These changes included adding [ ] connecting the surface plates to demonstrate that the structure will act as a unit under design-basis events. Further, design changes were made to the SC/RC connection, using mechanical connectors to directly transfer the forces from the SC structure to the RC structure, such that the connection will exhibit strength and ductility during seismic events. The applicant stated that the design of the critical features, such as the SC wall module, the SC/RC connection, and the tension ring/air-inlet region, was verified using benchmarked nonlinear analysis in order to demonstrate the overall strength and ductility of the AP1000 shield building. The applicant further stated that it performed benchmarked analyses (confirmatory analysis) and testing to demonstrate that the design has adequate margin to withstand the SSE in accordance with NRC regulations.

In Section 10.2 of the Shield Building Report, the applicant described the detailed analysis performed to support the basis for estimating the shield building system ductility (or drift ratio). The applicant calculated the drift ratio to access the level of system ductility provided in the shield building. The staff notes that the applicant's definition of drift ratio is the ratio of maximum displacement corresponding to a beyond-design-basis demand (e.g., review-level earthquake and the maximum displacement corresponding to the SSE-level demand. In its June 30, 2010, letter (page 63), the applicant provided an updated comparison of results shown in Table 10.2-5 of the Shield Building Report. The results were obtained using the Level 1-3 analysis models discussed in Section 3.8.4.1.1.3.2 of this SER. The applicant calculated a maximum drift ratio of 6.4 corresponding to the Level 3 analysis displacement (19.6 cm (7.7 in)) from 2.6 SSE loading divided by the SSE-level displacement (3.0 cm (1.2 in)). However, the staff was not able to correlate predicted drift ratios with system ductility. To address this concern, the staff asked the applicant to provide further clarification of its design in relation to ductility. In its response, the applicant supplemented the June 30, 2010, submittal with a letter dated September 3, 2010, which described its philosophy and approach to design and their implications to ductility.

The applicant stated that its design philosophy in relation to ductility is analogous to the "capacity design" approach in FEMA 356-2000, in which the designer identifies a ductile failure mechanism for the overall structure, designates structural fuses that will undergo inelastic deformations and dissipate energy, designs and details the fuses to prevent brittle failure modes from controlling their behavior, and designs the remaining portions of the structure with sufficient strength to resist the force demands delivered by the fuse regions. This approach is referred to as a "strong column-weak" beam design approach in accordance with ACI 349-01, Article 21.4.2.2, for the design of moment-resisting frames.

The applicant's approach is to identify, from the results of the analysis for the calculation of member forces and through confirmatory analysis, the locations in the SC structure that are predicted to become plastic hinges (called fuses by the applicant) when subjected to earthquake forces. In the case of the shield building, this requires earthquake forces beyond the design basis seismic loads. Design detailing for the regions in the shield building assumed to be plastic hinge regions conforms to requirements in ACI 349-01, Articles 21.3.3.1-21.3.3.3, which results in shear reinforcing spacing of depth divided by [ ] maximum. This detailing is intended to prevent brittle failure modes from pre-empting the ductility of the plastic hinge regions. In regions outside of these assumed plastic hinge locations, the applicant's design conforms to Article 21.3.3.4, which requires shear reinforcement ([ ]) spaced at no farther apart than half of the depth dimension. In addition, the design for these regions also provides sufficient strength to meet the calculated design demands. Although the ductility detailing requirements in Sections 21.3 and 21.4 of ACI 349 do not apply to the shield building structure, the applicant invoked them for the analogy of the applicant's design approach to the "capacity design" approach.

Continuing its analogy to the "capacity design" approach, the applicant stated that in regions of high out-of-plane shear demand, close to supports and connections with other structures, [ ]. At the connection to the basemat, this region extends [ ] above the connection region, [ ]. In SC to RC connection regions within the auxiliary building, [ ] spacing extends beyond the connection to about [ ] above and to the side of those regions of the shield building where other structures, such as the shield building roof, attach to the SC wall. The actual distance above this SC to RC connections is, [ ].

In regions away from supports and connections, the AP1000 uses SC modules with [ ], which provides sufficient strength to meet the calculated demands.

The following is the staff's evaluation of the safety of the shield building based on the applicant's method of demonstrating that there is ductility in the design of the shield building.

The staff finds that ACI 349-01, Article 21.4.2.2, is intended for moment frame structures and is not directly applicable to cylindrical shell structures, such as the AP1000 shield building. Cylindrical shells will distribute forces in a manner that differs from a 2D or 3D framed structure. Specifically, cylindrical shells primarily resist seismic lateral loads through membrane action by a combination of in-plane shear, to resist lateral shears, with tensile and compressive forces to resist overturning moments. Furthermore, ACI 349-01 has neither provisions nor requirements for ductility detailing for unique structures, such as the shield building. The staff also finds that the calculation of member forces for the design basis seismic loads for the shield building did not involve load reductions that invoke the formation of plastic hinges for the dissipation of energy. In addition, the applicant's own design methodology for the shield building, based on ACI 349-01, requires that shear strength capacity must be provided everywhere including the assumed hinge locations, which is done for the shield building.

Providing sufficient strength in the plastic hinge regions to meet the calculated shear demands is not a requirement for the "capacity design" approach. For the above reasons, the staff finds that the applicant's design methodology for the design of the shield building to resist seismic loads is not, in a strict sense, a "capacity design" approach.

However, the staff agrees that the inherent premise used in ACI 349, Article 21.4.2.2, of providing ductile detailing where demands are high, can be extended to a cylindrical shell if analysis has been performed to identify locations of high demands, and conservative out-of-plane shear strength to meet the calculated demands is provided elsewhere. For the AP1000 shield building, the applicant provides ductility detailing in the regions of high demands. In the regions of low out-of-plane shear demands, the applicant provides [ ] at a spacing less than one-half of the depth of the wall and conservative demand to capacity ratios

(Reference September 3, 2010 submittal, Figure 4-1, and Reference June 30, 2010, submittal, Figures F1.1.2-1 to F1.2.2-16).

Also in the September 3, 2010, submittal, the applicant stated that cylindrical shells, such as the shield building wall, primarily resist seismic lateral loads through membrane action by a combination of in-plane shear, to resist lateral shear together with tensile and compressive forces to resist overturning moments. Subsequently, the applicant concluded, based on this understanding and the results of a [ ] for seismic loads greater than the design basis loads, an overall ductile failure mechanism would develop in the shield building structure with the structural fuses located in the SC portions of the shield building as designed. According to the applicant, the structural fuses have small inelastic strains and are located either close to the base of the structure, or at support points, or where there are connections to the auxiliary building.

More specifically, also in Section 2.0 of the September 3, 2010, submittal, the applicant states that the [ ] indicates that for seismic loads greater than the design basis loads, the overturning moment and base shear at the base of the structure cause either tension yielding of the steel plates in the SC portion, or tension yielding of the steel reinforcement in the RC portion of the shield building, depending on the loading combination and direction. In this submittal, the applicant also states that for loads greater than the seismic design basis loads, yielding of the steel faceplates from in-plane shear can occur for certain loading directions. Thus, the ductile failure mechanism for the overall structure is governed by the yielding of steel plates or yielding of steel reinforcement in the RC portion of the structure. The applicant then concluded that for loads greater than the design basis loads, the shield building would develop a ductile failure mechanism with structural fuses in the SC portions located as designed.

The staff evaluated the applicant's design approach of providing ductility detailing in the regions of high stresses and of providing the strength necessary to meet the design demands in the regions of low demands and finds it to be reasonable. This approach conforms to the approach in ACI 349-01, Articles 21.3 and 21.4 for moment resisting frames, for which ductility design is required by ACI 349, as opposed to structures such as the shield building structure for which ACI 349 does not have ductility provisions or requirements. The staff also finds that the shield building structure, a complex cylindrical shell, distributes loads in a manner that differs from 2D or 3D frames and can be more uncertain. The staff finds that the shield building design provides conservative demand to capacity ratios in the regions of the wall with [ ] that can account for those uncertainties. Specifically, the calculated demand to capacity ratios for out of plane shear are for the most part less than or equal to 0.3. In addition, the regions of the wall where these demand to capacity ratios are higher than 0.3, and as high as about 0.6 in a few locations, are small in area and localized.

The staff finds that the combination of the low demand to capacity ratios for out-of-plane shears in the regions with [ ] spacing with ductility detailing in the regions of high demands provides reasonable assurance of the building safety under the design basis seismic loads by ensuring that the building has structural capacity in reserve, through a combination of structural strength and ductility, for the seismic design basis loads.

<u>Testing for Strength, Cyclic Loading and Ductility</u>

Section 7.11.1 of the Shield Building Report states that tests were conducted to demonstrate the cyclic behavior and ductility of the SC-portions of the shield building. [

]. Since there are two types of shear loads (the one perpendicular to the wall, which is called out-of-plane shear, and the other along the wall in the hoop direction, which is called in-plane shear) acting concurrently and simultaneously on any point of the shield building during earthquakes, [

]. One type of SC module is used at or near connection regions, which require high shear ductility and strength, and the proposed design and detail for that SC module was to use [ ] between faceplates, and spaced [ ] in both vertical and horizontal (hoop) directions. The other type of the SC modules is used for the remaining portion of the shield building wall with less shear ductility and strength demand, away from the connection regions, and the proposed design and detail for that SC module was to use [ ] between faceplates, [ ] in both vertical and horizontal (hoop) directions. The applicant's acceptance criteria for the ductility tests for each type of module under each kind of shear loads are listed below:

The applicant used the following acceptance criteria for the ductility tests:

<u>Acceptance Criteria for Ductility Tests</u>

For out-of-plane shear, ductility was to be established and measured through a loading protocol as follows:

– [

].

– [

]..

For in-plane shear

– [

].

<u>Out-of-Plane Shear Testing To Demonstrate Ductility</u>

The out-of-plane shear test specimen [ ] tie-bar spacing tested monotonically at shear span a/d=3.5 indicated a brittle failure mode at the load of [ ] and had less strength than the companion specimen tested monotonically at a/d=2.5, which attained a higher load [ ]. The test results for out-of-plane shear showed that the modules with [ ] [ ] failed in a brittle manner and that the case with a [
is the more critical shear case.

However, the staff notes that information provided by the applicant in its supplemental letter dated September 3, 2010, Figure 3-3 indicates that there is sufficient margin between the load corresponding to the maximum SSE-level demand (approximately 80k) and the failure load of the both out-of-plane specimens [ ]. According to the applicant's design methodology this margin will be less than that shown in this figure when only the contribution of the steel is taken into account to account for tensile forces. Even for these conditions, the staff finds that there is significant margin in the specimen to preclude a brittle failure under design-basis (or SSE) loads.

The staff also finds that the tests results show that there is conservatism in the use of the ACI 349 equation for strength, $V_n=V_s+V_c$, for the AP1000 SC structure in that the design strength is bounded by the load at which brittle failure in the SC specimens occurred.

<u>SC Modules under Cyclic Loads</u>

For SC modules under cyclic loads, the applicant stated that the test specimen with [ ] developed its plastic moment capacity and had excellent cyclic behavior during the [ ]. Further, the applicant stated that the specimen demonstrated some strength degradation during the [ ].

The staff reviewed these test data, and concludes that the SC module attained a higher load [ ] than the specimen [ ], and attained a displacement ductility ratio (the displacement value at failure divided by the displacement value at yield) of [ ].

The applicant stated that the specimen with [ ] developed its expected shear strength of [ ] and had excellent cyclic behavior during the [ ]. Some strength degradation during the [ ] cycles was observed, but the shear strength of the specimen was still greater than the expected shear strength. [ ].

The staff reviewed the test data, and finds that the applicant defined the yield displacement at the point at which the specimen achieved the strength (V_c + V_s), which is different from the Δy definition of Δy as stated for the above module with [ ], and is incorrect for this test. By judging the hysteretic curves, this test specimen had not been loaded to sufficiently high displacements to induce yielding of the steel faceplates. Therefore, referring to the loading cycles as [ ], as stated by the applicant, is incorrect. The applicant addressed the staff's concern by removing [ ] signs from the figure in its September 3, 2010, submittal.

However, the applicant provided in the September 3, 2010 submittal on ductility, Figure 4-2, which shows the measured cyclic shear force mid-span displacement response of the specimen [ ]. The staff finds that the cyclic test response shows [ ]. Further, the out-of-plane shear strength of the non-fuse specimen under cyclic loading can still be estimated using the ACI 349 Code equations and the specimen exhibited adequate cyclic load behavior at load levels equivalent to calculated out-of-plane shear demands.

The staff finds that testing of SC wall modules with [ ] spacing did not demonstrate that the SC wall module is ductile because it did not meet acceptance criteria for ductility as proposed by the applicant.

Nonetheless, in the staff's view, the SC module [ ], although it failed in the first cycle at [ ], showed appreciable ductility and is expected, if it were tested at [ ], to result in reasonable ductility in the design. Therefore, in the staff's view, this test demonstrates that sufficient ductility capacity exists for the SC module [ ].

<u>In-Plane Shear Cyclic Testing To Demonstrate Ductility</u>

In Section 7.12 of the Shield Building Report, the applicant described the in-plane cyclic shear tests designed to demonstrate the cyclic behavior and ductility of the SC shield building design for in-plane shear loading. [ ].

The staff's review of the test plan for the in-plane shear test (Section 7.12) finds that the test model and test set-up boundary conditions [ ], as shown in Figures 7.12-1 to 7.12-5, may provide additional resistance and can lead to an over-estimation of the actual strength of the SC wall module. The applicant had to terminate the test after [ ] due to laboratory safety constraints and, therefore, could not complete the ductility test. The staff believes that cyclic loading beyond the yield point is needed to ascertain the ductility of the SC module and to observe the deterioration of the concrete between the faceplates.

In the September 3, 2010, submittal, the applicant provided a plot of the [ ] (Figure 5-2) and an envelope plot of cyclic lateral load (Figure 5-3). The applicant stated that the test results demonstrated that the SC specimen could undergo loads with acceptable deformations up to [ ] the SSE level.

The staff's review finds that the test was inconclusive with respect to demonstrating ductility. However, the applicant, in Section 5.1 of the submittal dated September 3, 2010, described tests on SC modules conducted by Ozaki et al. (2004) to supplement the basis for demonstrating ductile in-plane behavior. These tests on SC panels were performed to determine the cyclic in-plane shear and to evaluate the effects of various plate parameters, such as plate thickness and axial force. One of the test specimens, S4-00NN, was judged by the applicant to be the most relevant to the AP1000 SC module. [ ]. The ratio of shear stud spacing to plate thickness is 30 for specimen S4-00NN and 11.33 for the AP1000 SC module. Consequently, the applicant concluded that the behavior of the AP1000 SC module will be slightly better than that of the S4-00NN specimen. Specimen S4-00NN had a measured ductility value, defined as ultimate strain to yield strain, of 2.82, as shown in Figure 5-1 of the September 3, 2010, submittal.

The staff reviewed the Ozaki paper, and found that the test was properly conducted and credible. In SER Table 3.8-1, staff performed a review of the Ozaki, et al. paper to compare a few key parameters of the AP1000 design and the S4-00NN specimen. Based on this comparison, and the good agreement of SC parameters, the staff finds the applicant's use of the test data to demonstrate ductility of the SC wall to be appropriate.

Table 3.8-1. Comparison of Test Specimen of S4-00NN and AP1000 SC Module

Parameter	Test Specimen S4-00NN	AP1000 SC Module
SC wall thickness/faceplate thickness	44.4	[ ]
Stud spacing/wall thickness	0.67	[ ]
Stud spacing/plate thickness	30	[ ]
Concrete compressive strength MPa (psi)	42.79 (6,206)	[ ]
Steel plate yield stress MPa (ksi)	346.1 (50.2)	[ ]

The staff finds that although there were concerns regarding the test setup at Purdue, the test results indicate that the design for the in-plane shear strength criteria used ([ ]) is adequate.

In addition, the staff finds that although the Purdue test specimen was actually a framed shear wall and the stiffness of the frames was added to that of the wall during the test, the test results (reported in the Osaki paper) help assure the staff of the behavior of the SC wall module under SSE loads.

<u>Conclusion of Design and Testing Related to Ductility and Safety of the Design</u>

In summary, the staff finds that the purpose of shear tests is to establish the minimum shear reinforcement ([ ]) to the SC module so that it can function as a unit to resist both out-of-plane and in-plane shear forces, provide sufficient ductility (energy absorption/dissipation capability) for seismic-induced energy, and provide sufficient stiffness for the shield building to meet the allowable building drift limit. The staff finds that the tests were an acceptable basis to establish this minimum.

The staff finds that ACI 349 (Article 21.4.2.2) is intended for moment frame structures and is not directly applicable to cylindrical shell structures, such as the AP1000 shield building. Cylindrical shells distribute forces in a manner that differs from a two- or three-dimensional framed structure. However, the staff agrees that the inherent premise used in Article 21.4.2.2 (providing ductile detailing where demands are high) can be extended to a cylindrical shell if analysis has been performed to identify the locations of high demands.

Also, the staff finds that for the AP1000 shield building, the applicant provided ductility detailing in the regions of high demands. In the regions of low out-of-plane shear demands, the applicant provided conservative demand-to-capacity ratios (Figure 4-1 of its June 30, 2010, submittal and Figures L.4-23 and L.4-24 of the Shield Building Report, Revision 4). The staff finds this approach to be acceptable.

In addition, the staff finds that the AP1000 shield building design has [ ] spacing to ensure that the SC modules will function as a unit. For the regions of the SC wall with higher out-of-plane shear loads, and where yielding of the SC wall would be expected to initiate under a combination of tensile forces and out-of-plane bending for seismic loads in excess of the design-basis loads, the applicant detailed the SC modules with [ ] spacing to provide out-of-plane shear ductility. For the regions of the SC wall with low out-of-plane shear demands [ ], and the SC wall detailing does not provide out-of-plane shear ductility. In these regions, the out-of-plane shear demands calculated by the applicant are low and the SC wall modules as detailed provide conservative strength demand to capacity ratios.

For the in-plane shear test, the staff finds that the test results indicate that the design for the ACI 349 the in-plane shear strength criteria used, [ ] is adequate. The test results were inconclusive with respect to measurable ductility. However, cyclic ductility tests performed in Japan (documented in the Ozaki paper) indicate that the wall will exhibit ductile behavior under cyclic in-plane shear. On these bases, the staff concludes that the SC wall will provide adequate strength, stiffness, and ductility under design-basis (or SSE) seismic loads.

The staff finds the design for strength, stiffness, and ductility to be acceptable.

3.8.4.1.1.3.6 Design of the Steel and Concrete Composite-to-Reinforced Concrete and Basemat Connections

Section 4.1.1 of the Shield Building Report describes the design details for the revised shield building connection. The applicant stated that the steel liner plates are connected to the RC wall reinforcing bars by [ ] of the SC/RC connection (Figures 4.1-2 through 4.1-5 of the Shield Building Report). [ ]. The [ ] connection is designed to the allowable working stress limits of ANSI/AISC N690 for loads in the reinforcing bars equivalent to 125 percent of the yield strength of the specimen.

In its review of the SC/RC connection design, the staff identified several concerns discussed at the June 9-11, 2010, meeting and documented as action items. In Action Item 7, the staff asked the applicant to clarify the design and load path for the SC/RC connection. In Action Item 8, the staff asked the applicant to provide justification that voids in the SC/RC connection region would not affect the load path in compression. In Action Item 9, the staff asked the applicant to provide verification that calculated shear friction values in the SC/RC connection are below the ACI 349 allowable limit. In Action Item 11, the staff asked the applicant to identify the type of [ ] connector used for the shield building, in accordance with ACI 318, Chapter 21, and to justify the use of [ ], as appropriate.

In its August 3, 2010, letter, the applicant provided responses to the above action items. In response to Action Item 7, the applicant, in Table 2.1.1-1, stated that it would implement a design change to the SC/RC connection. The applicant stated that [ ] will be used to connect the #14 reinforcement bars in the basemat to the [ ] connection. In addition the applicant compared connection yield capacities of the SC/RC connection components, such as the [ ]. In addition, the applicant summarized the stress ratio (i.e., demand to capacity ratio) for the various loading conditions on the SC/RC connection components. In Table 2.1.1-2, the applicant provided the stress ratios for tension (0.37), compression (0.84), moment (0.08), in-plane shear (0.84), out-of-plane shear (0.05), and combined tension, bending, and in-plane shear (0.64).

Based on the applicant's description and data for the SC/RC design change, component capacities, and component stress ratios that are all less than one, the staff finds the applicant's response acceptable.

Further, for Action Item 7, the applicant described the load path and showed that with the combination of 2.5 cm (1 in) thick liner plate, 5.1 cm (2 in) support plate, 5.1 cm (2 in) gusset plate, [ ], the RC/SC connection can transfer loads from tension, compression, bending moments, and shear. Hence, the load path is established through the SC/RC connection and is acceptable to the staff.

In response to Action Item 8, the applicant stated that small gaps under the connection support plates will not affect the load transfer in compression. The applicant stated that the gap under the support plates is considered for the calculation of the capacity of the connection for compression forces, as shown in Figure 2.1.2-1. Further, the direct transfer of compression force through the concrete is only considered in the region between the support plates. The applicant calculated a compression ratio for the concrete between the support plates to be less than one (0.84). Based on the applicant's calculation of compression ratio, which neglects the concrete contribution beneath the support plates, the staff finds the response to Action Item 8 to be acceptable.

In response to Action Item 9, the applicant stated that since the design of the SC/RC connection was changed from smooth bars to deformed reinforcement bars, the ACI 349 Code was applicable. The applicant calculated the SC/RC shear capacity in response to Action Item 7 and provided the demand-to-capacity ratios in Table 2.1.1-2. The reported demand-to-capacity ratio for in-plane shear was 0.84 and for out-of-plane shear was 0.05. This indicates that the capacity of the connection is 16 percent higher than the demand. Based on the applicant's design change from smooth to deformed reinforcement bars and the shear capacity being within ACI 349 limits, the staff finds the response to Action Item 9 to be acceptable.

In response to Action Item 11, the applicant stated that it will use the ACI 318 Type 2 mechanical splice and revised its qualification and production criteria for the Type 2 connectors in compliance with the ASME B&PV Code, Section III, Division 2, Subsection CC, "Code for Concrete Containments," Article CC-4333. In addition, the applicant will use the reinforcement mechanical splice examination criteria as defined by Article CC-5320. Based on this change, the staff finds the response to Action Item 11 to be acceptable.

Based on the applicant's responses to the above action items, the staff considers the design of the SC/RC connection to be acceptable. The staff notes that the applicant will provide a COL information item that will address the constructability of the shield building, including the SC/RC connection. Section 3.8.6 of this SER discusses and evaluates this COL information item.

<u>Testing of the Steel and Concrete Composite-to-Reinforced Concrete Connections</u>

In Section 7.3 of the Shield Building Report, the applicant stated that a full-scale anchorage test was performed to demonstrate the strength and ductility of the previous SC/RC connection design and its ability to develop the steel reinforcement on either side of the connection. Although the test specimen was representative of an earlier connection design, the applicant stated that the test specimen had some similarities with the revised connection. The test was also used to benchmark the [ ] analysis code for use in detailed analysis (Section 8.10 of the Shield Building Report).

In Section 7.13 of the Shield Building Report, the applicant described the results of the anchorage tests and found that the objectives and acceptance criteria were satisfied. The test demonstrated the capability of the SC/RC connection to transfer 125 percent of strength of the [ ] and the ductility of the connection region.

The staff's review of the test results confirmed that the SC/RC connection exhibited adequate strength and ductility to transfer 125 percent of the strength of the [ ]. Although the test was representative of the previous design, the staff considers the new design to have improved capacity because the [ ] bar connects [ ] to the support and liner plates. As a result, the staff does not believe that further testing is required for the SC/RC connection.

The staff finds the applicant's design of the SC/RC connection acceptable based on the applicant's revised design, demonstration of design stresses below code-allowable limits, the use of a [ ] mechanical [ ], and the anchorage test that involved testing of a connection with some similarities to the current design of the connection.

3.8.4.1.1.3.7 Design of the Tension Ring and Air-Inlet Region

Chapter 5 of the Shield Building Report describes the design of the tension ring and air-inlet structure. The tension ring is located at the interface of the SC air-inlet structures and the shield building RC roof (Figure 5.1-2 of the Shield Building Report). The top of the tension ring interfaces with the RC roof slab. The tension ring supports [ ] steel roof girders that are located under the RC roof slab. The bottom of the tension ring is attached to the air-inlet structure. The bottom of the air-inlet structure is attached to the top of the cylindrical SC wall of the shield building. The applicant revised the design of the tension ring in the Shield Building Report and reduced the air-inlet areas to provide more concrete for structural strength to the air-inlet region. The steel box girder for the tension ring consists of two closed sections, both of which are filled with concrete. The top section is triangular in cross-section and has sloping top surfaces in order to interface with the RC roof slab. The bottom section is rectangular in cross-section, with steel flanges and webs.

The air-inlet structure is an SC structure [ ]. The top of the faceplates of the air-inlet structure [ ]. The steel faceplates are connected together by [ ] vertical spacing. The air-inlet structure is an SC structure with through-wall openings for air flow. The air-inlet pipes are connected to the infill concrete by welded shear studs on their outside surface. The air-inlet openings consist of [ ]. The air-inlet pipes, spaced at approximately [ ] is poured into the air-inlet structure between the faceplates and bonds to the [ ] of the faceplates and the [ ] of the air-inlet pipes. That bonding makes the air-inlet SC structure act as a unit. The [ ] thick steel plates on each face, aligned with the inner and outer flanges of the tension ring, serve as primary reinforcement. The concrete infill is connected to these steel plates with [ ]. The steel face plates at the top of the air-inlet structure [ ] on the underside of the bottom tension ring web plate also function to attach the tension ring to the air-inlet structure. The faceplates at the bottom of the air inlets structure are welded to the faceplates of the SC wall.

The staff finds that the applicant's changes in the design of the tension ring girder, from an [ ], have resulted in a much improved design primarily because the design change makes the tension ring girder consistent with proven methods in ANSI/AISC N690. This change also provides a more predictable load path and stiffens the tension ring structure.

The tension ring is designed as a [ ], according to the design of the member forces in ANSI/AISC N690, and the concrete infill is credited only for stability of the steel plates. The design loads for the tension ring and air-inlet structure are established from the [ ] linear analysis. The tension ring is designed to have high stiffness and to remain elastic under required load combinations. The air-inlet structure was designed as an SC module.

In Section 5.1 of the Shield Building Report, the applicant stated that the current plan for construction of the air-inlet structure and tension ring is for the structures to be [ ] below the bottom of the tension ring.

As a result of its review, the staff raised a concern with the applicant (Action Item 13) that a construction joint in the air-inlet region [ ] below the tension ring would reduce the shear capacity of the concrete in this critical section. During construction, [ ] is poured through the holes in the horizontal web plate, and it is expected that the [ ] would flow and fill up to the top of the construction joint. The staff questioned whether the construction method for the tension ring girder/air-inlet region would disrupt the integrity of the structure and whether it would function as designed under design-basis loads.

In its June 30, 2010, letter response (page 93), the applicant provided a calculation to address shear friction loads at the air-inlet connection and construction joint in the tension ring. The applicant calculated the shear capacity of the air-inlet connection (based on ACI 349) to be [ ]. As a result, the applicant concluded that the capacity of the construction joint is governed by the shear transfer at the plate at the bottom of the ring girder-to-wall interface and not by shear transfer at the plane at the construction joint. The applicant also stated that this construction joint will be prepared by intentional roughening, in accordance with the requirements of ACI 349, Article 11.7.9.

The applicant also performed a calculation for the capacity of the shear ties to show that they are adequate to address the tapered transition from the [ ] thick SC wall to a [ ] thick air-inlet wall (page 96 of the June 30, 2010, letter). The calculation assumed an axial force demand of [ ] coupled with [ ] acting in tension (lower end of the taper) and [ ] acting in compression (upper end of the taper). The applicant assumed that over a height of 0.61 m (2 ft), the [ ] have a capacity [ ]. At the elevation of the transition, the maximum out-of-plane shear [ ]. As a result, the applicant stated that the [ ] can be credited for both tension caused by the inner plate transition and the out-of-plane shear demand. At the top of the transition, the applicant calculated a maximum compressive force [ ], resulting in a [ ] demand [ ].

The staff reviewed the results of these calculations and finds that the calculations' assumptions and technical bases are based on ANSI/AISC N690 and the criteria in ACI 349, and are, therefore, acceptable for the design of the tension ring and air-inlet region of the shield building. However, the staff notes that in the June 30, 2010, letter response (page 96); the applicant stated that because of the amount of congestion in this area, constructability studies are being performed. These studies will evaluate whether the current tie-bar configuration is adequate for concrete placement and will provide insight into design details that would enhance the design. During final design detailing, the applicant will consider increasing tie-bar capacity in this region based upon the results of the constructability studies.

As discussed in "Determination of Responses to Earthquake Loads" in Section 3.8.4.1.1.3.4 of this SER, the applicant did not properly implement the 100-40-40 combination method for seismic loading from the three earthquake directions (x, y, and z) when designing the tension ring and air-inlet regions. The applicant addressed this issue in its response to RAI-TR85-SEB1-27. Section 3.8 of the SER for the AP1000 DCD describes the staff's evaluation of the applicant's response about the implementation of the 100-40-40 method. The applicant's draft response to RAI-TR85-SEB1-27, transmitted on September 23, 2010, provided tabulations for the air-inlet region and tension ring to demonstrate the adequacy of the design using the applicant's 100-40-40 method. The staff's review of these tabulations determined that the applicant's 100-40-40 method results in lower member demands than the SRSS approach (the accepted method in RG 1.92). However, there were still substantial margins when the required member demands using the SRSS combination method were compared to the provided reinforcement for the air-inlet region and to the stress allowable values for the tension ring.

Based on the staff's review of the applicant's detailed design and analysis of the tension ring and air-inlet region as discussed above, the staff finds the design of the tension ring and air-inlet region to be acceptable.

The staff also performed a review of the seismic analysis of the PCS tank described in Section 6.2.2 of the Shield Building Report, Revision 4. The staff's review of this section found that the methodology used for the seismic analysis was consistent with AP1000 DCD Section 3.7.2 except for the use of the 100-40-40 method for all of the roof structural elements. Therefore, during the June 20-24, 2011 audit, the staff requested that the applicant justify the implementation of its 100-40-40 method. In Item 9 of the June 27, 2011 letter submittal the applicant performed additional analyses of the PCS tank using the SRSS method and compared it to the Westinghouse 100-40-40 method. The results showed that the calculated steel areas required tp meet design loads using the SRSS method were greater at some locations. However, the staff's review found that even with the higher SRSS results, the calculated steel areas required were still less than the steel areas provided in the design of the PCS tank.

Based on the staff's review of the applicant's detailed design and analysis of the PCS tank discussed above, the staff finds the design of the PCS tank to be acceptable.

3.8.4.1.1.3.8 Design of Roof and Tank Support

The cylindrical section of the shield building structurally supports the roof, which includes the PCCWST. The PCCWST has a stainless steel liner that provides a leak-tight barrier on the inside surfaces of the tank. The shield building PCCWST and the shield building roof are designed as RC sections in accordance with ACI 349. One of the significant loads on the PCCWST roof, and supporting shield building walls, is the seismic loading. To determine the seismic loading on the PCCWST, specific procedures need to be considered. The Shield Building Report indicates that the analysis and design took into account hydrodynamic loads (caused by sloshing during a seismic event) on the PCCWST walls. Detailed calculations were performed in accordance with the procedure described in ASCE 4-98. The finite element model considered the seismic loading of the water, which consists of the impulsive mode (effective fluid weight that acts as a rigid mass) and the convective mode (effective fluid weight that represents the sloshing mass).

Since the mass of water at the top of the shield building is significant, and to ensure that the seismic hydrodynamic loading of the water was properly considered in the analysis and design of the PCCWST and the shield building structural supporting members, the staff asked the applicant to describe in greater detail its method for calculating the seismic loading. Action Item 21 in the June 30, 2010, submittal asked the applicant to describe: (1) how it determined the seismically-induced pressure distributions of the water in the tank; (2) the maximum sloshing height of the water surface; (3) how it considered the potential sloshing impact forces on the tank roof; and (4) how it determined the maximum deflections of the supporting beams to the shield building roof and tank in order to demonstrate that these deflections meet code deflection limits.

In the RAI response, dated September 3, 2010, the applicant provided information to address the seismic-induced pressure distributions, sloshing height, and deflections of the supporting beams to the shield building roof and tank. Based on the staff's independent calculation, the staff found acceptable: (1) the magnitude of the hydrodynamic pressure at the bottom of the outer tank wall used to determine the hoop stress in the tank wall; (2) the hydrodynamic base shear used to calculate the shear stress in the tank wall; (3) the hydrodynamic moment on a section immediately above the tank base used to calculate the axial stress in the tank wall; (4) the hydrodynamic moment on a section immediately below the tank base used to design the tank supporting structure; and (5) the calculation of the water sloshing height used to ensure the water does not impact the tank roof. In addition, the maximum deflection of the supporting radial beams was within code limits. As a result, Action Item 21 is resolved and the design of the PCCWST is acceptable to the staff.

3.8.4.1.1.3.9 Use of Self-Consolidating Concrete

One of the staff's key issues, as identified in its October 15, 2009, letter, was that the applicant consider the self-consolidating concrete material properties and their effects (i.e., higher shrinkage and creep strains, less shear resistance and ductility) when compared to those of standard concrete. In its response, the applicant stated that in the Shield Building Report the use of self-consolidating concrete in the shield building would be limited to selected regions of the structure, including the knuckle regions of the roof, the tension ring, the air inlets, and selected portions of the SC-to-RC connection. Other portions of the structure would be constructed of standard concrete. Both the standard concrete and the self-consolidating concrete would have a compressive strength of f'c = 41.37 MPa (6,000 psi). The applicant stated that standard concrete will be used in most parts of SC construction, with limited use in a few congested areas. The applicant addressed concrete placement, shrinkage, and creep characteristics of the concrete and their effects on the shield building design.

The predicted compressive stress in the steel plate from concrete shrinkage would be 62.05 MPa (9,000 psi), and the stress in the concrete would be 387 psi. The concrete stress is slightly higher than $4\sqrt{f'c}$ = 2.14 MPa (310 psi). However, this is a very conservative estimate because the elastic modulus is lower and there is significant tensile creep at early ages when the shrinkage rate is largest. During the meeting on June 9-11, 2010, the staff asked the applicant, in Action Item 10, to further clarify the use of [ ] and the specific locations where it will be used for the shield building. In response to the action item, in its letter of June 30, 2010, the applicant stated that [ ] is used in select locations in the enhanced shield building where access is limited for a vibrator. The applicant also specified that [ ] is to be placed in the air inlets from about El. 75.0 m (246 ft) up to the top of the tension ring to about El. 83.8 m (275 ft), and below the PCCWST from about El. 89.6 m (294 ft) to about 94.2 m (309 ft).

Based on the applicant's explanations and evaluations regarding the specific concrete strength, its properties, the considerations for limiting the placement of the [ ] only to the congested areas, and the limited use of the [ ] throughout construction of the shield building to help enhance the integrity of the structure, namely in the air inlet regions and below the PCCWST tank, the staff finds the applicant's use of [ ] to be acceptable.

3.8.4.1.1.3.10 Daily Temperature and Thermal Effects

In its October 15, 2009, letter, the staff identified an issue that the applicant had not formally addressed: the daily and seasonal thermal cycling effect on the SC modular construction. In order to address the thermal cycling effect, the applicant performed thermal analysis to quantify the effect of daily and seasonal thermal cycling on the cylindrical wall.

The applicant used a cyclical temperature gradient of magnitude 43.33 °C (110 °F) over the course of 1 day to evaluate the effects of thermal cycling on the SC wall. The assumed temperature cycle is applied to the exterior shield building environment while maintaining an interior building temperature of 21.11 °C (70 °F). The result of the analysis indicated that the maximum stress in the wall is circumferential tensile stress of [ ], which is below the fatigue limit. The applicant concluded that the daily temperature cycling would not cause a fatigue problem. Based on its review of the applicant's analysis, the staff finds the applicant's evaluation of daily temperature and thermal effects acceptable.

3.8.4.1.1.3.11 Combined Normal Operating Thermal and Seismic Demands

During the review of Shield Building Report APP-1200-S3R-003, Revision 3, the staff identified that the applicant had not provided information relating to the combination of normal operating (i.e., ambient) thermal and seismic demands as required by ACI 349, Chapter 9, code provisions. The staff held public meetings on April 12, 2011 and May 17, 2011 to discuss the applicant's plan to address the issue. During the May 17 meeting, the applicant committed to revise APP-1200-S3R-003 to include the load combination of thermal and seismic demands. On June 13, 2011, the applicant submitted Shield Building Report APP-1200S3R-003, Revision 4, which included Appendix L, "Combination of Seismic and Thermal Loads." Shield Building Report, Appendix L, describes; (1) the three-dimensional steady state heat transfer analysis performed to develop thermal demands, (2) the development of reinforced concrete stiffness reduction ratios, and (3) the results of the combined thermal and seismic demands.

Heat Transfer and Thermal Stress Analysis

In Shield Building Report, Section L.1.1, the applicant assumed that the air-inlet, tension ring, and RC conical roof have no significant thermal demand from ambient thermal conditions due to negligible temperature differences between the inside and outside surfaces of these elements. The applicant identified the key regions of the shield building that see significant thermal demand as the region of the cylindrical wall adjacent to the annulus seal (approximately 40.7 m (133.5 ft) elevation), the connection of the cylindrical wall boundaries to the auxiliary building, and the outer wall of the passive containment cooling water system (PCS) tank. For the analysis of the shield building cylindrical wall and its connection to the auxiliary building, the applicant performed detailed three dimensional steady state heat transfer analysis, using the ANSYS NI05 shell model. This model accounted for thermal conduction and convection on the nuclear island building surfaces to provide a more realistic assessment of thermal gradients in key areas. A summary of temperatures used for the analysis is presented in Table 3.8-2 below. The applicant stated that the reference temperature for all materials was 21.1 °C (70 °F) and that the winter temperature condition (rows 2 and 4) was the controlling case for design.

Table 3.8-2, Assumed Temperatures in Shield Building Heat Transfer Analysis

	Location	Assumed Temperature °C (°F)
1	Below Grade	21.1 (70)
2	External Air (Winter)	-40 (-40)
3	External Air (Summer)	46.1 (115)
4	Upper Annulus Air (Winter)	-40 (-40)
5	Upper Annulus Air (Summer)	46.1 (115)
6	Internal Ambient	21.1 (70)

For the calculation of convective heat transfer coefficients, the applicant partitioned the exposed nuclear island building surfaces into three simplified geometries, a cylinder for the shield building exterior wall, a concentric annulus for the shield building upper annulus, and flat plate geometry for the auxiliary building roof and walls. The associated types of forced convection equations for these geometries were a cylinder in a cross flow, flow in a tube with concentric annulus, and mixed flow over a flat plate.

The assumed air (wind) velocity on the exterior walls was 6.25 m/s (20.5 ft/s), and the air velocity inside the upper annulus was 2.1 m/s (7.0 ft/s). The exterior air velocity is representative of weather data over 44 years from the Duluth, Minnesota Airport, which relates peak wind velocity to air temperature. The staff's review of the meteorological data from Duluth, Minnesota is discussed in Section 3.8.2.5 of this report. The applicant then conservatively assumed that the duration of the peak air velocity was sufficiently long (i.e., many hours) to achieve a steady state condition. The values of calculated forced convection coefficients ranged from 8.0 to 15.3 W/m^2 °C (1.4 to 2.7 BTU/(hr-ft^2-°F)) and were applied to each exposed surface.

Results from the NI05 heat transfer model (i.e., temperatures on inside and outside wall faces) were applied to a separate thermal stress analysis model using the NI05 shell element geometry to obtain thermal member forces. To account for concrete cracking from thermal stresses, the applicant reduced the calculated member forces and moments from the finite element model by multiplying them by assumed stiffness ratio factors (cracked/uncracked concrete modulus ratio). Seismic analysis of the AP1000 nuclear island (reviewed in

Section 3.7 of this SER) was performed assuming a 0.8 stiffness reduction factor to account for concrete cracking under seismic demands. For thermal analysis of SC modules and RC structures, the applicant assumed a stiffness reduction factor of 0.625, which results in an effective cracked-to-uncracked stiffness ratio of 0.5 (or 0.8 x 0.625). For concurrent axial tension and flexure, the axial stiffness was reduced to that of the steel plates for a resulting stiffness ratio of 0.22. The ratio of 0.22, to account for direct tension, was used in areas where maximum principal stresses exceeded the concrete cracking threshold represented by the direct tension capacity $[4(f'_c)^{0.5}]$ as defined in ACI 209R, "Prediction of Creep, Shrinkage, and Temperature Effects in Concrete Structures," Equation 2-4.

Shield building thermal demands were combined with seismic demands. Seismic demands were calculated using the NI05 ANSYS response spectrum model. The NI05 seismic model is described in AP1000 DCD Section 3G.2.2.4. The staff's review of the NI05 model is described in Section 3.7.2.4 of this report.

PCS Tank Analysis

Shield Building Report, Section L.4.4 describes the seismic and thermal load combination for the PCS tank. For the PCS tank, the applicant performed representative one-dimensional heat transfer analysis and analyzed for winter and summer conditions (see Table 3.8-2 above). The analysis assumed the same heat transfer coefficients as used for the SB cylindrical wall. The results of this analysis, which were distributions of inside and outside surface temperatures, were used as input to a more detailed ANSYS quarter-model (reference Shield Building Report, Figure 10.2-10) that used solid elements for concrete material. This model calculated nodal temperatures within the concrete wall, which were applied to a detailed quarter-model to determine thermal stress demands. Seismic demands, including PCS tank hydrodynamic loads from sloshing, were combined with thermal demands. The seismic analysis of the PCS tank is described in Shield Building Report Sections 6.2.2 and H.4.3.2 (hydrodynamic loads). The staff's review of the seismic analysis is described in Sections 3.8.4.1.1.3.4 and 3.8.4.1.1.3.8 of this report.

Results

Shield Building Report, Section L.4.1.1 provides results for the combination of thermal and seismic demands for the SB cylindrical SC wall. For the SC cylindrical wall region, plots (Figures L.4-17 through L.4-22) are provided showing the required SC plate reinforcement for the vertical, circumferential (hoop), and out-of-plane shear directions. These plots indicate that the provided SC plate reinforcement exceeds the ACI 349 code required reinforcement. The minimum ratios of provided, versus code required plate reinforcement, were 1.12 (vertical), 1.06 (hoop), 1.50 (out-of-plane shear; Type II Module tie-bar spacing), and 1.53 (out-of-plane shear; Type I Module tie-bar spacing). Table L.4-2 provides summary results for member forces with maximum out-of-plane shear demand. The reported maximum demand-to-capacity ratios for the wall modules are 0.648 (Type I Module tie-bar spacing) and 0.651 (Type II Module tie-bar spacing).

For the PCS tank, Shield Building Report, Section L.4.4, provides a summary (Tables L.4-4 through L.4-6) of required versus provided reinforcement ratios for the vertical, circumferential (hoop), and out-of-plane shear directions. These tables indicate that the provided steel reinforcement for the PCS tank exceeds the ACI 349 code required reinforcement with margin. The minimum ratios of provided, versus code required reinforcement, were 1.25 (vertical), 1.09 (hoop), and 6.70 (out-of-plane shear).

<u>Evaluation</u>

The staff performed a review of the applicant's technical basis for the seismic and thermal load combination for the shield building cylindrical wall and PCS tank as described in APP-1200-S3R003, Appendix L. The staff's review of Appendix L finds that for the analysis of the AP1000 shield building, thermal forces and moments were reduced in accordance with ACI 349-01 provisions. The staff notes that ACI 349-01, Appendix A, "Thermal Considerations," states that the thermal evaluation may be based on cracked section properties to account for redistribution of internal forces and strains due to concrete cracking. The use of cracked concrete section properties results in a reduced section modulus and subsequent reduction of thermal forces and moments. The applicant assumed reduction factors that were comparable to those recommended in FEMA 356, Table 6-5,"Effective Stiffness Values," and ASCE/SEI 43-05, Table 3-1, "Effective Stiffness of Reinforced Concrete Members. Based on the (a) commitment to use ACI 349 for the design of the shield building, which allows for reductions in thermal forces and moments, and (b) the use of concrete stiffness reduction factors comparable to those recommended in FEMA 356 and ASCE/SEI 43-05 standards, the staff finds the applicant's method of accounting for concrete cracking from thermal stresses to be acceptable.

On June 20-24, 2011, the staff performed an audit of significant Westinghouse calculation reports that support results described in Shield Building Report, Appendix L. These reports related to the shield building cylinder heat transfer analysis (APP-1200-S2C-126), PCS tank heat transfer analysis (APP-PCS-M3C-028), and analysis and design of the PCS tank (APP-1278-CCC-007). In a June 27, 2011 letter, the applicant provided responses to staff audit questions.

Based on the applicant's acceptable method for accounting for concrete cracking and the seismic analysis of the SB cylindrical wall and PCS tank performed in accordance with NUREG-0800 Section 3.7, the staff finds the applicant's consideration of the thermal and seismic load combination for the shield building satisfies ACI 349 code provisions and is therefore acceptable.

3.8.4.1.1.3.12 Local Buckling Analysis

During its review of Revision 1 of APP-1200-S3R-003, the staff found that the applicant had not provided sufficient information to demonstrate that the SC design addressed the effects of local buckling of the SC module faceplates. In response to the staff concerns, the applicant revised the design of the SC wall module by increasing both the inner and outer plate thickness from [ ]. In Section 3.3.1 of the Shield Building Report, the applicant summarized the adequacy of surface plates to resist buckling.

The applicant assumed that the buckling modes for analysis were horizontal ripples caused by vertical loading [ ], vertical ripples caused by horizontal loading [ ], and diagonal ripples caused by in-plane shear loading [ ]. Based on these wavelengths, the applicant concluded that the longest wavelength [ ] controlled the design. The applicant assumed the plate to behave as a [ ] long column, with partial moment restraint at the ends. Appendix A to the Shield Building Report provides the empirical relationships used to evaluate the SC plate buckling capacity. The applicant referenced testing conducted to support the finding that [

]. This buckling stress is lower than the Euler value. Using these assumptions, the applicant calculated the elastic buckling stress of [ ]. Since this buckling stress exceeds the steel plate yield stress, the applicant concluded that inelastic properties of the plate govern.

The applicant verified the performance of the steel plate under construction loads and found that the midspan deflection between [ ]. This deflection resulted in a maximum steel stress of 19.3 MPa (2.8 ksi). As a result of these small displacements and stresses, the applicant concluded that the effect of wet concrete loads on reducing buckling capacity was minimal.

In Section 3.3.1 of the Shield Building Report, the applicant stated that the compression loads in the shield building cylindrical wall are well below the strength of the section. The maximum compression is [ ].

The staff reviewed the applicant’s technical basis for analyzing steel plate buckling, including empirical buckling relationships, in Appendix A to the Shield Building Report and finds the basis acceptable given the geometric similarity of the tested panels with the AP1000 design. On the basis that the applicant has performed a buckling analysis using acceptable empirical design equations and that the applicant has predicted relatively low compressive stresses from all load combinations, the staff finds the applicant’s design to resist local buckling of steel plates to be acceptable.

3.8.4.1.1.3.13 Global Stability Analysis

During its review of the Shield Building Report, the staff identified that the applicant had not addressed global stability of the shield building. The global stability issue was discussed and identified under Action Item 6 at the June 9-11, 2010, meeting.

To address Action Item 6, the applicant provided an analysis of global stability in its letter dated June 30, 2010. The applicant concentrated on demonstrating that the PCCWST does not add significant weight to the structure and that the long-term effects of creep are negligible. As such, the cylindrical wall was analyzed for stability under hoop and axial compression. The applicant reported that the compressive stress resulting from the dead weight of the structure was [ ]. Consequently, the applicant stated that because the dead weight stress is small the effects of creep are negligible. The applicant performed an analysis for axial buckling and calculated that the elastic buckling compressive stress was [ ]. Because the concrete compressive stress is [ ], the applicant concluded that the concrete would crush before buckling occurred.

The staff reviewed the applicant’s technical basis for global stability and found it to be consistent with the ACI Committee 334 report, “Concrete Shell Structures Practice and Commentary.” The staff found the analysis to be acceptable based on an independent calculation of the critical buckling strength of elastic shells under compressive loads.

Pushover Analysis

The applicant performed nonlinear confirmatory analysis to predict the behavior of the shield building up to and beyond design basis seismic loading and assess the potential for collapse. The applicant used its [ ] model of the nuclear island to perform a nonlinear pushover analysis of the shield building. The model included the shield building and the entire auxiliary building. This finite element model did not impose constraints that would force a mode of deformation of the shield building structure. Using this model, the applicant's analysis tracked tensile stresses and strains in the steel faceplates, in-plane and out-of-plane shear deformations and stresses, stresses and strains in the [ ], deformations in the connection regions and stresses and strains in the [ ] in the RC wall below the SC wall. The applicant's analysis explicitly modeled the interaction of the shield building with the roof and walls of the auxiliary building. The applicant's model also did not exclude the possibility of shear failures. Instead, it considered concrete cracking for out-of-plane loads as well as in-plane loads and the subsequent distribution of forces to the steel reinforcement. Since the applicant's verification and validation of the model against its own test data did not capture brittle failures, the applicant tracked the possibility of local onset of such brittle shear failures through the use of limiting strains in the [ ] as well as through the combined use of analysis methods with increasing refinement, that is, the combination of [ ] models.

For its analysis, [ ]. In addition, the applicant considered various combinations of the directions and intensity of the seismic loads in the two horizontal directions and in the vertical direction. Under these loading conditions and without constraints in the response modes of the structure the applicant calculated the response of the structure to proportionally increasing loads. Proportional increase of the loads is an approximation in a static pushover analysis. As the structure yields and the response becomes increasingly inelastic, there is a potential for redistribution of the loads through the height of the structure that may affect the subsequent response mode of the structure. The results of the applicant's analysis show that significant inelastic behavior of the wall, other than concrete cracking, will not occur at the design basis loads and will only start at loads closer to the review level earthquake (RLE). On this basis, loading conditions that deviate significantly from those used by the applicant are not expected up to the SSE and RLE levels.

The applicant's analysis results showed that the highly stressed regions of the shield building were near structural discontinuities such as the connection to the basemat at the 30.40 m (100 ft) elevation, in the region above the roof of the auxiliary building and at the connection of the SC wall to the RC walls. The analysis predicts yielding initiation through yielding of the [ ].

The results of the pushover analysis confirm that the shield building stresses, strains and deformations remain small at the design basis loads and that significant yielding in the SC wall does not start until loading levels beyond the SSE and of the order of the RLE. The results of the analysis confirm that the high stress areas of the wall with complex states of stress from the combination of high membrane forces and out-of-plane forces are the areas of the wall for which [ ], described in Section 4.3.5.2 of this report, showed that these models exhibit ductile out-of-plane behavior under cyclic loading.

As a result of the above global stability calculation and confirmatory pushover analysis, the staff considers the issue of global stability and related Action Item 6 to be resolved.

3.8.4.1.1.3.14 Construction and Inspection Methods

The staff had concerns about the construction and inspection methods that the applicant had planned to use to ensure the integrity and safety of the shield building design. The staff's concerns centered on the sequence of construction and considerations for the wet concrete loads, thermal loads, and welding processes to be used. The staff was also concerned about how the applicant would inspect for voids, cracking, delaminating, and substandard construction of concrete. During a meeting on February 23, 2010, the staff raised concerns related to the use of a qualified inspector in accordance with the ACI 318 Code and the need for continuous inspection throughout construction.

As indicated in Section 9.2 of the Shield Building Report, the applicant plans to construct the shield building in an alternating sequence with the construction of the CV. After setting the first ring of the CV, approximately 12.2 m (40 ft) high, the shield building modules will be installed and filled with 3 m (10 ft) concrete lifts. To help ensure the integrity of the design of the shield building, the applicant will undertake a mockup program focused on three critical areas:

(1) the vertical RC-to-SC connection
(2) the horizontal RC-to-SC connection
(3) the air-inlet/tension ring structure

The results of the mockup program will be used to gain insights into any modifications to the design that may be needed before construction.

In Section 9.5 of the Shield Building Report, the applicant specified that the welding codes and process and welding inspection criteria for structural welding are in accordance with ANSI/AISC N690 and AWS D1.1, “Structural Welding Code—Steel.” In Section 9.6 of the Shield Building Report, the applicant specified that ANSI/ASME NQA-1, “Quality Assurance Requirements for Nuclear Facility Applications,” as well as ANSI/AISC N690 and AWS D1.1, govern the design requirements for the fabrication, assembly, and installation of the SC wall module components and construction inspection.

The staff is concerned that the proposed SC/RC connection and the tension ring/air-inlet connection may have constructability problems, such as steel rod alignment, aggregate size, air entrapment, and bleed water accumulation. Further, the staff is concerned that the proposed connection may have design implications, such as elongation in the reinforcing bars, shear friction transfer, and compression force transfer. The goal is to increase the confidence that the success of carefully designed mock-up tests would be replicated during construction.

In particular, the staff believes that concrete placement plans for the SC and RC connection region, tension ring and air inlet should be fully developed with emphasis on ensuring venting of air and complete filling of cavities. The applicant states in Revision 2 of the Shield Building Report that horizontal construction joints at the top of each concrete placement, including those near the bottom of the ring girder, would be prepared in accordance with ACI 349, Article 11.7.9. Since this reference does not specify a preparation procedure, the applicant should prepare one as the construction plans progress.

With respect to staff concerns raised about the method of inspecting the SC wall module given that the design includes concrete between two steel plates without visual access, in Section 9.8 of the Shield Building Report, the applicant evaluated several nondestructive examination (NDE) technologies for their potential for determining concrete defects and proposed to use the [

]. The [ ] approach is acceptable to the staff when used in conjunction with acceptance criteria for defects that would trigger more detailed evaluations when necessary. In Section 9.8 of Revision 2, the applicant developed criteria for acceptable levels of defects, and in Table 9.8-2, criteria for spacing between defects.

The staff understands that the spacing of defects [ ], both the maximum spacing and the spacing used for acceptance; involve both horizontal and vertical dimensions and not just a single linear dimension. On page 33 of Revision 2, the applicant wrote that a 95/95 sampling methodology would require a random grid of 59 total sampling point locations in each of the three critical areas of the inner shield building. The staff understands this to mean that for each sampling scan in each of these critical areas, 59 sampling points would be required, and not to mean that the inspection would consist of only three scans, one per critical area, and each with 59 sampling points. The staff notes that the applicant did not provide in Revision 2 specific technologies for the more detailed evaluations when acceptance criteria are not met. Finalized inspection procedures should include those technologies. On page 9-33 of the Revision 2 report, the applicant wrote that if inspection ports cut in the steel plates become necessary for NDE, the location of those ports would be at those sample point locations. The staff notes that the Revision 2 report does not indicate if a location of inspection points is a single point location or a grid of test points. This needs to be specified in the completed inspection program.

Based on its review, the staff found that the applicant has addressed the staff's concerns. Particularly, the applicant has described the construction sequence; and the use of mock-ups in order to help ensure the integrity of the designed structure during construction. However, the staff believes that the applicant should complete its development of all construction and inspection implementation procedures, establish the QA/quality control procedures, finalize its selection of the NDE technology, and determine a method to help ensure that the results of the mock-up program and the qualification of the inspectors are implemented at the site. This topic is discussed further in Section 3.8.4.1.1.4 below.

3.8.4.1.1.4 Inspections, Tests, Analyses, and Acceptance Criteria

AP1000 DCD, Revision 17, Tier 1, Table 3.3-6 addresses the NI structures, including the critical sections. The acceptance criteria require a report that reconciles deviations during construction and concludes that the as-built shield building structures, including critical sections, conform to the design-basis loads without loss of structural integrity or the safety function. The staff finds that the AP1000 DCD Tier 1 ITAAC included sufficient requirements for the design acceptance of the shield building and its critical sections. Hence, the staff did not identify any additional ITAAC based on its review of the shield building design.

In Chapter 9 of the Shield Building Report, the applicant described the construction and inspection methods for the shield building. The staff's review found that the applicant must provide a COL information item to ensure that the shield building is constructed as designed to perform its intended safety function.

In RAI-SRP3.8.4-SEB1-04, the staff asked the applicant to provide commitments for unique construction and inspection procedures, such that the COL applicant will develop and follow procedures described in the COL information item. Further, the staff requested that the COL information item include the construction sequence, mockup requirements for the critical areas of the shield building, concrete placement methods, inspection of modules before and after concrete placement, and QA procedures.

In its response dated September 3, 2010, the applicant proposed a new COL information item including construction procedures and inspection procedures for SC construction. The applicant stated that these procedures derive from Chapter 9 of the Shield Building Report and will be added to AP1000 DCD Section 3.8. Further, the applicant stated that for SC construction, the construction inspection will be done in accordance with the applicable codes and standards listed in AP1000 DCD Section 3.8.4.2. For the shield building mockup program, the applicant proposed to use the heavily reinforced sections, which are deemed to be the sections of the design that present difficult construction issues. These sections include the lower section of RC/SC interface, horizontal RC/SC connection, and the air-inlet structure/tension ring. Additionally, the applicant stated that similar mockups will also be performed for the SC module and that insights from these mockups will be applied in construction.

The COL information item states that COL holders referencing the AP1000 DC will develop construction and inspection procedures to implement the commitments for concrete-filled steel plate modules. Further, these procedures will address concrete placement, use of construction mockups, and inspection of modules before and after concrete placement.

The staff reviewed the response to RAI-SRP3.8.4-SEB1-04 and the proposed COL information item and finds that the applicant's commitment to perform shield building mockups and develop construction and inspection procedures is acceptable. In a subsequent revision to the AP1000 DCD, the applicant made appropriate changes to the DCD text and table, which resolve this issue.

3.8.4.1.1.5 Shield Building Conclusion

The staff evaluated the adequacy of the design of the shield building, as provided by the applicant in the Shield Building Report dated May 7, 2010, and as supplemented by 2010 submittals dated June 24, June 30, July 30, and September 3, and a June 15, 3011 submittal, and finds that the design of the shield building meets the relevant requirements of the regulations as provided in 10 CFR 50.55a and GDC 1 and 2 of Appendix A to 10 CFR Part 50.

Based on its evaluation, the staff finds that the design of the shield building demonstrates reasonable assurance that it will perform its intended safety function, and, therefore, is acceptable. Moreover, the staff finds that the shield building is adequately designed to withstand the effects of natural phenomena, thereby ensuring it will perform its intended safety function.

The staff recognizes that design standards or industry codes specific to the design of the SC wall module do not exist in the United States. However, the staff finds that the applicant used an alternative approach and implemented an integrated design methodology, including design, analysis, confirmatory analysis, testing, construction, and inspection, applicable for the development of the design of the AP1000 shield building. Specifically, the design methodology uses ACI 349 for RC design and supplements it with confirmatory analysis and confirmatory testing for its application to the AP1000 design of the SC wall module. Specifically, for the design of the SC cylindrical wall, air inlets, and SC/RC connection, the ACI 349 methodology was used for the design and the applicant supplemented its design with confirmatory analysis and testing. In view of the integrated methodology adopted for the shield building design, the staff believes the applicant's alternative approach is acceptable for this first-of-a-kind engineering design.

In addition, the staff finds that the applicant's modifications to improve the original design of the shield building, such as the use of the [ ] in the SC wall module and enhancements to the SC-to-RC and basemat connections, the roof, and tension ring/ring girder and air-inlet regions, make significant improvements in the design. Specifically, the applicant's inclusion of [ ] significantly improves the capacity of the SC wall module and enables the structure to function as a unit under design-basis loads. Further, the staff finds that the design possesses the basic elements of strength, stiffness, and ductility. The revised SC-to-RC connection allows for a [ ], while the revisions to the design of the tension ring and air-inlet region significantly improve the load path and thus, the transfer of forces.

The applicant's analysis of strength and ductility is acceptable for SSE demand, and the use of confirmatory tests in conjunction with confirmatory analysis demonstrates that the capacity based on ACI 349 equations for the design of SC structures is adequate to meet the SSE demands. With regard to the analysis supporting the design of the shield building, the applicant performed three levels of analysis to determine the load magnitudes, response spectra and member forces and the required design strength in accordance with the ACI 349 Code. In addition, the applicant's consideration of thermal effects, fatigue, creep, and construction loads in the design of the shield building were reasonably well supported by modeling and detailed confirmatory analyses.

As part of the integrated design methodology, the applicant conducted confirmatory tests of the SC wall module to confirm the adequacy of those portions of the AP1000 shield building design that fall outside the scope of existing design codes and to demonstrate the level of conservatism in using ACI 349. Specifically, [ ] resulted in demonstrating the desired ductile behavior, and the out-of-plane shear test with [ ]. In addition, the [ ] of the SC wall module indicated substantial strength margin to design loads, but the module was not tested to capacity; therefore, the test did not demonstrate that the SC module would not fail in a brittle manner under cyclic loading. In a report referenced by the applicant, the staff found that a Japanese test of scaled models of SC structures (with geometry similar to the AP1000 shield building design) had demonstrated sufficient ductility for cyclic in-plane shear loading. However, the Japanese tests were not performed for cyclic out-of-plane shear loading.

The applicant addressed ductility for out-of-plane loading by referencing ACI 349, Article 21, pertaining to moment-resisting frames. The staff finds that ACI 349 (Article 21) is intended for moment frame structures and is not directly applicable to cylindrical shell structures, such as the AP1000 shield building. Cylindrical shells will distribute forces in a manner that differs from a two- or three-dimensional framed structure. However, the staff agrees that the inherent premise used in ACI 349, Article 21, of providing ductile detailing where demands are high, can be extended to a cylindrical shell if analysis has been performed to identify locations of high demands.

The staff finds that to resist out-of-plane shear loading, the shield building design uses [ ] to ensure that the SC modules will function as a unit. For the regions of the SC wall module with higher out-of-plane shear loads, and where yielding of the SC wall module would be expected to initiate under a combination of tensile forces and out-of-plane bending for seismic loads, the applicant detailed the SC modules with [ ] to provide out-of-plane shear ductility. For the regions of the SC wall with low out-of-plane shear demands and [ ], the SC wall detailing does not provide out-of-plane shear ductility based on the test results. In these regions, the out-of-plane shear demands calculated by the applicant are low, and the SC wall modules as detailed provide conservative strength demand-to-capacity ratios. Based on: (1) demonstration of conservative strength and adequate cyclic behavior for the SC module with [ ] ; (2) confirmatory analysis that identified locations of potential SC steel plate yielding; and (3) the analogy with ACI 349, Articles 21.3 and 21.4, which require ductile detailing only where demands are high and plastic hinges are expected to form, the staff finds the applicant's use of [ ] at [ ] spacing to be acceptable.

Furthermore, the staff finds SC module design is acceptable on the basis that the applicant demonstrated that its lowest margin is 18 percent (in-plane shear) under design-basis SSE loads and on the staff's determination that other SC modules with design characteristics similar to the AP1000 shield building possessed sufficient ductility under in-plane shear cyclic loading. Regarding out-of-plane shear loading of the SC module with [ ], the staff finds that although these specimens failed in a brittle manner, there is significant margin between the failure loads of the two test specimens [ ] and the maximum SSE demand of [ ]. Lastly, the applicant's construction and inspection processes involving the use of mock-ups for two key areas, the SC-to-RC connection and the ring girder-to-SC connection, are acceptable, although the staff finds that the applicant should finalize its implementation of its construction and inspection procedures and methods. The applicant should also determine a method to help ensure that the results of the mock-up program are correctly implemented at the site.

In summary, based on the above discussions, the staff finds that the design of the AP1000 shield building is acceptable.

3.8.4.2 Conclusion

In NUREG-1793 and its Supplement 1, the staff documented its conclusions that the AP1000 design and the DCD (up to and including Revision 15 of the AP1000 DCD) were acceptable and that the application for the DC met the requirements of Subpart B to 10 CFR Part 52 that are applicable and technically relevant to the AP1000 standard plant design.

The staff reviewed the applicant's proposed changes to the AP1000 as they relate to other seismic Category I structures as documented in AP1000 DCD Revision 19, against the relevant acceptance criteria as listed above and in NUREG-0800 Section 3.8.4.

In subsequent revisions to APP-1200-S3R-003, "Design Report for the AP1000 Enhanced Shield Building," the applicant made appropriate changes to the report. Based on the review of these changes, staff concludes that APP-1200-S3R-003, Revision 4, is acceptable because the analyses and design were performed in accordance with the ACI 349 Code, applicable RGs, and NUREG-0800, Section 3.8.4.

The staff concludes that the design of the other seismic Category I structures meets all applicable acceptance criteria. In summary, based on the above discussions, the staff finds that the design of other seismic Category I structures including the AP1000 shield building is acceptable.

The applicant proposed to amend the existing design certification rule, in part, to address the requirements of the aircraft impact assessment (AIA) rule. The AIA rule itself mandated that a design certification rule (DCR) be revised (either during the DCR's current term or no later than its renewal) to address the requirements of the AIA rule. In addition, the AIA rule provided that any combined license issued after the effective date of the final AIA rule must reference a DCR complying with the AIA rule, or itself demonstrate compliance with the AIA rule. The AIA rule may therefore be regarded as inconsistent with the finality provisions in 10 CFR 52.63(a) and Section VI of the AP1000 DCR. However, the NRC provided an administrative exemption from these finality requirements when the final AIA rule was issued. See June 12, 2009; 74 FR 28112, at 28143-45. Therefore, the NRC has already addressed the finality provisions of applying the AIA rule to the AP1000 with respect to the AP1000 and referencing COL applicants.

3.8.5 Foundations

Using the regulatory guidance in NUREG-0800 Section 3.8.5, "Foundations," the staff reviewed areas related to the foundations of all seismic Category I structures. The specific areas of review provided in NUREG-0800 Section 3.8.5 are as follows: (1) description of the foundations; (2) applicable codes, standards, and specifications; (3) loads and load combinations; (4) design and analysis procedures; (5) structural acceptance criteria; (6) materials, quality control, and special construction techniques; (7) testing and inservice surveillance programs; (8) ITAAC; and (9) COL action items and certification requirements and restrictions. Not all of these areas were applicable to the review of the proposed changes to AP1000 DCD Section 3.8.5 and the following SER sections provide the staff's evaluation for the relevant areas.

In its previous evaluations of AP1000 DCD, Section 3.8.5, the staff identified acceptance criteria based on the design meeting relevant requirements in 10 CFR 50.55a, "Codes and Standards"; 10 CFR Part 50, Appendix A, GDC 1; GDC 2; and GDC 4. The staff found that the design of the AP1000 foundations was in compliance with these requirements, as referenced in NUREG-0800 Section 3.8.5 and determined that the design of the AP1000 foundations, as documented in the AP1000 DCD, Revision 15, was acceptable because the design conformed to all applicable acceptance criteria.

In the AP1000 DCD, Revisions 16 and 17, the applicant made the following changes to Section 3.8.5 of the certified design:

1. As a result of the extension of the AP1000 design from just hard rock sites to sites ranging from soft soils to hard rock, various seismic re-analyses of the NI structures were performed. Whereas the original design relied upon the equivalent static method of analysis for seismic loading, the re-analyses included the additional use of response spectrum and time history methods of analysis. Appendix G of DCD Revision 17 indicates that the response spectrum analysis was used for the 3D refined finite element model of the NI and for the analysis of the PCS valve room and miscellaneous steel-framed structures, flexible walls, and floors. Time history analyses were used to determine maximum soil bearing

pressures under the NI and, subsequent to the submittal of DCD Revision 17, to perform an updated NI stability evaluation.

2. In DCD Revision 16, the applicant revised Section 3.8.5.4.1 - Analyses for Loads during Operation, regarding the reinforcing steel under the shield building and the auxiliary building. Additional reinforcement is provided in the design of the basemat for soil sites such that the basemat can resist loads 20 percent greater than the demand calculated using the equivalent static acceleration analyses on uniform soil springs. The design accommodates potential site specific soil variability beneath the basemat in the horizontal (lateral) directions.

3. In DCD Revision 16, the applicant included in Section 3.8.5.4.2 a description of the analyses which evaluate the effects of different construction sequences on settlement and the design of the basemat. DCD Revision 17 made some additional revisions to describe the concrete placement sequence in the basemat and in the auxiliary building during construction.

4. In DCD Revision 16, the applicant revised Section 3.8.5.4.3 - Design Summary Report. DCD Revision 15 indicated that the results of the evaluation will be documented in an as-built summary report by the COL applicant. In DCD Revision 16, this was revised to state, “The results of the evaluation will be documented in an as-built summary report.”

5. In DCD Revision 16, the applicant revised Section 3.8.5.4.4 - Design Summary of Critical Sections. The design approach of the basemat for two of the critical sections was revised to design these sections as two way slabs.

6. In DCD Revisions 16 and 17, several revisions were made in Section 3.8.5.5 - Structural Criteria, regarding the sliding and overturning stability evaluations. In DCD Revision 16, Section 3.8.5.5.3 - Sliding, the sliding coefficient of friction between the basemat and the soil was revised from 0.55 to 0.70. In DCD Revision 17, Section 3.8.5.5.4 - Overturning, the equation used to calculate the factor of safety for overturning due to the safe shutdown earthquake was revised.

7. In DCD Revision 16, the applicant revised Section 3.8.5.6 - Materials, Quality Control, and Special Construction Techniques. DCD Revision 15 indicated that the COL applicant would provide information related to the excavation, backfill, and mudmat. In DCD Revision 16, this was revised to state that Section 2.5.4.5.3 describes the information related to the excavation, backfill, and mudmat.

8. In DCD Revision 16, the applicant revised Section 3.8.5.7 - In-Service Testing and Inspection Requirements. DCD Revision 15 indicated that the COL applicant has the responsibility to determine the need for foundation settlement monitoring. In DCD Revision 16, this was revised to state that the need for foundation settlement monitoring is site-specific as discussed in subsection 2.5.4.5.10.

The evaluation of changes to the description of foundations, applicable codes, standards, and specifications, loads and load combinations, and the design and analysis procedures may be found in the evaluation of TR-85, presented below.

3.8.5.1 Nuclear Island Basemat Technical Report TR-85

Since the AP1000 design was previously certified for use at an HR site, the applicant submitted TR-85, Revision 0, to summarize the design of the NI basemat and exterior walls below grade for both HR and soil sites. This report also describes interface demands to be satisfied at a site. TR-85 Revision 0 indicates that the report also provides an updated baseline for the as-designed configuration and validates the basemat and foundation design against the updated seismic spectra and soil foundation conditions. TR-85 was subsequently modified in Revision 1 to address a number of the outstanding RAIs. Some of the information in TR-85 is included in the AP1000 DCD, Revision 17.

As a result of the staff's review of TR-85, a number of RAIs were sent to the applicant. Based on these RAIs, the applicant made a number of revisions in the analyses and design methods to address the issues raised. The description provided below presents the staff's evaluation of the key issues.

3.8.5.1.1 Design of NI Walls below Grade

As a result of the staff's review of TR-85, a number of questions were identified related to the design of the foundation walls below grade. These questions were captured in RAI-TR85-SEB1-02, RAI-TR85-SEB1-04, RAI-TR85-SEB1-34, and RAI-TR85-SEB1-40. As a result of these RAIs, the applicant made a number of revisions in the analyses and design methods to address the issues raised. The description provided below presents the staff's evaluation of the key issues related to the design of the foundation walls below grade.

As described in the applicant's response to RAI-TR85-SEB1-02, the analytical approach to calculate the pressure loads on the side walls below grade (embedded walls) consisted of hydrostatic pressure from ground water, at rest earth pressure, surcharge pressure, dynamic earth pressure, and passive earth pressure. The seismic earth pressure was calculated in accordance with ASCE 4-98, Section 3.5.3, which utilizes the elastic solution for dynamic soil pressures. In addition to designing the foundation walls to the seismic earth pressure, the RAI response also indicates that the NI exterior walls are designed for the passive soil pressure in the load combinations that include SSE.

The staff finds that the approaches used by the applicant to calculate these various soil pressure loads were in accordance with industry-wide soil mechanics methods and were consistent with the criteria presented in NUREG-0800 Section 3.7 for seismic loads and Section 3.8 for design methods, and, therefore, are acceptable.

3.8.5.1.2 Maximum Soil Bearing Pressure beneath the Basemat during SSE

As a result of the staff's review of TR-85, a number of questions were identified related to the calculation of the maximum soil bearing pressures beneath the basemat due to the SSE. These questions related to soil bearing pressure were captured in RAI-TR85-SEB1-03, RAI-TR85-SEB1-04, RAI-TR85-SEB1-06, RAI-TR85-SEB1-15, RAI-TR85-SEB1-26, and RAI-TR85-SEB1-40. As a result of these RAIs, the applicant made a number of revisions in the analyses and design methods to address these issues. The description provided below presents the staff's evaluation of the key issues related to the soil bearing pressure evaluations.

Based on the response provided to RAI-TR85-SEB1-03, the maximum dynamic bearing pressure on soils resulting from SSE was 5745.6 kPa (120,000 pounds per square foot (psf)) for the HR case in the previous AP1000 certified design using the more conservative equivalent static analysis method. The 5.746 MPa (120,000 psf) pressure was reduced to 1.331 MPa (27,800 psf) for the HR case by using a more realistic 2D [ ] nonlinear (liftoff) analysis. The 2D [ ] nonlinear (liftoff) analysis showed that the SM soil case gives a somewhat higher dynamic bearing pressure, 1.652 MPa (34,500 psf), than that of the HR case. The applicant also calculated the maximum dynamic bearing pressure on soils by using the [ ] 3D finite element NI20 model with a seismic time history SSI analysis. This analysis was performed for the HR case and five soil conditions, and the resulting maximum dynamic bearing pressure is 1.676 MPa (35,000 psf). This analysis is described in detail in Section 2.4.3 of TR-85, Revision 1, and TR-03 (November 2008). The maximum soil bearing pressure demand of 1.676 MPa (35,000 psf) for the NI is presented in AP1000 DCD Tier 1, Section 5.0, "Site Parameters." The applicant also explained how the time history analyses removed a number of conservatisms inherent in the equivalent static seismic analysis, which led to the large reduction in the soil bearing pressure. Based on this explanation and the use of a more accurate [ ] 3D finite element NI20 model analysis, which was also confirmed with the independent 2D nonlinear liftoff [ ] analysis, the staff concludes that the applicant has used proper methods to obtain the maximum dynamic bearing pressure on the soil.

3.8.5.1.3 Stability Analysis (Sliding and Overturning) of the Basemat and Foundation Waterproofing Systems

As a result of the staff's review of TR-85, a number of questions were identified related to the calculation of the stability analysis of the NI basemat and the foundation waterproofing systems. These questions were captured in RAI-TR85-SEB1-04, RAI-TR85-SEB1-07, RAI-TR85-SEB1-10, RAI-TR85-SEB1-11, RAI-TR85-SEB1-34, RAI-TR85-SEB1-35, and RAI-TR85-SEB1-40. As a result of these RAIs, the applicant made a number of revisions in the analyses and design methods to address these issues. The description provided below presents the staff's evaluation of the key issues related to the stability evaluations.

Based on the response to RAI-TR85-SEB1-10, for the overturning and sliding stability evaluation, the applicant initially used the 3D [ ] NI20 model. For the SSE loading, an equivalent static analysis was performed and demonstrated that without the use of passive soil pressure resistance, the overturning factors of safety were met. However, for sliding, difficulties were identified in satisfying the sliding factor of safety. Therefore, the applicant performed another more realistic nonlinear analysis with sliding friction elements using a modified 2D [ ] model that was used previously to study the basemat uplift. This model, which is described in Section 2.4.2 of TR-85, was modified to use sliding friction elements at the interface of the basemat and the soil. The model considered basemat vertical uplift in addition to sliding. A direct integration time history analysis using the modified 2D [ ] model was performed to evaluate the basemat stability issue. Three soil cases that have the lowest factor of safety-related to sliding were evaluated. These three cases are HR soil, UBSM soil, and SM soil. The seismic input was increased by 10 percent so as to maintain the factor of safety against sliding of 1.1. No passive soil resistance was considered in the analyses. The resulting maximum deflection at the base using a coefficient of friction of 0.55 was 0.08 cm (0.03 in) for all three soil cases. This horizontal sliding deflection was considered to be negligible and no passive soil pressure resistance was necessary from the backfill. Therefore, the applicant concluded that the NI is stable against sliding and there is no passive pressure required to maintain stability. The AP1000 DCD requires COL applicants to demonstrate by testing that soils beneath their basemat possess a minimum coefficient of friction of 0.7, which is equivalent to the soil friction angle of 35 degrees, and this provides additional conservatism for the basemat against sliding stability.

The staff's review of the RAI-TR85-SEB1-10 response related to the seismic stability evaluation of the NI concludes that the overall 2D [ ] nonlinear sliding analysis approach appears to be appropriate; nevertheless, a review of the applicant's calculation was needed to confirm the proper implementation of this methodology is appropriate. At the seismic audit conducted during the week of June 14, 2010, the staff reviewed the 2D [ ] non-linear sliding stability evaluation. As a result of this review a change was made to the [ ] sliding/contact finite element that resulted in larger horizontal displacements. The resulting maximum displacement at the base of the NI basemat was 0.356 cm (0.14 in) without buoyant force consideration, and 0.61 cm (0.24 in) with buoyant force effects. These values are larger than the previously reported results, 0.76 mm (0.03 in) without buoyant force and 1.14 mm (0.045 in) with buoyant force effects. However, these values are still judged to be negligibly small, especially when the conservative analysis approach of neglecting sliding resistance from the soil passage pressure and neglecting the additional fictional forces along the barrier portions of the NI side walls are considered. Therefore, it is concluded that the NI is stable against sliding. However, the staff notes the need to revise the response to RAI-TR85-SEB1-10 to reflect the revised finite element for sliding and the increase in displacements, and provide the DCD and TR-85 changes to reflect the sliding evaluation.

Since wind and tornados generate less horizontal sliding force and overturning bending moment than the SSE does, the applicant concluded that the NI, which does not have stability problems against SSE, will not have problems against wind and tornados.

As a result of the staff's structural audit conducted during the week of August 10, 2009, the staff requested justification as to why TR-85 is not identified as Tier 2* since it is referenced in AP1000 DCD Section 3.8.5 and it includes key details of the design of the foundation. Similarly, justification was not provided for identification of Tier 2* for TR-09, TR-57, and the updated shield building reports. Therefore, in a follow-up to RAI-TR85-SEB1-10, the staff requested that TR-09, TR-57, and TR-85 be identified as Tier 2* information in the AP1000 DCD, or an acceptable justification be provided.

At the seismic audit conducted during the week of June 14, 2010, the staff reviewed the 2D [ ] nonlinear sliding stability evaluation. As a result of this review, a change was made to the [ ] sliding/contact finite element, which resulted in larger horizontal displacements. The resulting maximum displacements, reported in the applicant's letter dated August 25, 2010, at the base of the NI basemat were determined to be 0.30 cm (0.12 in) without buoyant force consideration, and 0.48 cm (0.19 in) with buoyant force effects considered. These values are larger than the previously reported results of 0.77 mm (0.03 in) without buoyant force consideration, and 1.14 mm (0.045 in) with buoyant force effects. However, these values are still judged to be negligibly small, especially when the conservative analysis approach of neglecting any sliding resistance from the soil passive pressure and neglecting the additional frictional forces along the buried portions of the NI side walls are considered. Therefore, it can be concluded that the NI is stable against sliding. However, the applicant must revise the response to RAI-TR85-SEB1-10 to reflect the revised finite element for sliding and the increase in displacements, and provide the mark-ups for the AP1000 DCD changes and TR-85 to reflect the changes in the sliding evaluation.

In response to the above requests, the applicant's letters dated July 30, 2010, and August 25, 2010, indicated that the applicant would review the information in the RAI responses and the structural TRs for the key analysis and design information that should be included in the AP1000 DCD, and would provide DCD mark-ups for the complete Sections 3.7 and 3.8, as well as Appendixes 3G, 3H and 3I, identifying the Tier 2* information. In addition, the applicant provided the mark-ups for the AP1000 DCD and TR-85 to reflect the changes in the sliding evaluation due to modifications for the sliding/contact finite element. The staff's review of the RAI responses in the two letters concluded that the proposed approach, to add the specific Tier 2* information from the applicable TRs and shield building report(s) to the AP1000 DCD, is acceptable because mark-ups will be provided and give the staff an opportunity to confirm that the required information will be identified as Tier 2* in the AP1000 DCD. The response regarding the revised NI seismic sliding evaluation is also acceptable because it provides the mark-ups for the changes to the AP1000 DCD and TR-85 to reflect the changes in the sliding evaluation and the increases in seismic displacement due to sliding. The staff notes that the applicant clarified the design basis by letters dated October 21, 2010, whereby they withdrew TR-57 and provided mark-ups of the DCD to show the removal of references to TR-57 and stated the location where the information, as updated, appears in the proposed DCD and an appendix thereto. In a subsequent revision to the AP1000 DCD, the applicant made appropriate changes to the DCD text, tables and figures and TR-85 report. In addition, to document proprietary design detail information, including Tier 2* information, for the AP1000 Shield Building cylinder and connections to the auxiliary building and basemat, the applicant proposed a proprietary report, APP-GW-GLR-602, entitled "AP1000 Shield Building Design Details for Select Wall and RC/SC Connections." The staff reviewed APP-GW-GLR-602 and determined that it resolved the issues discussed above and is, therefore, acceptable.

A concrete mud mat consisting of an upper and a lower mud mat is placed on top of the soil foundations to provide a level support for the structural concrete basemat. A waterproofing membrane is placed between the upper mud mat and the lower mud mat. In RAI-TR85-SEB1-35, the staff requested that the applicant describe, in greater detail, the types of waterproofing materials to be used and how the coefficient of friction for these materials, assumed in the sliding stability evaluations, will be demonstrated. In response, the applicant explained that one of three types of waterproofing systems is used: plasticized polyvinyl chloride (PVC) membrane, HDPE membrane, or a crystalline spray type material. The AP1000 DCD requires COL applicants to demonstrate by testing that the waterproofing membrane will achieve a minimum coefficient of friction of 0.55 (the value which was used for the NI sliding stability analysis) between it and the concrete mud mat.

The staff's review of the applicant's responses to RAI-TR85-SEB1-35 determined that the information provided to describe the waterproofing materials was not sufficient and that further revisions in the AP1000 DCD were required to reflect the revised details of the waterproofing materials. The remaining items that needed to be addressed relate to the proposed mark-up in the AP1000 DCD describing the waterproofing materials, more detailed information about the type and industry standards used for the waterproofing membrane, and information that demonstrates the adequacy of the crystalline waterproofing material.

In the applicant's letter dated June 30, 2010, the response to RAI-TR85-SEB1-35 indicated that the waterproofing system for the below grade walls and mud mat would consist of either the HDPE double-sided textured membrane; HDPE single-sided adhering sheet membrane; self-adhesive, rubberized asphalt/polyethylene membrane (for walls only); or sprayed-on waterproofing membrane based on polymer-modified asphalt or polyurea. The response explained that the use of the crystalline waterproofing material had been eliminated as an option. In addition, the industry standards used to specify performance requirements and other design requirements (e.g., maximum crack width) for the waterproofing systems were provided.

The proposed mark-ups to the AP1000 DCD describing the waterproofing materials and performance requirements were also provided and found to be acceptable based on the use of the applicable industry standards and industry practices. Also, the elimination of the use of the crystalline material resolves the questions raised regarding the adequacy of this material. In a subsequent revision to the AP1000 DCD, the applicant made appropriate changes to the DCD text, which resolves this issue.

3.8.5.1.4 The Effect of Basemat Liftoff from the Ground

Section 2.4.2 of TR-85, Revision 1, and the response to RAI-TR85-SEB1-14 described analyses performed using a 2D [ ] nonlinear model to evaluate the potential effects of liftoff. This was needed because [ ] analyses cannot model nonlinear behavior, such as liftoff of the NI structure from the soil. The [ ] analyses permit tension to be transferred across the interface between the basemat and the soil. Therefore, analyses were performed with the 2D [ ] nonlinear model, which allowed for liftoff, and the results were compared to 2D [ ] analyses, which do not have liftoff. The NI superstructures (i.e., structures above the basemat) were represented as stick models in both the 2D [ ] model and the 2D [ ] model. In the 2D [ ] model, the soil was represented by horizontal and vertical springs. The springs were only effective when the basemat was in contact with the soil (i.e., when the springs were in compression).

The results of the two analyses were compared in terms of FRS in the structures, member forces, and soil bearing pressures. The applicant provided comparisons of in-structure FRS, member forces and soil bearing pressures. The applicant indicated that these comparisons show that there is no significant difference between the 2D [ ] nonlinear analyses and the 2D [ ] linear analyses. On this basis the applicant concluded that the NI superstructure may be designed neglecting liftoff, but the basemat design does need to consider the effects of liftoff. Thus, Section 2.6 in TR-85 provides the analysis and design of the NI basemat, which uses a 3D [ ] model that does consider liftoff.

The staff review of the tabulated comparisons of the member forces at representative locations between the 2D [ ] and the 2D [ ] analyses showed a maximum difference of 2.7 percent. The in-structure generated response spectra comparisons at key locations showed that the 2D [ ] nonlinear analysis spectra were often below or within about 10 percent above the 2D [ ] linear results, except at the very low frequency of about 4.8 Hz in the vertical direction where the difference is about 15 percent. For soil bearing comparisons, the differences for the maximum soil bearing pressures were within about 6 percent. Since the applicant performed a nonlinear [ ] analysis with liftoff capability and showed that the results are reasonably close to the [ ] results without liftoff capability, the staff finds the applicant’s approach for addressing the NI liftoff effects acceptable. Therefore, RAI-TR85-SEB1-14 is resolved.

3.8.5.1.5 Basemat Design

3.8.5.1.5.1 Seismic Analysis of NI Basemat and Soil Reaction Force (Pressure) at the Bottom of the Basemat

The seismic analysis was based on the 3D [ ] finite element NI05 model using seismic equivalent static accelerations, which were obtained from the time history analysis of the NI on HR, prior to the design changes made to enhance the shield building. This 3D [ ] NI05 analysis of the basemat is described in Section 2.6.1 of TR-85, Revision 1, and in the responses to RAI-TR85-SEB1-21, RAI-TR85-SEB1-22, and RAI-TR85-SEB1-23. The model is nonlinear because soil springs can only take compression but not tension when the basemat lifts off the ground. To verify the adequacy of the equivalent static accelerations used in the 3D [ ] NI05 model another study was performed. First, a linear analysis using the equivalent static accelerations discussed above was performed to determine the total base reactions and soil bearing pressures. Then, a time history fixed base analysis, which accounted for the various soil profiles, was performed. The time history inputs for this analysis were developed based on the envelope of the basemat responses given by the 3D [ ] analyses. The 3D [ ] analyses considered five soil cases: FR, SR, UBSM, SM, and SS. Based on the comparison of the base reactions and soil bearing pressures from the equivalent static analysis (for the HR condition) and the time history analysis (for the range of soil conditions), the applicant concluded that the study demonstrated that the equivalent static accelerations from the prior time history analysis of the NI on HR, are still acceptable.

The staff finds that the 3D [ ] NI05 model is appropriate since it was developed in accordance with industry methods and is consistent with the guidance presented in NUREG-0800 Section 3.8.5. The applicant's use of the equivalent static analysis as described above is reasonable because the applicant compared the base reactions from the NI and soil bearing pressures obtained from the equivalent static analysis with the results from the time history analysis that considered the range of possible soil conditions.

The soil pressure imposed on the bottom of the basemat, obtained from the above seismic analyses, is based on the assumption that the NI rests on a uniform soil site. For a site to be considered uniform, the variation of Vs in the material below the foundation to a depth of 36.7 m (120 ft) below the finished grade within the NI footprint shall meet the criteria as stated in AP1000 DCD Section 2.5.4.5.3.

A 20 percent margin was provided in the design of the basemat, which was intended to account for possible soil property variations beneath the basemat at a site that may not meet the criteria for uniform soil sites. Additional analyses would be required for nonuniform soil sites. If the soil variations exceed the criteria as defined in AP1000 DCD Section 2.5.4.5.3, then the AP1000 DCD requires that an evaluation for nonuniform soil conditions be performed and this evaluation needs to be provided as part of the COL application. A procedure for evaluating the site-specific nonuniform soil condition is also provided in AP1000 DCD Section 2.5.4.5.3.

3.8.5.1.5.2 Soil Subgrade Modulus

In RAI-TR85-SEB1-05, the staff requested that the applicant provide a complete set of soil subgrade modulus values used for the AP1000 rock and soil cases. In a letter dated March 31, 2008, the applicant provided its response as follows:

- Subgrade moduli of 984.5, 502.7, 157.1, and 300.2 MPa/m^3 (6267, 3200, 1000, and 300 kips per cubic feet (kcf)) were used for HR, SR, SM and SS sites in the 2D [ ] parametric linear dynamic analyses described in Section 2.4.2 of TR-85. The results of the analyses for SR and SS were not used.

- Subgrade moduli of 984.5 MPa/m^3 (6267 kcf) and 157.1 MPa/m^3 (1000 kcf) were used for the HR and SM soil sites in the 2D [ ] nonlinear dynamic analyses described in Section 2.4.2 of TR-85.

- A subgrade modulus of 984.5 MPa/m^3 (6267 kcf) was used for HR in the 3D [ ] equivalent static nonlinear analysis for design of the basemat as described in Section 2.3.1 of TR-85.

- A subgrade modulus of 81.7 MPa/m^3 (520 kcf) was used for soil sites in the 3D [ ] equivalent static nonlinear analysis for design of the basemat as described in Section 2.6.1 of TR-85.

- A subgrade modulus of 40.8 MPa/m^3 (260 kcf) was used in the 3D [ ] equivalent static nonlinear parametric analysis for evaluation of the effect of a lower subgrade modulus as described in Section 2.7.1.1 of TR-85.

TR-85, Revision 1, indicates that the design of the NI basemat is based on the soil subgrade modulus corresponding to 81.7 MPa/m^3 (520 kcf) (comparable to the SM soil condition). This value of soil subgrade modulus was determined to be the governing soil case for design of the basemat considering the range of soil properties from HR to SS. To address soil conditions potentially softer than 81.7 MPa/m^3 (520 kcf), a study was performed to evaluate the effects of using lower stiffness values for the soil. Based on the applicant's March 31, 2008, and January 9, 2009, letters, the staff identified a number of items that still needed to be addressed regarding the evaluation for the appropriate range of subgrade modulus values. One of the concerns was that at other similar soil sites, subgrade modulus values as low as 6.3 MPa/m^3 (40 kcf) (static case) and about 12.6 MPa/m^3 (80 kcf) (dynamic case) have been identified. Therefore, in a follow-up to RAI-TR85-SEB1-05, the applicant was requested to explain whether the use of such low values had been considered and, if not, to provide the technical basis for not considering these values.

In a letter dated August 4, 2009, the applicant described the results of a study that was performed for a low soil modulus value of 12.6 MPa/m^3 (80 kcf) whose results were compared to the analysis using 81.7 MPa/m^3 (520 kcf) and 40.8 MPa/m^3 (260 kcf) soil moduli. To address the concern related to the design of the foundation, the RAI response indicates that a comparison of the 2D [ ] analysis results for all soil cases (FR, SR, UBSM, SM, and SS) was made to the soil case corresponding to a subgrade modulus of 12.6 MPa/m^3 (80 kcf). The results show that the soil bearing pressures for the 12.6 MPa/m^3 (80 kcf) soil case are very close to the 40.8 MPa/m^3 (260 kcf) (SS) case and they are bounded by the results for the 81.7 MPa/m^3 (520 kcf) case, which was used in the design of the basemat. The bending moments for the shield building at the base using the 81.7 MPa/m^3 (520 kcf) soil case bound the moments for the 12.6 MPa/m^3 (80 kcf) soil case. Therefore, the applicant concluded that these results demonstrate that the design of the foundation using a soil modulus value of 81.7 MPa/m^3 (520 kcf) is valid for soil subgrade moduli as low as 12.6 MPa/m^3 (80 kcf). For the soil bearing pressure demand, the comparisons presented in the RAI response show that the soil bearing pressure demand, used as interface criterion in the AP1000 DCD Tier 1, is acceptable since it bounds the soil bearing pressure for the 12.6 MPa/m^3 (80 kcf) case.

The staff found that the 2D [ ] analysis results demonstrate that the building responses for the 12.6 MPa/m^3 (80 kcf) soil modulus are bounded by the results for the 81.7 MPa/m^3 (520 kcf) soil case, which was used for design of the structures and for determining the soil bearing pressure demand. Also, for stability evaluation, the results presented in TR-85, Revision 1, show that the seismic shear force and overturning moment are lower when softer soil conditions are considered. Therefore, the stability evaluation performed by the applicant would also bound the results obtained with a reduced soil modulus of 12.6 MPa/m^3 (80 kcf). Based on the above discussion, the staff concludes that the soil cases used by the applicant for design, soil bearing pressure demand, and stability evaluation address the staff's concerns regarding subgrade moduli values lower than 81.7 MPa/m^3 (520 kcf). Therefore, RAI-TR85-SEB1-05 is resolved.

3.8.5.1.5.3 Assumption of Uniform Soil Pressure beneath the Basemat

The applicant assumed uniform soil pressure acting on the bottom of the basemat in its analysis for bending moments and shear forces in the basemat. It is a well-known phenomenon in soil mechanics that the soil pressure is higher at the edge of the basemat than it is away from the edge, which is referred to as the Boussinesq effect. Therefore, in RAI-TR85-SEB1-32, the staff requested that the applicant demonstrate that the use of the uniform soil springs for the design of the basemat is justifiable, where the actual distribution of the soil stiffness would not be uniform.

The RAI responses, dated June 23, 2009, and October 19, 2009, presented the results of a study that compared soil bearing pressures due to dead load at the bottom of the basemat from the uniform soil springs and the finite element representation of the soil. However, these results showed that the soil bearing pressure along the horizontal interface between the basemat and the soil do not appear to compare well in some regions. Furthermore, separate moment contour plots were provided for the basemat corresponding to each soil stiffness representation; however, without a direct quantitative comparison of member forces it is difficult to judge that the use of the uniform soil springs for the design of the foundation is acceptable. In a follow-up RAI, the staff requested that the applicant clearly demonstrate that the bending moments and shear forces in the basemat using uniform soil springs are acceptable by providing quantitative data from the study at locations in the basemat that govern the design.

Based on the applicant's letter dated June 19, 2010, a study was performed to compare the uniform soil spring approach with the more accurate finite element soil representation that is able to capture the Boussinesq effect in soils. This study showed that the soil pressures are not uniform and that some member forces in the critical sections in the basemat were larger using the finite element soil model. The applicant tried to scale the prior design results to show that the design is still adequate for the increased loads. However, the response to the RAI did not adequately demonstrate that the design met the code limits.

In a letter dated July 30, 2010, the applicant provided the re-evaluation for the basemat design using the increased loads from the finite element model for the critical (governing) sections and using the permissible redistribution of moments in accordance with the ACI 349 Code. In addition, the applicant provided the results for the various 100-40-40 seismic combination methods used for the design of the basemat. The staff's review of the response determined that several items still needed to be addressed, primarily because the response to the RAI still did not adequately demonstrate that the design met the code limits. Nor was the use of the Westinghouse 100-40-40 method appropriate. Therefore, in a follow-up RAI, the staff requested that the applicant justify the use of the 20 percent moment redistribution; show that the reinforcement design meets code requirements; provide the comparison for the Westinghouse 100-40-40 method versus the ASCE 4-98 industry method; and demonstrate that there are no significant increases in the basemat forces due to potential concrete cracking.

In response to the above requests, the applicant's letter dated September 8, 2010, provided detailed information justifying the use of the 20 percent moment redistribution in accordance with the ACI 349 Code. In addition, according to the letter, a new study was performed to compare the results from a 2D nonlinear (with lift-off capability) equivalent static analysis using the Westinghouse 100-40-40 method with those from a 2D nonlinear (with lift-off) time history analysis. The study shows that the maximum basemat bearing pressure from the 2D static analysis with the Westinghouse 100-40-40 method in two dimensions is about 30 percent higher (i.e., more conservative) than that of the bearing pressure from the more accurate 2D dynamic time history analysis approach. To address the effect of concrete cracking on the basemat forces, the applicant performed another study, which provided a comparison of the FRS at representative locations in the NI, which shows that the ZPAs obtained from the nonlinear analysis (that considers cracking of concrete) were reasonably close to the ZPAs obtained from the linear analysis using a stiffness reduction factor of 0.80, which was assumed in the design basis analysis.

The staff review of the response concluded that: (1) the justification for the use of 20 percent moment redistribution is acceptable because the information provided demonstrates that the provisions in ACI 349 regarding negative moment redistribution have been satisfied; (2) the basemat design based on the 2D nonlinear (with lift-off) equivalent static analysis using the Westinghouse 100-40-40 method is conservative based on the applicant's study comparing the results to the more accurate 2D nonlinear time history analysis, which inherently includes the phasing of the different input components; and (3) there is no significant increase in the basemat forces due to concrete cracking in the NI, because another study was performed to demonstrate that the use of the 0.8 stiffness reduction factor adequately accounts for cracking. In a subsequent revision to the AP1000 DCD, the applicant made appropriate changes to the DCD text and TR-85, which resolve this issue.

3.8.5.1.5.4 Load Combinations and Reinforcement Design

As a result of the staff's review of TR-85, a number of questions were identified related to the load combinations and design of the basemat reinforcement. These questions were captured in RAI numbers TR85-SEB1-28, TR85-SEB1-29, and TR85-SEB1-30. As a result of these RAIs, the applicant made a number of revisions in the analyses and design methods to address these issues. The description provided below presents the staff's evaluation of the key issues related to the load combinations and design of the basemat reinforcement.

In RAI-TR85-SEB1-28, the staff requested that the applicant explain why the load combinations presented in the TR-85 were not consistent with those in Table 3.8.4-2 of the AP1000 DCD. In a letter dated December 2, 2008, the applicant provided a mark-up of AP1000 DCD Table 3.8.4-2 to be consistent with the revised TR-85. The staff finds that the new load combinations in the mark-up of AP1000 DCD Table 3.8.4-2 and in the revised TR-85 are in accordance with the ACI 349-01 Code, and, thus, are acceptable. In a subsequent revision to the AP1000 DCD, the applicant made appropriate changes to the DCD table, which resolves this issue.

In RAI-TR85-SEB1-29, the staff requested that the applicant describe the design approach used for the basemat in accordance with ACI 349-01. The staff also asked whether every 3D [ ] finite element is designed for the resultant forces in accordance with the ACI 349 Code and whether this process is automated by using a computer code or by hand calculations. In a letter dated October 19, 2007, the applicant stated that the design procedure is described in [ ], Revision 1, Section 4.2, "Calculation Approach/Methodology," and the calculation process is automated by a computer code. During the review of the shield building design, the staff found a potential error in the code. In the applicant's letter dated July 9, 2010, the response provided an explanation as to why some of the results from the computer code may have appeared as an error but they were not. The RAI response explained that the negative value of shear shown in the computer code results indicates that the code has detected that the concrete is in tension beyond its limit. The computer code does not use the strength provided by the concrete in that case. Based on the review of the design approach presented by the applicant for the basemat, the use of the ACI 349-01 Code for sizing the concrete sections and selection of reinforcement, and the information provided in the RAI response, which explained why negative values for shear may appear in the results generated from the computer code, the staff concludes that the design approach is acceptable. Therefore, RAI-TR85-SEB1-29 is resolved.

3.8.5.1.5.5 Minimum Required Soil Friction Angle, Settlement Criteria for the NI Structure, and Construction Sequence

Section 5.1 of TR-85 presents the proposed revisions to AP1000 DCD Tier 2, Table 2-1, which includes the site parameters including those for the soil media. Section 5.2 presents the proposed revisions to AP1000 DCD Tier 1, Table 5.0-1, which also includes the site parameters for the soil. Considering that the foundation of the AP1000 design has been extended to soil sites, in RAI-TR85-SEB1-36, the staff requested that the applicant include, in both tables, two additional parameters, which are needed for the structural design of the NI: a minimum required soil friction angle of 35 degrees beneath the basemat and settlement criteria for the NI structure.

In a letter dated March 31, 2008, the applicant provided the following response:

a) The minimum required soil friction angle of 35 degrees has been added to both Tables 2-1 and 5.0-1.

b) AP1000 DCD Section 2.5.4.6.11 requires the COL applicant to evaluate settlement at soil sites. The effect of settlement on the NI basemat during construction has been considered in the design of the NI as described in Section 2.5 of the report and in AP1000 DCD Section 3.8.5.4.2. These analyses considered the flexibility of the basemat during construction by performing a nonlinear analysis of the soil and NI. The nonlinear analyses are described in the applicant’s response to RAI-TR85-SEB1-19, dated March 31, 2008. The analyses used the NI05 building model described in AP1000 DCD Appendix 3G. The analyses considered an SS site with properties selected to maximize the settlement during construction. Immediate settlements were based on elastic properties of the foundation medium, while the time-related settlements used creep parameters established by comparison against one-dimensional consolidation theory. These analyses show total settlements of about one foot.

The applicant has established guidance on settlement for the COL applicant in the RAI response. The acceptable criteria are as follows: Acceptable differential settlement between buildings without additional evaluation is identified as 7.6 cm (3 in) between the NI and the Turbine Building, the Annex Building, and the Radwaste Building. The 7.6 cm (3 in) is measured from the center of the Containment Building to the center of the Turbine Building, center of the Annex Building, or the center of the Radwaste Building. Each building, including the NI, also has a settlement criterion of no more than 1.3 cm (½ in) in 15.2 m (50 ft) in any direction. The NI also has an acceptable maximum absolute settlement value of 7.6 cm (3 in). If site-specific settlement analyses predict settlements below the values in this table, the site is acceptable without additional evaluation. If the analyses predict greater settlement, additional evaluation will be performed. This may include specification of the initial building elevations, specification of the stage of construction and settlement for making connections of systems between buildings, etc. It would also include review of the effect of the rotation of buildings and its effect on the gap between adjacent structures. These analyses would provide the basis for review of settlement measurements during construction and subsequent operation.

Regarding part a) of the RAI response, the staff noted that in a letter dated June 10, 2009, the applicant indicated that a soil internal friction angle of 35 degrees is required beneath the basemat and it is specified in Table 2-1 of the AP1000 DCD, and that the second paragraph of AP1000 DCD Section 2.5.4.6.2 is revised to state that if the minimum soil angle of internal friction is below 35 degrees, the COL applicant will evaluate the seismic stability against sliding as described in Section 3.8.5.5.3 using the site-specific soil properties. The applicant also decided to remove the criterion for the soil friction angle of 35 degrees from the prior versions of AP1000 DCD Tier 1, Table 5.0-1, “Site Parameters.” After reviewing the applicant’s submittals, the staff requested that the applicant address several issues discussed below.

During the August 10, 2009 audit, the staff informed the applicant that if a site-specific evaluation is required for sliding because the soil friction angle is less than 35 degrees, then Section 3.8.5.5.4 of the AP1000 DCD should also add the evaluation requirement for overturning stability. In addition, the staff considered the demonstration of a site soil friction angle of 35 degrees to be a key site parameter in the stability evaluations and other analyses, such as determining the soil pressure loads for the design of the NI foundation walls. Therefore, this criterion should remain in AP1000 DCD Tier 1, Table 5.0-1. In a letter dated September 22, 2009, the applicant provided a proposed mark-up of AP1000 DCD Tier 1, Table 5.0-1, and AP1000 DCD Tier 2, Section 2.5.4.6.2, to incorporate the requirement for a site-specific evaluation when the soil friction angle is less than 35 degrees. However, the wording in AP1000 DCD Table 5.0-1, for the requirement of a site-specific evaluation, needs to be clarified so that it is clear that a stability evaluation should be performed for both sliding and overturning stability. In a letter dated May 14, 2010, the applicant revised the wording in the proposed mark-ups to AP1000 DCD Tier 1, Table 5.0-1, and AP1000 DCD Tier 2, Section 2.5.4.6.2. Since the AP1000 DCD markups specify the requirement for a minimum soil angle of internal friction of 35 degrees, and if it is less than 35 degrees, then the COL applicant will perform a site-specific analysis to demonstrate stability (sliding and overturning), the staff’s review of the information concluded that the response is acceptable. In a subsequent revision to the AP1000 DCD, the applicant made appropriate changes to the DCD text and table, which resolve this issue.

Regarding part b) of the RAI response, the staff observed that if acceptable soil sites are already known to cause potential settlements of as much as one foot as previous studies have indicated, then the construction settlements will in fact exceed the listed limitation of 7.6 cm (3 in) for most soil sites. The staff requested that the applicant explain: (a) what should be the detailed plan that the COL applicant needs to implement when the predicted settlements in fact exceed 7.6 cm (3 in); and (b) if any of the predicted settlements are less than 7.6 cm (3 in) for the total settlement, as well as less than the other acceptance values presented in AP1000 DCD Table 2.5-1, while the actual measured settlements during construction are found to exceed these values before completion of construction, what is the impact on the ongoing construction process and what the COL applicant is supposed to do at that time.

In the applicant’s letters dated December 2, 2008, and July 21, 2009, additional information was provided and one of the settlement threshold values was revised. The limit of acceptable settlement without additional evaluation was raised to 15.2 cm (6 in) for the total NI foundation mat. The RAI response also explained what steps would be taken in case the COL applicant’s predicted settlement analysis for the site-specific conditions exceeds these limits.

The staff reviewed the information regarding the settlement criteria and concluded that the applicant has evaluated the effects of settlement on the structural integrity of the NI and that conservative settlement threshold values (i.e., lower than the settlement values used for evaluation of the NI) have been proposed for inclusion in the AP1000 DCD. However, as requested in the original RAI and supplemental RAIs, the settlement criteria in the proposed mark-up of AP1000 DCD Tier 2, Table 2.5-1, should also be presented in AP1000 DCD Tier 1, Table 5.0-1.

In response to the above request, the applicant's letter dated June 21, 2010, indicated that the settlement criteria in the proposed mark-up of AP1000 DCD Tier 2, Table 2.5-1, are added to AP1000 DCD Tier 1, Table 5.0-1. In a subsequent revision to the AP1000 DCD, the applicant made appropriate changes to the DCD text, which resolves this issue.

In Section 2.5 of TR-85, the first paragraph states that in the expected basemat construction sequence, concrete for the mat is placed in a single placement. The last sentence of the same paragraph states that once the shield building and auxiliary building walls are completed to El. 25.1 m (82 ft-6 in), the load path changes and loads are resisted by the basemat stiffened by the shear walls. In RAI-TR85-SEB1-17, the staff requested that the applicant address several items related to the construction sequence. The applicant was requested to address issues related to the concrete pour of such a massive single concrete placement, how residual stresses at the junction between the shear walls and the shield building are calculated considering the construction sequence, and where in the AP1000 DCD the requirement to follow the construction sequences considered by the applicant in the design of the NI structures is located.

In a letter dated March 31, 2008, the applicant provided information to address the various items identified in the RAI. Regarding the construction sequence, the applicant described three construction sequences that were evaluated for an SS site to demonstrate construction flexibility within broad limits. The acceptability of the construction sequence used by the COL applicant is addressed by an ITAAC. The three construction sequences are as follows:

- A base construction sequence, which assumes no unscheduled delays.
- A delayed shield building case, which assumes a delay in the placement of concrete in the shield building while construction continues in the auxiliary building.
- A delayed auxiliary building case, which assumes a delay in the construction of the auxiliary building while concrete placement for the shield building continues.

The applicant indicated that analyses of alternate construction scenarios showed that member forces in the basemat are acceptable subject to the following limits imposed for SS sites on the relative level of construction of the buildings prior to completion of both buildings at El. 25.1 m (82 ft 6 in):

- Concrete may not be placed above El. 25.6 m (84 ft 0 in) for the shield building or CIS.
- Concrete may not be placed above El. 35.8 m (117 ft 6 in) in the auxiliary building, except in the CA20 structural module where it may be placed to El. 41.1 m (135 ft 3 in).

Based on the staff's evaluation of this response and follow-up RAI responses, the applicant was requested to revise the RAI response and Sections 2.5 and 3.8.5 of the AP1000 DCD to clearly state that in addition to satisfying settlement criteria the construction sequence limitations presented in Section 3.8.5.4.2 must be satisfied by the COL applicant. In the letter dated October 19, 2009, the applicant provided the proposed mark-up of AP1000 DCD Sections 2.5 and 3.8.5.4.2. The proposed wording indicates that the construction sequence limitations are only applicable to soil sites and not foundations identified by the applicant as SR, FR, or HR. The staff requested that the applicant justify why no construction sequence limitations are needed for the stiffer foundation materials.

In the applicant's letter dated July 15, 2010, the response to RAI-TR85-SEB1-17 indicated that the construction of the AP1000 will satisfy the construction sequence limits shown in AP1000 DCD Section 3.8.5.4.2 or a site-specific analysis of settlement and member forces will be completed. These limits do not apply to AP1000 units with a soil profile where Vs exceeds 2286.0 m/s (7500 fps). The Vs at the bottom of the basemat (i.e., locally) can drop to 2286.0 m/s (7,500 fps), while maintaining a Vs equal to or above 2438.4 m/s (8,000 fps) at the lower depths. The staff reviewed the proposed mark-ups to the AP1000 DCD and concluded that they are acceptable because: (1) the AP1000 was designed for the various construction sequences; and (2) the construction sequence limitations used in the SS evaluation are imposed on all soil conditions except for rock conditions having a Vs greater than 2286.0 m/s (7,500 fps). In a subsequent revision to the AP1000 DCD, the applicant made appropriate changes to the DCD text, which resolves this issue.

3.8.5.1.5.6 The Effect of Ground Water on Nuclear Island Structures

The design of the AP1000 plant is based on saturated soil conditions. In RAI-TR85-SEB1-40, the staff requested that the applicant explain whether unsaturated conditions were also considered in performing any SSI analyses to determine the effects of unsaturated soils on the response of the NI in terms of member forces, deformations, and FRS.

In a letter dated May 27, 2009, the applicant indicated that it performed a time history analysis using a saturated and unsaturated SM soil profile (Poisson's ratio = 0.35) and compared the FRS of the two analyses. Generic SSI analyses for the AP1000 assume the water table to be at grade level with saturated soil properties supporting the NI. The unsaturated soil profile was produced from a SHAKE analysis where the water table was assumed to be well below the NI. The results of this analysis indicated that the depth of the water table used for SSI analyses has a negligible effect on the FRS at the key nodes. This study shows that generally the FRS for these two cases are very close to one another, with the spectra from saturated conditions somewhat higher in a few isolated cases. Since the FRS differences between the two models are negligible, no additional analyses are required to compare member forces or deformations.

The staff reviewed the applicant's submittal regarding the effect of saturated and unsaturated soil conditions on NI structures, and found the applicant's approach to address the issue reasonable and acceptable. Since the study shows that, generally, the FRS for both saturated and unsaturated cases are very close to each other, with the spectra from saturated conditions somewhat higher in a few isolated cases, and the design of the AP1000 plant is based on the saturated conditions, the staff concludes that the AP1000 design using saturated soil conditions adequate and acceptable. Therefore, RAI-TR85-SEB1-40 is resolved.

3.8.5.1.5.7 Potential Uplift/Sliding between CIS and Containment, and between Containment and Basemat

In RAI-TR85-SEB1-12, the staff requested that the applicant explain how the potential uplift and sliding between the CISs concrete base and the steel containment shell is addressed for the various soil conditions, and provide the basis for the statement in Section 3.8.2.1.2 of the AP1000 DCD, which indicates that the shear studs provided between the containment and concrete basemat below the containment are not required for design basis loads, but provide additional margin for earthquakes beyond the SSE.

In a letter dated October 19, 2007, the applicant stated that its analyses of stability for the HR site demonstrated that there was no uplift or sliding at the interface of the CIS and the CV. These analyses showed potential uplift of the CV and CISs from the NI basemat for the RLE. Based on these analyses, the applicant provided shear studs between the CV and the NI basemat to provide additional margin for the RLE. These studs were then designed to accommodate pressurization of the CV. The number of studs required for containment pressure was more than double the number required for seismic overturning for the RLE at the HR site. Revision 1 of TR-85 describes the analysis, which demonstrated that no uplift or sliding occurs between the CIS and the containment, and between the containment and the basemat for both design basis SSE level of 0.3g and RLE level of 0.5g PGA for HR and all soil conditions. Based on this, RAI-TR85-SEB1-12 is resolved.

3.8.5.1.5.8 The 100-40-40 Method for Combining Three Components of Earthquake Motions

AP1000 DCD Section 3.7.2 states that the 100-40-40 method is used for combining the three components of earthquake motions for the NI basemat analyses, CV analyses and shield building roof analyses. NRC regulatory guidance in RG 1.92 and NUREG-0800 Section 3.7.2 indicates that the use of the 100-40-40 combination method is only acceptable for combining the co-directional responses, such as Mxx due to north-south, east-west, and vertical directions in order to obtain a combined Mxx. However, it does not appear from a review of TR-85 and AP1000 DCD Section 3.8 that the applicant has combined the three components in accordance with RG 1.92 and industry standard ASCE 4-98. This issue was also identified during the staff's evaluation of TR-57 and APP-1200-S3R-003 for the shield building, which is discussed in Section 3.8.4.1.1 of this report. The issue of the proper implementation of the 100-40-40 method was captured under RAI-TR85-SEB1-27.

As indicated in a letter dated July 3, 2010, the applicant's approach for the 100-40-40 method (Westinghouse 100-40-40 method) was used for both seismic linear and nonlinear equivalent static analyses for the design of the NI basemat, the SCV and the shield building roof. In addition, the applicant also indicated that: (1) for the basemat, the justification for using the applicant's 100-40-40 method was addressed under RAI-TR85-SEB1-32; (2) for the SCV, the adequacy of using the applicant's 100-40-40 method for the SSE loading condition was confirmed by a direct comparison of the combined seismic stress results against those from the more accurate time history analysis; and (3) for the shield building roof, a comparison of the applicant's 100-40-40 method to the ASCE 4-98 method was made. For the shield building roof analysis and design, the applicant developed equivalent static accelerations, such that the resulting member forces would envelope those from the RSA, performed for the input motion applied at the foundation level enveloping all the soil cases. The justification for using the applicant's 100-40-40 method was provided by comparing the combined member forces corresponding to the 24 cases of the applicant's 100-40-40 method with the member forces from the ASCE 4-98 method.

The staff's review of the information provided to the staff concluded that: (1) the justification for using the applicant's 100-40-40 method under RAI-TR85-SEB1-32 is acceptable since this approach is coupled directly with the basemat design issue under RAI-TR85-SEB1-32, which was previously reviewed above; and (2) the response for the SCV is acceptable, because the results provided show that the applicant's 100-40-40 method produced conservative results when compared with the more accurate time history analysis results. However, the response for the shield building roof provided insufficient information, primarily because the comparison of the applicant's 100-40-40 method with the ASCE 4-98 method is only made for member forces and not the final design parameter (e.g., required reinforcement for concrete members or stress level for steel members). Therefore, it is not clear that the applicant's 100-40-40 method is adequate. To address the issue of the proper implementation of the 100-40-40 method for the shield building roof design, the staff requested that the applicant identify the locations where the 100-40-40 method was applied in the shield building roof design; determine the maximum required reinforcement (or stress levels for steel members) using the 24 cases of the applicant's 100-40-40 method (as is done in the applicant's design process) and compare these results with the required reinforcement (or stress levels for steel members) using the NRC-accepted SRSS method or the ASCE 4-98 100-40-40 method.

In response to the above requests, the applicant's letter dated September 23, 2010, identified that the air inlet, the tension ring and the composite radial steel beams were designed using the applicant's 100-40-40 method, and provided figures and descriptions of the models used for the design of the shield building roof. To justify the use of the applicant's 100-40-40 method, the applicant presented comparisons for the final design parameters for these members showing that, although in some cases the applicant's 100-40-40 method was nonconservative when compared with the SRSS method or the ASCE 4-98 method; in all cases the design of these members is still acceptable. This was demonstrated for concrete members by showing that the required reinforcement using the NRC-accepted SRSS method was less than the provided reinforcement and for steel members by showing that the calculated stresses using the NRC-accepted SRSS method were less than the code allowable.

In a subsequent revision to the AP1000 DCD and TR-85, the applicant made appropriate changes to the DCD and TR-85 text, which resolve this issue.

3.8.5.1.6 Record Keeping Issues

Sections 2.3.1, 2.4.1, 2.4.2, and 2.6.1 of TR-85 indicate that equivalent static nonlinear analysis, 2D [ ] analysis, 2D [ ] linear dynamic analysis, 2D [ ] nonlinear time history analysis, 3D [ ] equivalent static nonlinear analysis, and others were performed. In RAI-TR85-SEB1-04, the staff requested that the applicant develop a table (or tables) similar to AP1000 DCD Tables 3.7.2-14 and 3.7.2-16 to show: (1) the purpose of each analysis; (2) the model type(s); (3) analysis method(s); (4) soil condition(s); (5) loads, load combinations, combination method (for combining loads and directional combinations for SSE); (6) governing design loads; and (7) reference location in TR-85 or other reports for the detailed description.

In a letter dated December 4, 2007, the applicant provided revisions to the AP1000 DCD tables to show the additional information requested in this RAI and to reflect the changes in the methodology described in other RAI responses. Although sufficient information to describe the evaluations performed for the bearing pressure demand, foundation stability, and design of the basemat, has been provided in this and other RAI responses and in TR-85, Revision 1, the staff could not identify where a description of the evaluations for bearing pressure demand and foundation stability are presented in the AP1000 DCD. Therefore, the staff requested that the applicant include in the AP1000 DCD a description of the evaluations performed for the bearing pressure demand and foundation stability, which consists of a summary of the analyses presented in TR-85, Revision 1.

In a letter dated June 4, 2009, the applicant provided the proposed changes to the AP1000 DCD that describe in more detail the soil bearing pressure evaluation in TR-85. This information will be added to Appendix 3G of the AP1000 DCD. In addition, the applicant indicated that the changes to the AP1000 DCD related to the stability evaluation are given in a revision to RAI-TR85-SEB1-10, along with a summary of the 2D nonlinear sliding evaluation. Thus, the description of the stability evaluation for inclusion in the AP1000 DCD is evaluated separately under the staff's assessment of RAI-TR85-SEB1-10 in this SER. In a subsequent revision to the AP1000 DCD, the applicant made appropriate changes to the DCD text, which resolves this issue.

TR-85 is referenced in AP1000 DCD Section 3.8.5 and it includes key analysis and design information of the foundation. TR-09 is referenced in AP1000 DCD Section 3.8.2.4.1 and it includes key analysis and design information for the containment. TR-57 is referenced in Revision 17 to the AP1000 DCD Section 3.8.4 and it includes key analysis and design information for the CIS, auxiliary, and the shield building critical sections. The staff notes that the applicant clarified the design basis by letters dated October 21, 2010, whereby they withdrew TR-57 and provided mark-ups of the DCD to show the removal of references to TR-57 and stated where the information, as updated, appears in the proposed DCD and an appendix thereto. APP-1200-S3R-003 is referenced in AP1000 DCD Section 3.8.4 and it describes key analysis and design information for the shield building. Any revisions to the Tier 2* information will be subject to the NRC review and approval to avoid unintended safety consequences. In a subsequent revision to the AP1000 DCD, the applicant made appropriate changes to the DCD text and table, which resolve this issue.

In RAI-TR85-SEB1-39, the staff requested that the applicant identify the specific design reports, calculations, and reports related to various studies that are applicable to the analysis and design of the AP1000 NI basemat and foundation.

In a letter dated October 19, 2007, the applicant stated that:

> APP-1010-S3R-001, "AP1000 Design Summary Report: Nuclear Island Basemat," provides a detailed summary of the design of the NI basemat. It satisfies the guidelines of NUREG-0800 Section 3.8.4 and is available for NRC review during the structural audit.

The design summary report identifies the applicant's specific design reports, calculations, and reports applicable to the analysis and design of the AP1000 NI basemat and foundation. Some of the documents referenced therein are listed below. The criteria and methodology documents were previously reviewed during the audit of the basemat design on HR.

1. APP-GW-C1-001, "AP1000 Civil/Structural Design Criteria," Revision 1

2. APP-GW-S1-008, "Design Guide for Reinforcement in Walls and Floor Slabs," Revision 1

3. APP-GW-S1-009, “Design Guide for Thermal Effects on Concrete Structures,” Revision 0

4. APP-1000-CCC-001, “Verification of Design Macro for Reinforced Concrete Walls and Floors,” Revision 2

5. APP-1000-CCC-002, “Guidance on Checking Results of Design Macro Calculation,” Revision 0

6. APP-1010-S2C-003, “Macro to Calculate Required Reinforcement in Solid Elements,” Revision 0

7. APP-1010-S2C-004, “Basemat Liftoff, and CV Pressure Analyses for Nuclear Island with Soil,” Revision 0

In an e-mail dated April 30, 2009, the applicant updated the documents related to the basemat design that are available for review. In the audit conducted during the week of May 4, 2009, the staff reviewed a number of these documents to ensure that the evaluations were performed in accordance with the AP1000 DCD and NRC regulatory guidance. The staff concluded that the applicant had identified the design reports, calculations, and reports related to the AP1000 NI basemat and foundation, and the staff had an opportunity to review some of these documents for technical adequacy. Therefore, RAI-TR85-SEB1-39 is resolved.

3.8.5.1.7 Conclusion

In NUREG-1793 and its Supplement 1, the staff documented its conclusions that the AP1000 design and the DCD (up to and including Revision 15 of the AP1000 DCD) were acceptable and that the applicant’s application for the DC met the requirements of Subpart B to 10 CFR Part 52 that are applicable and technically relevant to the AP1000 standard plant design.

The staff reviewed the applicant's proposed changes to the AP1000 foundations as documented in AP1000 DCD, Revision 19, against the relevant acceptance criteria as listed above and in NUREG-0800, Section 3.8.5.

In subsequent revisions to TR-85, the applicant made appropriate changes to the report. Based on the review of these changes, staff concludes that APP-GW-GLR-044, TR-85, "Nuclear Island Basemat and Foundation," Revision 3, is acceptable because the analyses and design were performed in accordance with the ACI 349 Code, applicable RGs, and NUREG-0800, Section 3.8.5.

Therefore, the staff concludes that the design of the AP1000 foundations will continue to meet all applicable acceptance criteria. In summary, based on the above discussions, the staff finds that the design of the AP1000 foundation is acceptable.

The changes to the DCD implementing the revised AP1000 design meet the standards of Criterion vii of 10 CFR 52.63(a)(1) in that they contribute to increased standardization; without these DCD changes each COL applicant would have to address these issues individually.

3.8.6 Combined License Information

Section 3.8.6, "Combined License Information" of the AP1000 DCD, Revision 15, was approved by the staff in the certified design. In AP1000 DCD, Revisions 16 and 17, the applicant made the following changes to Section 3.8.6 of the certified design:

1. In DCD Revision 16, the applicant revised Section 3.8.6.1, Containment Vessel Design Adjacent to Large Penetrations. This revision eliminated this COL information item because the applicant indicated that the information had been addressed in APP-GW-GLR-005 (TR-09) and the applicable changes were incorporated into the DCD.

2. In DCD Revision 16, the applicant also revised Sections 3.8.6.2 through 3.8.6.4, to delete the remaining COL information items relating to the PCS water storage tank examination, as-built summary report, and in-service inspection of containment vessel. No explanation for this deletion was provided in DCD Section 3.8.

The staff evaluation of the changes to the COL information item in AP1000 DCD Section 3.8.6.1 related to the CV design adjacent to large penetrations is presented in Section 3.8.2.4.1 of this report, where the staff reviewed APP-GW-GLR-005, Revision 0 (TR-09). In subsequent revisions to the AP1000 DCD and TR-09, the applicant made appropriate changes to the DCD and report text, which resolve this issue.

The staff noted that the applicant removed the COL information items in AP1000 DCD Sections 3.8.6.2 through 3.8.6.4 that relate to the PCS water storage tank examination, as-built summary report, and the inservice inspection of containment vessel. Therefore, in RAI-SRP3.8.6-SEB1-01, the staff requested that the applicant restore these items in AP1000 DCD Section 3.8.6 which were discussed in the prior versions of AP1000 DCD Sections 3.8.1 through 3.8.5. In a letter dated February 19, 2009, the applicant indicated the following:

For the COL information item in AP1000 DCD, Section 3.8.6.2, the requirement to examine the PCCWST is redundant with Design Commitment 10, ITAAC Item ii of Tier 1, Table 3.3-6.

For the COL information item in AP1000 DCD Section 3.8.6.3 the requirement to prepare an as-built summary report is redundant with Design Commitment 2.a, ITAAC Item I of Tier 1 Table 3.3-6.

For the COL information item in AP1000 DCD Section 3.8.6.4, the inservice inspection of the containment is required by NRC regulations including 10 CFR 50.55a. There is also a commitment for inservice inspection of the containment in AP1000 DCD Section 6.6.1.

The staff's review of the information provided in the RAI response has led to the conclusion that the deletion of the COL information item in AP1000 DCD Section 3.8.6.3 is acceptable because the information is redundant with an ITAAC and, in the case of Section 3.8.6.4, is already required in 10 CFR 50.55a. However, in the case of the COL information item in AP1000 DCD Section 3.8.6.2, the ITAAC referred to by the applicant does not fully capture the examination requirements in AP1000 DCD Section 3.8.4.7 that the previous COL information item referred to. The ITAAC addresses examination for leakage and measurement of elevation at two locations before and after filling of the PCS storage tank. AP1000 DCD, Section 3.8.4.7, however, provides additional requirements for examination of excessive cracks in accordance with ACI 349.3R-96. Therefore, in a follow-up RAI, the applicant was requested to include this additional commitment as part of the subject ITAAC or provide the technical basis for excluding it.

In a letter dated September 9, 2009, the applicant agreed to revise the ITAAC in AP1000 DCD Tier 1, Table 3.3-6, to fully capture the examination requirements in AP1000 DCD Section 3.8.4.7 for the PCS storage tank. In addition, the applicant identified that a revision in AP1000 DCD Tier 2, Section 3.8.4.7, was required for testing to be performed to measure the leakage from the PCS storage tank based by measuring the water flow out of the leak chase collection system.

The staff's review of the applicant's September 9, 2009, response determined that the proposed revisions to ITAAC Table 3.3-6 and AP1000 DCD Section 3.8.4.7 are still not consistent. The commitment in AP1000 DCD Section 3.8.4.7 to inspect the PCS tank for significant cracking in accordance with ACI 349.3R-96 is not included in the ITAAC. In addition, the inspection identified in the ITAAC is applicable to the PCS tank boundary and the shield building tension ring while in the case of AP1000 DCD Section 3.8.4.7, the inspection is applicable to the PCS boundary and the shield building roof above the tension ring. The applicant needed to explain whether the inspection would be performed for all three structural regions (PCS tank boundary, shield building roof, and tension ring) and revise both sections of the AP1000 DCD to be consistent. In a follow-up RAI, the staff requested that the applicant address both items discussed above.

In response to the above requests, the applicant's letter dated June 18, 2010, explained that the references to specific standards, such as ACI 349.3R-96, are not included in Tier 1 because this is an established practice in the preparation of Tier 1 information. Since ITAAC Table 3.3-6 in the AP1000 DCD, Revision 15, did not identify the ACI 349.3R-96 standard, but AP1000 DCD Section 3.8.4.7 did, the staff concludes that it is acceptable now to follow the same approach in the current AP1000 DCD.

To address the inconsistency between the proposed revisions to the ITAAC and the AP1000 DCD on the inspection regions, the applicant explained that the design now has steel plates as the outer surface of the tension ring for the enhanced shield building, and concrete cracking in the tension ring region will not be visible; therefore, Table 3.3-6 in the ITAAC will be revised to clarify that the inspection for visible excessive cracking will be performed for the roof above the tension ring and the PCS tank boundary. Since the proposed revisions to the ITAAC Table 3.3-6 and AP1000 DCD Section 3.8.4.7 are now consistent, the staff concludes that this part of the response is also acceptable. In a subsequent revision to the AP1000 DCD, the applicant made appropriate changes to the DCD text and table, which resolve this issue.

Shield Building COL Items

In NUREG-1793 and its Supplement 1, the staff documented its conclusions that the AP1000 design and the DCD (up to and including Revision 15 of the AP1000 DCD) were acceptable and that the application for the DC met the requirements of Subpart B to 10 CFR Part 52 that are applicable and technically relevant to the AP1000 standard plant design.

The staff concludes that if the items identified above are resolved, the COL information items will meet the applicable acceptance criteria, and that the proposed changes are properly documented in the updated AP1000 DCD. This is based on the additional evaluation report (TR-09) for the containment design adjacent to large penetrations, the inclusion of two ITAAC for the examination of the PCS water storage tank and the as-built summary report, and the existing requirements in 10 CFR 50.55a for the inservice inspection of the containment.

3.8.7 Conclusions

The NRC staff concludes that the proposed changes to the AP1000 DC, related to the design of Category I Structures, as described in the evaluation above, are acceptable because they satisfy the applicable requirements of 10 CFR Part 50, Appendix A, GDC 1, 2, 4, 5, 16 and 50; 10 CFR 50.44; and 10 CFR 50.55(a).

Revision 19 to the AP1000 DCD provides sufficient information to satisfy the applicable requirements of the above regulations.

The changes to the DCD implementing the revised AP1000 design meet the standards of Criterion vii of 10 CFR 52.63(a)(1) in that they contribute to increased standardization; without these DCD changes each COL applicant would have to address these issues individually.

3.9 Mechanical Systems and Components

3.9.1 Special Topics for Mechanical Components

The evaluation is performed for AP1000 DCD, Revision 17. The applicant proposed editorial and minor technical changes and clarifications to the section including adding daily load follow operations to the Level A service conditions; redefining RCP startup and shutdown cases; and defining loading and unloading operations. In addition, the applicant proposed to add WESTEMS design computer code to AP1000 DCD Table 3.9-15 for application of the fatigue analysis of components.

3.9.1.1 Evaluation

AP1000 DCD Tier 2 Section 3.9.1.1.1.4 addresses the unit loading and unloading operations associated with power changes of 5 percent per minute between 15 percent and 100 percent power levels. The number of loading and unloading operations is defined as 2,000 each for the 60-year plant design. RAI-SRP3.9.1-EMB1-01 requested that the applicant provide the technical basis for splitting the 2,000 occurrences from the original 19,800 occurrences for the plant loading and unloading at 5 percent of the full power per minute for the normal plant startup/shutdown, and loading resulting from all service Levels B, C, and D transients that result in a reactor trip.

In its September 5, 2008, response to RAI-SRP3.9.1-EMB1-01, the applicant indicated that when the design transients for the AP1000 were initially established, it was decided to use the unit loading and unloading transient to cover the load follow and increase the number of these transients to cover a daily load follow. It is noted that this was a conservative approach since the load follow transient is less severe than the unit loading and unloading transient. As such, the daily load follow transient will be appropriately addressed rather than assuming the unit loading and unloading transient for most of the load follow requirement. The applicant used 2,000 occurrences of unit loading and unloading each to account for shutdowns and the recovery from service Level B, C, and D transients. The applicant noted that the 2,000 occurrences will cover the approximately 700 total service level B, C, and D transients and 1 (one) per month for loading and unloading each for 60 years. The applicant also noted that this frequency is larger than that at currently operating units and is considered bounding. The staff concurs with the applicant on the basis of its operating experience and concludes that use of 2,000 occurrences of unit loading and unloading is conservative and acceptable. RAI-SRP3.9.1-EMB1-01 is, therefore, closed.

AP1000 DCD Tier 2 added a new Section 3.9.1.1.1.19, “Daily Load Follow Operations” to Revision 16 to account for the one load follow operation per day that was included as a portion of the plant loading and unloading events for the design transients. RAI-SRP3.9.1-EMB1-02 requested that the applicant provide the basis of how the 17,800 cycles were determined for the daily load follow operations during the plant design of 60 years which with a 90 percent availability factor could result in 19,800 occurrences, and to discuss the basis that the load follow event could not coincide with the plant loading and unloading transients while they might occur at the same time.

In its September 5, 2008, response to RAI-SRP3.9.1-EMB1-02, the applicant noted that the total of unit loading and unloading transients combined with the daily load follow transient is 19,800 transients for 60 years of plant operation based on one transient per day with 90 percent plant availability factor. With the case of reduced power or in a load following mode, the nuclear power plant typically runs on a weekly cycle not a daily cycle. As such, it is assumed that a unit unloading and a daily load follow event would not occur on the same day. With 2,000 occurrences (each) for unit loading and unloading transients, the remaining 17,800 occurrences are made up of the daily load follow transients. The staff agrees with the applicant’s determination to use 17,800 occurrences for a daily load follow transient considering 2,000 occurrences conservative for unit loading and unloading transient as this case is much more severe than the daily load follow transient. Therefore, RAI-SRP3.9.1-EMB1-02 is closed.

As a result of the onsite technical review on October 20, 2008, the staff found that the fatigue analyses for the design of AP1000 seismic Category I components and supports were performed using a computer program called WESTEMS, which is not discussed in the AP1000 DCD Section 3.9.1.2, “Computer Code Used in Analyses,” nor listed in Table 3.9-15, “Computer Programs for Seismic Category I Components.” In its response to the staff’s

RAI-SRP3.9.1-EMB1-03, the applicant indicated that the DCD will be revised to add the WESTEMS computer program to Table 3.9-15. It also stated that the WESTEMS computer program was not previously reviewed and approved by the staff. On May 26 to 28, 2009, the staff conducted an audit of WESTEMS at the applicant's headquarters in Monroeville, Pennsylvania. The audit was not completed because not all the documents requested were available at the time of the audit. The follow-up review was completed at the end of September 2009 in the applicant's Twinbrook office in Rockville, Maryland.

During the audit, the staff discussed with the applicant the theoretical background, formulation, validation methods, and benchmarking problems pertaining to WESTEMS. The discussions including, in part, the RAIs the staff presented to the applicant during the exit meeting are described in the following paragraphs.

The staff reviewed the WESTEMS basis documents and identified that the stress peak/valley selection option using the stress evaluated with algebraic summation of three orthogonal moment components requires justification. The staff noted that the algebraic summation of three orthogonal vectors is mathematically incorrect and physically meaningless. The staff requested that the applicant provide technical justification for this option in selecting peak and valley times for the fatigue evaluation. This concern was identified as Open Item OI-SRP3.9.1-EMB1-05.

The WESTEMS program provided an option to eliminate peak/valley points during calculation. The staff noted that the computer output should not be modified after executing the program. The staff requested that the applicant provide the configuration control and limitations of the program for this option. This concern was identified as Open Item OI-SRP3.9.1-EMB1-07.

The staff performed an onsite review to discuss/resolve the above mentioned open items. The staff's onsite review summary report, dated December 9, 2010, identified the WESTEMS deficiency.

By a letter dated September 29, 2010, the applicant requested to remove WESTEMS from the DCD markup that adds WESTEMS to Table 3.9-15 of the DCD. In this letter, the applicant stated that the DCD need not include the WESTEMS program because the analyses in question are identified as COL Information Item 3.9-7 in the DCD and are not within the scope of the design certification amendment. The applicant also stated that it would use an appropriate analytical tool for performing the aforementioned analyses and the COL applicant has responsibility to close out the COL Information Item. The staff agreed that the COL applicant is responsible to close out COL Information Item 3.9-7 and fatigue analysis is part of the piping analysis. However, the staff was concerned that this tool should be provided as part of the methodology in the DCD. The staff acknowledged that the methodology available in the DCD in Revision 15 was complete such that the fatigue analysis could be performed without an additional tool. Also, DCD Tier 2, Section 3.9.2.1, states that the COL applicant will implement the NRC benchmark program using AP1000 specific problems if a piping analysis program other than those for design certification (PIPESTRESS, GAPPIPE, WCAN, and ANSYS) is used. This statement is marked as Tier 2*. The staff notes that use of a computer code as an analytical tool, as stated above, would require departure from the DCD based on the closure of the COL Item in Section 3.9.8.6 of the application. The closure is discussed in Section 3.12.1.2 of this report. On the basis that the applicant would return to the previously certified methodology, which was complete, and that any computer code added in the future would require benchmarking, the staff finds this acceptable. Therefore, Open Items OI-SRP3.9.1-EMB1-05 and OI-SRP3.9.1-EMB1-07 are closed.

3.9.1.2 Conclusions

Based on the letter dated September 29, 2010, the staff concludes that the applicant's request to remove WESTEMS from the DCD markup that adds WESTEMS to Table 3.9-15 of the DCD results in no change to the DCD for this item. On the basis mentioned above, the staff determined that all the open items related to WESTEMS are closed. The staff will evaluate piping design fatigue analysis to ensure piping integrity for safety at the time of COL item closure. The staff concludes that the DC amendment for Section 3.9.1 is acceptable.

3.9.2 Dynamic Testing and Analysis of Systems, Components and Equipment

3.9.2.3 Preoperational Flow – Induced Vibration Analysis and Testing of Reactor Internals

3.9.2.3.1 Summary of Technical Information

In AP1000 DCD, Revision 17, Section 3.9.2, "Dynamic Testing and Analysis," the applicant proposed changes to reactor internals and analysis. These changes included: addition of a flow skirt to the reactor vessel lower head, addition of neutron panels, relocation of radial support keys and tapered periphery on lower core support plate (LCSP), downcomer excitations and related responses, reduction of core shroud brace thickness, and RCP induced loads.

3.9.2.3.2 Evaluation

Section 3.9.2 of NUREG-1793 describes the AP1000 reactor vessel internals conformance with RG 1.20, "Comprehensive Vibration Assessment Program for Reactor Internals During Preoperational and Initial Startup Testing," November 2006, and NUREG-0800 Section 3.9.2, "Dynamic Testing and Analysis of Systems, Structures, and Components." The first AP1000 reactor internals design is classified as a prototype, as defined in RG 1.20. However, as stated in WCAP-16716, "AP1000 Reactor Internals Design Changes," the applicant does not consider the AP1000 reactor vessel internals a first-of-a-kind or unique design. Several units that have operating experience collectively have similar reactor vessel internal design features and are referenced in support of the AP1000 reactor vessel internals design.

The original reference plant for the applicant's three-loop plant reactor internals flow-induced vibration is H. B. Robinson. The results of vibrations testing at H. B. Robinson are reported in WCAP-7765-AR, "Westinghouse PWR Internals Vibrations Summary Three-Loop Internals Assurance," November 1973. With the addition of neutron panels to the reactor vessel internals design, the applicable referenced plant test has changed from Paluel 1 (no reactor shielding) to Trojan 1 (similar to current neutron panel AP1000 configuration). The applicant believes, as stated in WCAP-16716, that the change in referenced plant tests will not impact the conclusions in WCAP-15949-P, "AP1000 Reactor Internals Flow-Induced Vibration Assessment Program," Revision 2, April 2007.

The vibration testing for 17x17 fuel internals and inverted hat upper internals is reported in WCAP-8766, "Verification of Neutron Pad and 17 x 17 Guide Tube Designs by Preoperational Tests on the Trojan 1 Power Plant," May 1976 and WCAP-8516-P, "UHI Plant Internals Vibrations Measurement Program and Pre- and Post-Hot Functional Examinations," March 1975. The vibration testing of three-loop XL type lower core support structure in DOEL 4 is reported in WCAP-10846, "Doel 4 Reactor Internals Flow-Induced Vibration Measurement

Program," March 1985. The vibration evaluations of upper and lower internals assemblies for a four-loop XL plant are reported in WCAP-10865, "South Texas Plant (TGX) Reactor Internals Flow-Induced Vibration Assessment," February 1985. The vibration testing of the core shroud lower internals design is reported in CE Report 10487-ME-TE-240-03, "A Comprehensive Vibration Assessment Program for Yonggwang 4 Nuclear Generating Station, Final Evaluation of Pre-Core Hot Functional Measurement and Inspection Programs," August 22, 1995.

The results of the Doel 3 and Doel 4 reactor internals vibration test programs have been utilized to perform the vibration assessment of the AP1000 reactor internals. The measured responses from Doel 3 and Doel 4 have been adjusted to the higher AP1000 flow rate to support the determination of the expected upper internals and lower internals vibration levels, respectively. The velocity through the core is approximately the same as that of Doel 4.

The results of the Trojan 1 tests showed that the lower internals vibrations are lower with neutron panels than with a circular thermal shield as reported in WCAP-8766.

The staff reviewed the relevant documents as stated above and evaluated the impact of changes in the reactor internals on the vibration evaluations of upper and lower internals assemblies. In addition, the staff reviewed the basis of the applicant's contention in WCAP-16716 that there is no impact on the conclusions in the DCD.

3.9.2.3.2.1 Addition of Flow Skirt to the Reactor Vessel Lower Head

The results of the computational fluid dynamics (CFD) calculations using the existing structures in the lower plenum along with the LCSP flow hole geometry indicated that the core inlet flow distribution needed to be adjusted to create a more uniform core inlet flow distribution. The core inlet flow distribution was improved by the addition of a flow skirt to the lower plenum of the reactor vessel.

CFD analyses of numerous configurations of the hardware in the lower reactor vessel have been made with the objective of obtaining a core inlet flow distribution that meets specifications established by the applicant's fuel group. It has been determined that flow distributions that meet the requirements are obtained with a flow skirt. A flow skirt is a perforated cylinder in the lower reactor vessel head that is attached to the reactor vessel bottom head. The flow skirt is attached to the lower head of the reactor vessel at the plant site after measurements for machining of the core barrel clevises have been completed. The attachment consists of welds across eight tabs that rest on support lugs provided on the reactor vessel lower head.

There is a circumferential weld between the spherical bottom vessel head and the conical transition to the cylindrical portion of the reactor vessel. The weld is just above the top surface of the flow skirt support lugs. There is some radial clearance between the outside of the flow skirt and the inside surface of the reactor vessel at the circumferential weld location. Examination Category B-N-2 of Section XI, Subsection IWB-2500, provides requirements for the visual (VT-3) examination of "interior attachments beyond the beltline region" of the reactor vessel. Vertical access for a pole-mounted camera is possible around the full circumference of the flow skirt with partial blockage at the four lower radial support keys located on the cardinal axes. It has been judged that the flow skirt and attachment welds could be inspected using VT-3 examinations. If any relevant condition is detected, IWB-3122 (prior to service) or IWB-3142 (inservice) provides options for correcting the condition. The staff reviewed the impact of the welds in generating additional vorticity and turbulence in the lower plenum region.

Based on its review the staff determined that additional information is needed for the staff to complete its review. Several welded joints have been introduced as a result of the addition of the flow skirt, as stated earlier. In RAI-SRP3.9.2-EMB1-07, the staff requested that the applicant discuss the potential for generation of vortices in the region of the flow skirt due to the presence of these welded joints as well as the flow skirt itself and the potential adverse effects on the response of other internals components. The applicant was also requested to discuss any tests related to the evaluation of the flow skirt performance.

In its June 20, 2008, response, the applicant stated, “Any vortices in this region would be proportional in size to the minimum open dimension between the vessel and the flow skirt. This will be on the order of 0.955 cm (0.376 in). Any vortices generated will therefore be too small and of too high a frequency (frequency is proportional to velocity divided by vortex dimension) to be of concern. If anything, the flow skirt will tend to dissipate any larger vortices that may be produced by the flow around the radial keys. The fact that the flow skirt makes the lower plenum flow field more uniform is an additional benefit. Because of this, there is a diminished possibility of large velocity gradients entering the lower plenum from the vessel down comer. Lower velocity gradients (greater flow uniformity) also diminish the probability of large vortex-formation. Flow skirts of similar design have been successfully used in operating System-80 plants. A scale model flow test, which includes the flow skirt and its connections to the reactor vessel, is planned as a confirmatory test.”

Based on its review, the staff finds that the applicant has provided a reasonable and satisfactory explanation for a diminished likelihood of large vortex formation in the lower plenum region and Open Item OI-SRP3.9.2-EMB1-07 is closed.

3.9.2.3.2.2 Addition of Neutron Panels

To provide flexibility in the core design over the life of the plant, end-of-life reactor vessel fluence calculations were made assuming a radial core power distribution of higher power fuel assemblies in the outmost peripheral locations than in a normal low leakage core. To maintain the end-of-life reactor vessel fluence values at less than the maximum allowed in RG 1.99, neutron panels were attached to the outside diameter of the core barrel. The resulting reactor vessel fluence is 8.9E19 n/cm2 (E > 1.0 MeV) at the end of the 60-year life. Neutron panels have been used on the recent Westinghouse reactor internals designs. They reduce the reactor vessel fluence at the circumferential locations that have the highest fluence values and provide a relatively rigid structure that has a smaller downcomer cross-sectional area than a full cylinder.

The neutron panels are located at four circumferential locations where fuel assemblies are closest to the reactor vessel (0, 90, 180, and 270 degrees). Each pad covers ~30 degrees circumferentially and extends over the entire length of the active core region (4.26 m (14 ft)). The pads are contoured to minimize the impact on the downcomer annulus flow area and to reduce the probability of vortex generation in the downcomer.

Based on its review the staff determined that additional information was needed for the staff to complete its review. In RAI-SRP3.9.2-EMB1-02 the staff requested that the applicant discuss the potential fluid forces created by the redesigned neutron panels and their potential effects on the flow-induced vibration (FIV) excitation of the core barrel/core shroud. In its June 20, 2008, response, the applicant stated “The circumferential extent of the neutron panels was limited to correspond to the high vessel fluence levels, and thus minimize the flow blockage in the downcomer. The neutron panels are tapered circumferentially (following the reduction in fluence level) to minimize the flow area reduction. In addition, the reactor vessel inside diameter was increased by two inches over the core elevations when the panels were added. This results in a net flow area increase of 4 percent relative to the vessel-core barrel downcomer flow area before the panels were added. The lower average downcomer velocity is expected to offset the effects of the turbulence added by the neutron panels."

Based on its review, the staff finds that the applicant has provided a satisfactory explanation of how the additional effects of turbulence due to the neutron panels are neutralized. Therefore, the concerns related to RAI-SRP3.9.2-02 are resolved and the addition of the neutron panels is likely to have no detrimental effects.

3.9.2.3.2.3 Relocation of Radial Support Keys and Tapered Peripheral on the LCSP

The four lower radial support keys for the core barrel are currently located 45 degrees from the cardinal axes. There is also a spherical radius on the outer diameter of the LCSP. Core inlet flow distribution and reactor vessel pressure drop results from CFD computer analysis showed that the core inlet flow distribution and the reactor vessel pressure drop were acceptable with a 6-degree slope on the outer diameter of the LCSP. Having the slope instead of the spherical radius on the outer diameter of the LCSP results in sufficient room for the radial support keys to be relocated to the cardinal axes, which is the preferred location. This relocation of the radial support keys eliminates the potential for interference with the core shroud attachment studs and nuts at the 45-, 135-, 225-, and 315-degree locations.

Based on its review the staff finds that relocation of the radial support keys and providing a tapered surface instead of a spherical one has no detrimental effects and is, therefore, acceptable.

3.9.2.3.2.4 Downcomer Excitations and Related Responses

The nozzle region of the reactor vessel has not been changed so that the entering flow turbulence excitations do not change. The addition of the neutron panels and the increase in the inside (and outside) diameter of the reactor vessel over the core elevations, since the original calculations have been made, change the overall area of the downcomer slightly. The reactor vessel inside diameter below the nozzle has been increased. The flow area including the addition of the neutron panels, increased vessel diameter, and different specimen basket design is increased by approximately 4 percent. This tends to offset the turbulence and increase in local velocities generated by the presence of the neutron panels. Due to the addition of a flow skirt to the lower head of the reactor vessel, the excitations of the structures in the lower vessel head plenum are likely to be lower which also contribute to a lower core barrel vibration level.

Based on its review, the staff determined that additional information was needed for the staff to complete its review. Therefore, in RAI-SRP3.9.2-EMB1-10, the staff requested that the applicant provide analytical or test data to quantitatively validate this statement that the increase in the increase flow area by 4 percent is expected to offset the turbulence and increase in the local velocities generated by the presence of the neutron panels.

In its June 20, 2008, response, the applicant stated that all previous test data show that, for a given geometry and inlet flow pattern, the turbulence excitation decreases-usually by an exponent greater than 2-with decreased flow rate. The staff finds this response satisfactory and acceptable because the applicant has provided quantitative data to satisfy staff's concern. Therefore, concerns related to RAI-SRP3.9.2-EMB1-10 are considered resolved.

Based on its review, the staff finds that the changes in the vessel diameter, addition of the flow skirt and the presence of the neutron panels will have no detrimental effects on the downcomer excitations and related responses. These changes are, therefore, acceptable.

3.9.2.3.2.5 Reduction of Core Shroud Brace Thickness

Design modifications have been evaluated for the AP1000 core shroud subsequent to the analyses discussed above. The modification is to thin the core shroud braces to reduce thermal stresses. The staff concluded that this modification will not have a detrimental effect on the structural integrity of the core shroud and is therefore acceptable.

3.9.2.3.2.6 Reactor Coolant Pump-Induced Loads

RCP-induced forces are included in the responses reported in Section 7.7.2 of WCAP-15949-P Revision 2. A calculation to predict the pressure differences across the various reactor vessel internals components due to RCP pulsations was performed. However, since the original acoustic calculation using the ACSTIC code was completed, several design changes were made to the AP1000 reactor vessel and reactor vessel internals as discussed above. Specifically, the reactor vessel diameter was increased, the lower core restraints were relocated, neutron panels were added, specimen baskets were redesigned and relocated, and a flow skirt was added. To evaluate the impact on predicted pressure differences due to the previously noted design changes, an updated ACSTIC calculation was completed.

The updated calculation performs a similar analysis at hot full-power as the original calculation while considering the previously noted design changes. Additionally, the updated calculation also considers the hot functional test (HFT) conditions, including the absence of the core with 25 percent of the core pressure drop simulated near the exit of the LCSP. Consistent with the original calculations, three frequency ranges were evaluated with all RCPs in-phase and with two RCPs out of phase with the other two. The three frequency ranges are ±10 percent of the rotating speed frequency, the first blade passing frequency and the second blade passing frequency. The impact of the results of the updated calculation have been addressed in the individual component analyses for the guide tube, upper support column, core barrel, and core shroud.

The reactor internals were evaluated for the RCP startup conditions shown in Table 5-9a of WCAP-15949-P. The updated reactor conditions are shown in Table 5-9b of WCAP-15949-P. The updated conditions are less severe since the time to reach hot standby is the same for the new and old conditions but the flow rates during heat-up are lower for the new conditions. Therefore, fluid velocities are lower for the updated startup conditions than for the evaluated startup conditions. Lower flow rates would result in lower flow turbulence loads. Since the calculated high-cycle fatigue factors of safety are greater than one, the staff concluded that the AP1000 internals are adequately designed.

Based on its review as discussed above, the staff determined that it needed additional information to complete its review. Therefore, the staff requested that the applicant provide this information in the areas of concerns.

In RAI-SRP3.9.2-EMB1-01, the staff requested that the applicant describe the design and modeling of the core barrel/upper core plate as they relate to FIV structural dynamic analysis. The staff also requested that the applicant discuss the uncertainty associated with the modeling of the support interface employed in the modal analysis of the support. In its June 20, 2008, response, the applicant stated that the upper core plate is modeled as a part of the upper internals in the system model. The gaps between the upper core plate (and core shroud) slots and the alignment plates mounted on the core barrel are also modeled. To ensure that the entire range of possible gaps between the upper core plate and the core barrel alignment plates is evaluated, time-history analyses were performed with various sets of gaps (upper core plate, top core shroud plate, and core barrel lower supports). Table 6-9 in WCAP-15949-P, Revision 2 (Reference 1), shows the gaps modeled and the resulting loads. The resulting highest load was used in the structural analysis.

The staff finds the applicant's response reasonable and acceptable. Also, AP1000 DCD Section 3.9.2.3 was revised. Therefore, concerns related to RAI-SRP3.9.2-EMB1-01 are resolved.

3.9.2.3.2.7 Evaluation of WCAP-15949-P Revision 2

The staff's review and acceptance of WCAP-15949-P, Revision 1 is documented in Section 3.9.2.3 of NUREG-1793. The additional information in WCAP-15949-P, Revision 2 includes information to justify that there will be no impact on the vibration evaluation of the reactor internals as a result of the changes in the standard design. The staff's review in this safety evaluation includes this additional information. A preoperational HFT is to be carried out on the first AP1000 reactor internals, classified as a prototype, per requirements of RG 1.20, Revision 2. The AP1000 reactor internal design is the latest product of evolutionary changes to three-loop plants, starting with H. B. Robinson as the first prototype and the most recent ones being Doel 3 and Doel 4 (3XL), as described in Section 1.2 of WCAP-15949-P, Revision 2. The significant design changes in the AP1000 reactor internals relative to the Doel 3 and Doel 4 designs are described in Section 3 of WCAP-15949-P, Revision 2. The plant and scale model tests associated with each prototype (including the upper internal test of Doel 3 and the lower internal test of Doel 4) are summarized in Section 4, which also demonstrates the consistency among the various Westinghouse plant and scale model tests. The sources of the flow-induced vibration, considered in Section 5, of WCAP-15949-P, Revision 2 are the following:

- Flow turbulence
- RCP related
- Turbulence excitation of system fundamental acoustic mode
- Vortex shedding

In Section 5 of this WCAP, forcing functions simulating the various excitations are developed through correlation with the 3XL and other plant and scale model test data and put on AP1000 system models and sub-models. The results, in terms of peak stresses, on the various AP1000 critical components are presented in Section 6 and summarized in Table 2-1. The applicant has developed detailed CFD and finite-element models of both the 3XL and the AP1000 reactor vessel and internals designs as discussed in Sections 5 and 6 of this report. The 3XL finite-element model is used to calculate vibratory-induced deflections, and the calculated values are compared to applicable plant test data taken during the Doel 4 HFT. The finite-element modeling techniques are refined to accurately predict the Doel 4 test results, and these modeling techniques are applied in the AP1000 model. The CFD model was used to determine the steady-state flow loads on the upper internals components. Section 7 presents the detailed plan for the preoperational HFT and Section 8 presents the pre- and post-hot functional inspection program.

There is no instrumentation between the upper end of the core shroud and the LCSP. In RAI-SRP3.9.2-EMB1-03, the staff requested that the applicant discuss the rationale for and the location of instrumentation to provide predicted stresses and also provide the value and location of the maximum stresses for the core barrel/core shroud assembly. In its June 20, 2008, response the applicant stated, "A detailed description of the internals model is provided in WCAP-15949, Revision 2. The instrumentation is designed to provide adequate information to describe the vibration time histories and modal content. In the case of the core barrel, the beam modes can be inferred from the core barrel flange strain gages. The fundamental shell modes of the core barrel cover the entire length, the approximate midpoint being at the top of the core shroud where three radially sensitive accelerometers are mounted."

The staff finds the rationale for the panel location of the instrumentation reasonable and acceptable. With regard to the locations of the maximum stresses and adequacy of the instrumentation, the applicant stated…"the motions are defined by an assembly model. Where needed, sub-models are made to accurately define local, maximum stresses. Detailed core shroud models and sub-models are used to define maximum vibratory stress levels in the core shroud. Similarly, for the core barrel, models are used to define stresses at key locations such as core barrel flange (dominantly beam mode-induced stresses), and shell mode stresses) and barrel shell LCSP stresses (includes vertical motion-induced stresses). The strain gages and other transducers are located such that they are not in an extremely high gradient area and so that, with the analytical models they can adequately define the vibration so that maximum stresses can be determined from the analytical models. The maximum stresses for the core barrel/core shroud are provided in Table 2-1 of WCAP-15949. The maximum core barrel stress is at the core barrel wall to core barrel flange interface. The maximum core shroud stress is at the corner of the panel."

Based on its review of the above response, the staff finds that the instrumentation supported by the structural model (which is supported by the calculated versus measured mode shapes and natural frequencies) is adequate to define the maximum stresses due to flow and RCP-induced vibration. Therefore, the concerns related to RAI-SRP3.9.2-03 are resolved.

In WCAP-15949, Table 5.3, "Comparison of calculated and measured 3XL responses," it is stated that the accelerations are considered to be influenced by accelerometer pressure sensitivity and that vertical vibration content in the core barrel strain gages is difficult to ascertain because of masking by other contributors. Therefore, in RAI-SRP3.9.2-EMB1-04, the staff requested that the applicant discuss: (a) how the vibration content affects the strain gage data; (b) how associated conversion factors from 3XL to AP1000 are affected; and (c) the uncertainties in the conversion factors.

In its response, the applicant stated, "The strain gages are used to measure mean and oscillatory reactor internal responses. For example, in the core barrel flange strain gages, the oscillatory content includes contributions from core barrel beam modes, the vertical modes of the core barrel, and the shell modes of the core barrel. Supported by the core barrel analytical model and data from other transducers, the contribution of the various modes can be determined. This information is used to support the determination of the maximum stress in the core barrel flange.

During the 3XL hot functional vibration testing, it was observed that the accelerometer data included an unexpected magnitude of response at a particular frequency that was postulated to be due to system pressure pulsations. The accelerometer pressure sensitivity was confirmed by the accelerometer vendor. It is considered that this was adequately recognized in the interpretation of the 3XL data. The 3XL test data are used only to benchmark the analytical methods used to predict AP1000 responses, primarily the CFD based prediction of core barrel vibration. There are no conversion factors used in developing the AP1000 responses, since all of the AP1000 predictions are from analytical models."

Based on its review of the above response, the staff finds that the applicant has provided a satisfactory response to the staff's concerns related to how the vibration content affects the strain gage data, associated conversion factors from 3XL to AP1000 are affected, and the uncertainties in the conversion factors. Therefore, the concerns related to RAI-SRP3.9.2-EMB1-04 are resolved.

The overall methodology for estimating the vibration forces and using these forces to predict the response of the reactor internals is outlined in Figure 5-1 of WCAP-15949. In RAI-SRP3.9.2-EMB1-05, the staff requested that the applicant describe the methodology for determining bias errors and uncertainties associated with data obtained from various sources for evaluating AP 1000 reactor internals responses.

In its response, the applicant stated, "The transducers are calibrated prior to use. From this calibration, the voltage conversions at the temperature that the data were acquired are applied. Any uncertainty in the factors that convert voltages to physical units will also be recognized. It is also noted that expected and measured responses were similar in past tests. In view of these factors, it is considered that bias errors and uncertainties are less than the minimum margin to allowable values-presently 0.2 for AP1000 (per WCAP-15949-P, Revision 2, Table 2-1)."

The staff finds the applicant's explanation for justifying the bias errors and uncertainties as being less than 0.2 to be reasonable and satisfactory. Therefore, concerns related to RAI-SRP3.9.2-EMB1-05 are resolved.

NUREG-1793 discusses the evaluation of WCAP-15949-P, Revision 1 in Section 3.9.2.3. In RAI-SRP3.9.2-EMB1-06, the staff requested that the applicant discuss and summarize the significant additional information/items provided in WCAP-15949-P, Revision 2, dated June 2007.

In its response the applicant stated that the most significant changes between Revision 1 and Revision 2 of WCAP-15949 are the addition of the neutron panels, the reactor vessel diameter increase in the core region, the revised specimen basket arrangement, and the addition of a flow skirt to the reactor vessel. The overall conclusion that the vibration amplitudes are sufficiently low for structural adequacy of the AP1000 reactor internals has not changed. The applicant also provided an itemized list of changes between WCAP-15949-P, Revision 1 and Revision 2, in the RAI response. The staff reviewed this itemized list of changes and concerns related to RAI-SRP3.9.2-EMB1-06 are resolved.

Past experience related to testing of reactor internals indicates that instrument failures do occur during testing. Thus, it is prudent to provide redundancy in the data acquisition process. Therefore, in RAI-SRP3.9.2-EMB1-08, the staff requested that the applicant discuss the redundancy in the instrumentation proposed for the AP1000 reactor internals preoperational test program.

In its response the applicant stated, “Some redundancy is included in the number, location, and types of transducers installed during the Hot Functional Test program. For example both accelerometers and strain gages are installed on the core barrel, which provides some redundancy in the event that an individual transducer would fail.” In previous prototype tests conducted by the applicant, the instrument failures were not of sufficient quantity to preclude drawing the needed conclusions.

The transducers are installed on the reactor internals and subjected to known static and dynamic inputs prior to the HFT. These calibration tests relate displacements to measured strains and accelerations and this data is used to interpret the mean flow loads and flow-induced vibration amplitudes. The operability of these transducers is also verified during these static and dynamic calibration tests. In addition, some redundancy is included in the interpretation of the results in that a narrow band response centered on a particular frequency can be associated with a particular mode and the damping of that mode. This enables the stress distribution associated with this mode to be used to completely describe the stresses related to this mode.

Based on its review of the applicant’s response as discussed above, the staff finds that there is adequate redundancy in the instrumentation and satisfactory calibration procedures are in place. Therefore, the concerns related to RAI-SRP3.9.2-EMB1-08 are resolved.

In RAI-SRP3.9.2-EMB1-09, the staff requested that the applicant provide the following topical reports, which relate to preoperational test programs for the Trojan 1 and Doel 4 plants that are referenced in the AP1000 DCD Revision 17: (1) WCAP-8766, and (2) WCAP-10846. Additionally, the applicant was requested to provide test data from the core shroud at the Yonggwang 4 plant, which is relevant to the evaluation of the AP1000 reactor internals.

In its June 20, 2008, response, the applicant provided the two WCAP reports and the Yonggwang core shroud test report for staff’s review at the applicant’s Rockville, Maryland office. The staff reviewed these documents. The results of the Doel 3 and Doel 4 reactor internals vibration test programs were used to perform the vibration assessment of the AP1000 reactor internals. The measured responses from Doel 3 and Doel 4 were adjusted to the higher AP1000 flow rate to support the determination of the expected upper internals and lower internals vibration levels respectively. The velocity through the core is approximately the same as that of Doel 4. Based on its review the staff was satisfied that the applicant had used an acceptable methodology to perform the vibration assessment of the AP1000 reactor internals. The results of the Trojan 1 tests confirmed that the lower internals vibrations are lower with neutron panels than with a circular thermal shield as reported in WCAP-8766.

The staff is satisfied with the results, and concerns related to RAI-SRP3.9.2-EMB1-09 are resolved.

An acoustic analysis of the primary coolant loop has been provided in Section 5.1.3.1 of WCAP-15949. The impact of the results of the updated calculations has been addressed in the individual component analyses for the guide tube, upper support column, core barrel, and core shroud. The reactor internals were evaluated for the RCP startup conditions shown in Table 5-9a. The updated reactor conditions are shown in Table 5-9b of WCAP 15949. It is noted that the updated conditions are less severe since the time to reach hot standby is the same for the new and old conditions but the flow rates during heat-up are lower for the new conditions. Therefore, fluid velocities are lower for the updated startup conditions than for the evaluated startup conditions. Lower flow rates would result in lower flow turbulence loads. The applicant therefore concludes that there would be no overall impact due to the design changes.

In order to evaluate the impact on predicted pressure differences due to the design changes, an updated acoustic analysis using the computer code ACSTIC, was performed. However, simplifying assumptions were made in the acoustic modeling. The staff contended that the conclusions are not necessarily valid unless adequate justification is provided that the uncertainties associated with the ACSTIC calculation have been taken into consideration. In RAI-SRP3.9.2-EMB1-11, the staff requested that the applicant discuss how the uncertainties associated with acoustic analysis were factored into the results of the updated calculations.

In its response, the applicant stated, “The uncertainties associated with the ACSTIC calculation were considered by employing a general design basis in which the RCP-related responses are taken to be coincident with natural frequency if the natural frequency is within ±10 percent of the RCP excitation frequency. The calculated maximum forces from this resonance condition were then utilized in the reactor internals component structural evaluation.”

The staff finds the applicant’s response reasonable and acceptable, and concerns related to RAI-SRP3.9.2-EMB1-11 are resolved.

Based in its review of WCAP-15949-P, Revision 2, and Revision 17 of AP1000 DCD, Section 3.9.2.3, the staff finds that there is no overall impact due to the design changes.

3.9.2.3.3 Conclusion

This report supplements NUREG-1793 for the AP1000 standard plant design. NUREG-1793 was issued by the NRC in September 2004 to document the staff’s technical review of the AP1000 design. With the closure of OI-SRP3.9.2-EMB1-07 documented in this report, the staff concludes that the applicant has provided sufficient information to satisfy 10 CFR Part 50 Appendix A, GDC 1 and GDC 4 with regard to the dynamic testing and analysis of SSCs.

3.9.2.4 Dynamic System Analysis of Reactor Internals Under Faulted Conditions

3.9.2.4.1 Introduction

In Revision 16 to the AP1000 DCD, the applicant proposed to address COL Information Item 3.9-2 pertaining to irradiation-assisted stress-corrosion cracking (IASCC) and void swelling susceptibility evaluations for reactor internal core support structure materials.

In Section 3.9.2.4 of NUREG-1793, the NRC identified COL Action Item 3.9.2.4-1, in which the COL applicant will provide the design reports for the reactor internal core support structures including a final stress analysis conforming to the design provisions of the ASME Code, Section III, Subsection NG. The following section addresses the adequacy of the analyses for the reactor internals for IASCC and void swelling phenomena.

AP1000 Standard COL TR-12, APP-GW-GLR-035, Revision 0, was provided by the applicant under WCAP-16620-P, Revision 0, “Consistency of Reactor Vessel Internals Core Support Structure Materials Relative to Known Issues of Irradiation-Assisted Stress Corrosion Cracking (IASCC) and Void Swelling for the AP1000 Plant,” (hereafter designated as TR-12) dated July 31, 2006. TR-12 addresses AP1000 COL Information Item 3.9-2 pertaining to IASCC and void swelling in reactor internal core support structure materials for the AP1000 plant. COL

Information Item 3.9-2 corresponds to AP1000 DCD, Tier 2, Section 3.9.8.2 (DCD Section 3.9.8.2), Revision 15 and Action Item 3.9.2.4-1 from NUREG-1793. COL Information Item 3.9-2 is addressed in a proposed revision to DCD Sections 3.9.8.2 and 3.9.9. The staff reviewed the information provided in TR-12, including the proposed changes to DCD Sections 3.9.8.2 and 3.9.9. The revised DCD subsections are included in Revision 16 to the AP1000 DCD. The staff's findings regarding TR-12 are summarized below.

In TR-12, the applicant addressed the provisions of COL Information Item 3.9-2 pertaining to IASCC and void swelling susceptibility evaluations for reactor internal core support structure materials for the AP1000 plant. The applicant proposed to revise COL Information Item 3.9-2, in part, through the implementation of Revision 16 to DCD Section 3.9.8.2. In Revision 15 to the AP1000 DCD, Section 3.9.8.2, the COL Information Item stated:

> Combined License applicants referencing the AP1000 design will have available for NRC audit the design specifications and design reports prepared for ASME Section III components. COL applicants will address consistency of the core support materials relative to known issues of irradiation-assisted stress corrosion cracking and void swelling. [*The design report for the ASME Class 1, 2, and 3 piping will include the reconciliation of the as-built piping as outlined in subsection 3.9.3. This reconciliation includes verification of the thermal cycling and stratification loadings considered in the stress analysis discussed in subsection 3.9.3.1.2.*]

It should be noted that TR-12 only addresses the second sentence of DCD, Revision 15, Section 3.9.8.2. The other sentences in this revision to DCD Section 3.9.8.2 are addressed in separate AP1000 Standard COL TRs.

In Revision 16 to the AP1000 DCD, the applicant proposed to address the COL Information Item on a generic basis and revise Section 3.9.8.2 as it relates to IASCC and void swelling to state:

> The consistency of the reactor internal core support materials relative to known issues of irradiation-assisted stress corrosion cracking and void swelling has been evaluated and addressed in APP-GW-GLR-035 (Reference 21).

Revision 16 to DCD Section 3.9.8.2 specifically references TR-12 (i.e., APP-GW-GLR-035) as the technical basis for the evaluation of IASCC and void swelling phenomena in AP1000 reactor internal components. In addition to the above, Revision 16 to the AP1000 DCD adds the following reference (Reference No. 21) for TR-12 to DCD Section 3.9.9, "References":

> 21 APP-GW-GLR-035, "Consistency of Reactor Vessel Internal Core Support Structure Materials Relative to Known Issues of Irradiation-Assisted Stress Corrosion Cracking and Void Swelling for the AP1000 Plant," July 2006.

3.9.2.4.2 Background

IASCC is an age-related degradation mechanism where materials exposed to high levels of neutron radiation become more susceptible to SCC with increasing neutron fluence. The current consensus is that susceptibility to IASCC is a significant concern for austenitic stainless steel and nickel-based alloy reactor internal components in both boiling-water reactors (BWRs) and PWRs. This is due to the fact that these components are exposed to elevated neutron fluence levels over the lifetime of the plant. The exact mechanisms for IASCC damage in reactor internal components are not well known. However, numerous studies suggest that IASCC results from the synergistic effects of irradiation damage to the material, changes in the local coolant-water chemistry, and the stress state in the component.

Irradiation-induced void swelling is an environmental degradation phenomenon that can affect reactor internal structural alloys exposed to high levels of neutron radiation. Void swelling is characterized by an increase in a component's volume due to the formation of voids as a result of neutron irradiation at elevated temperatures. Void formation occurs due to the migration and condensation of lattice vacancies in response to radiation-induced displacement of atoms from their lattice sites. Void swelling becomes more pronounced at higher structural temperatures due to higher diffusion rates. Some amount of swelling can occur in virtually all structural alloys under sufficiently high conditions of neutron fluence and temperature. However, austenitic stainless steels and nickel-based alloys, the primary alloys used in reactor internal core support components, are known to be susceptible to void swelling earlier and faster due to the multiple slip systems and close-packed nature of their face-centered cubic crystal structure. As many PWRs age, void swelling behavior in austenitic stainless steel and nickel-based alloy reactor internal components has become the subject of increasing attention. Excessive void swelling can lead to dimensional instability of the component and significant decreases in fracture toughness. It could also influence or contribute to the susceptibility of the component to IASCC, stress relaxation, and irradiation embrittlement.

3.9.2.4.3 EPRI Topical Report MRP-175

The U.S. Nuclear Power Industry is conducting ongoing studies of IASCC and void swelling phenomena in reactor internal structural components. The IASCC and void swelling data that have been accumulated thus far were summarized in a report issued by the EPRI Topical Report MRP-175, "Materials Reliability Program: PWR Internals Material Aging Degradation Mechanism Screening and Threshold Values (MRP-175)," dated December 2005. This report provided screening criteria and their technical bases for the age-related degradation evaluation of PWR reactor internal component items.

Appendix B of MRP-175 addressed IASCC in PWR reactor internal components and the establishment of an IASCC threshold and screening criteria for determining susceptibility to IASCC behavior. The report provided a comprehensive review of the open literature and industry operating experience regarding IASCC in American Iron and Steel Institute (AISI) Type 304 and 316 austenitic stainless steels; the differences in IASCC behavior of cold-worked versus solution-annealed SSs; and IASCC behavior in nickel-based alloys. In general, this review confirmed that IASCC may be a significant concern for reactor internal components during later stages in plant operating life. Although the exact mechanisms for IASCC are not yet known, the MRP-175 review cited numerous studies conclusively demonstrating that both the stress state in reactor internal components and radiation damage caused by increasing neutron fluence levels during plant service will result in increased susceptibility to IASCC. The review pointed to various studies indicating that radiation hardening is directly linked to IASCC. Radiation-induced segregation, a phenomenon of accelerated solute diffusion brought about by radiation-induced increases in vacancy concentration, was also cited as a possible contributor to IASCC. The IASCC studies and limited industry operating experience reviewed by MRP-175 were used as a basis for recommending IASCC screening criteria based on stress levels in the component and accumulated radiation-induced displacement damage, quantified in units of displacements per atom (dpa). For a given material exposed to specific radiation energy spectra, increasing neutron fluence values correlate directly with increasing dpa levels.

The MRP-175 review cited studies suggesting that thermo-mechanical history and chemical composition can potentially have a significant impact on IASCC resistance in austenitic stainless steel materials. In particular, cold-working has been shown to be potentially favorable for delaying the onset of radiation damage at lower damage levels (less than 10 dpa). This phenomenon has been attributed to the presence of a high density of dislocations for trapping radiation-induced point defects, thereby delaying the development of the microstructure responsible for radiation hardening. However, at higher damage levels (greater than 10 to 20 dpa), studies indicate that both solution-annealed and cold-worked materials attain the same degree of radiation hardening. Studies also indicate that differences in bulk alloy composition among various austenitic stainless steel reactor internal components can potentially have varying effects on IASCC initiation and progression. The higher nickel content of Type 316 was cited as a contributor to its greater resistance to radiation damage, compared with Type 304 stainless steel.

Oversize solutes such as titanium and niobium may also contribute to IASCC resistance by serving as trapping sites for point defects. Overall, MRP-175 concluded that, while IASCC susceptibility among various austenitic stainless steel materials is recognized to be affected by thermo-mechanical history and chemical composition, no consistent or quantitative correlation has yet been established. Thus, it was determined that a conservative set of IASCC screening criteria should be applied to all stainless steel alloys.

Section B.3 of MRP-175 stated that, based on numerous studies of IASCC phenomena, certain neutron fluence levels are a necessary precondition for the occurrence of IASCC in reactor internal components. For austenitic SSs, the MRP-175 review of data in the literature points to a conservative fluence threshold for IASCC in PWR reactor internal components of approximately 7×10^{20} n/cm^2 (E > 1.0 MeV), or a radiation damage level of about 1 dpa. However, the only known PWR IASCC incidents, observed in European PWR baffle bolts, have indicated an IASCC threshold level of approximately 2×10^{21} n/cm^2 (E > 1.0 MeV), or about 3 dpa. Additional evidence for the higher IASCC damage threshold was provided by studies which determined that IASCC initiation at 1 dpa can only occur under extremely high strain conditions (40 percent decrease in laboratory specimen cross section); such high strains are not representative of conditions in PWR reactor internal components. Further studies demonstrated that an IASCC damage threshold of 3 dpa existed for various heats of cold-worked 316 stainless steel, where stress levels in lab specimens exceeded the yield strength for the material. Based on these studies and the incidents that were observed in European PWR baffle bolts, the MRP-175 report concluded that 3 dpa represented a reasonable consensus estimate of the IASCC damage threshold for austenitic stainless steel reactor internal components. However, the MRP-175 report emphasized that, at the current time, the understanding of IASCC is not sufficiently advanced to suggest a definitive IASCC fluence or radiation damage threshold that is universally applicable to all PWR reactor internal materials.

Despite significant uncertainty regarding a precise IASCC threshold and the definitive prediction of IASCC susceptibility in PWR reactor internal components, the studies reviewed in the MRP-175 report point to a definite correlation of IASCC behavior with neutron fluence and stress levels in the component. Figure B-1 of MRP-175 presented curves, based on IASCC laboratory studies, depicting the stress level required for specimen failure by IASCC as a function of radiation damage, in dpa. A recommended IASCC screening curve was presented in Figure B-3 of MRP-175. This screening curve was derived by shifting the empirical curve for long term IASCC failure downward (to more conservative stress levels) to account for the observed baffle bolt failures in Europe. MRP-175 recommended that this lower bound IASCC screening curve be utilized at this time for developing IASCC screening criteria for PWR reactor internal components where radiation damage levels exceed 3 dpa.

Appendix G of MRP-175 addressed void swelling in PWR reactor internal components and recommended void swelling screening criteria. In general, MRP-175 found that void swelling may be a significant concern for reactor internal components in PWRs because it produces volume and dimensional changes that could potentially result in distortions within structural components as well as changes in fracture toughness properties. The MRP study of void swelling phenomena found that when volume changes in the material exceed approximately 5 percent, significant increases in embrittlement associated with the void swelling start to occur.

Furthermore, the MRP review of fast reactor data found that when volume changes in the material due to void swelling exceed 10 percent, the tearing modulus for 300-series stainless steels is dramatically reduced and falls to zero at room temperature, corresponding to severe embrittlement with little energy required for crack propagation.

Based on a comprehensive review of the literature and industry operating experience regarding void swelling behavior in austenitic stainless steels, MRP-175 concluded that void swelling behavior in reactor internal components is primarily influenced by structural temperature in the component and accumulated radiation damage (dpa level), with components becoming more susceptible to void swelling at higher temperature and damage levels. Studies also demonstrate that neutron flux (corresponding to the dpa rate) can affect void swelling behavior, with lower dpa rates resulting in greater swelling for a given accumulated dpa level. However, the effect of dpa rate on void swelling in PWRs has not been well quantified, and MRP-175 cited several other void swelling studies that did not observe a strong effect.

Numerous studies cited by MRP-175 have reported that other factors are known to affect void swelling behavior in reactor internal components. Void swelling data demonstrate that cold work has the beneficial effect of prolonging the void swelling incubation period, due to the elevated concentration of dislocations acting as traps for point defects in cold-worked materials. Chemical composition of stainless steel alloys is also known to affect void swelling behavior. For instance, nickel and chromium content strongly affect vacancy diffusivity, and therefore, the onset of void swelling. On this basis alone, Type 304 stainless steel always swells more than Type 316 with the same thermo-mechanical starting state. Stress is generally regarded as a factor that accelerates swelling, although it is not thought to be an important factor for most PWR applications. MRP-175 also pointed to various studies showing that a high helium content or helium production rate can affect void swelling behavior. Several studies suggest that the presence of preexisting helium gas bubbles may prolong the incubation period of void swelling under high dpa rates in fast reactors. This is thought to be due to helium gas bubbles acting as sinks for point defects, thereby delaying the onset of rapid swelling. However, under normal neutron irradiation conditions in PWRs, various studies have given conflicting results regarding the overall impact of helium on void swelling behavior in reactor internal components. For instance, helium atoms generated as a result of the transmutation of boron during irradiation can increase the swelling rate, as helium atoms combine with vacancy clusters, thereby facilitating void nucleation and growth. Furthermore, the production of helium gas bubbles in components during transmutation could have the net effect of increasing the overall swelling, thereby negating any beneficial effects of vacancy elimination.

MRP-175 suggested that screening of austenitic stainless steel reactor internal components for void swelling should be determined primarily by the structural temperature of the material, the accumulated dpa level, and the dpa rate that the material will experience during service. MRP-175 emphasized that the screening criteria should focus on the volume changes that occur as a result of void swelling behavior because embrittlement and distortion of the component, the primary structural consequence of significant void swelling, occurs as a result of these volume changes. MRP-175 cited numerous studies suggesting that the onset of void swelling-induced embrittlement occurs at a local void swelling percentage of approximately 5 percent. It was therefore recommended that void swelling of one-half this level (~2.5 percent) should necessitate further examination of the component. If it can be ascertained that local swelling in a component would never approach 2.5 percent, then void swelling is not a concern.

To date there have been no reports of PWR reactor internal components showing significant distortion or failures as a result of void swelling. The only PWR void swelling data comes from baffle bolts removed for IASCC evaluations. Very minor void concentrations were observed with transmission electron microscopy (TEM) in several baffle bolts removed from Point Beach, Unit 1; Farley, Unit 1; and Tihange (Belgium), Unit 1. MRP-175 summarized the results of these evaluations. The highest localized void fraction was estimated at 0.24 percent in one of the bolts removed from the Tihange plant. All other local void swelling measurements were significantly less, with half of the measurements showing no voids present. Furthermore, 0.24 percent void swelling would not be expected to significantly impact structural performance. Based on these data, MRP-175 determined that for austenitic stainless steel reactor internal components, localized regions with structural temperatures less than 320 °C (608 °F) and projected damage levels less than 20 dpa (~ 1.3×10^{22} n/cm^2, E > 1.0 MeV) would be expected to experience local void swelling levels of less than 2.5 percent. This was recommended as the preliminary criterion by which void swelling in the component may be ruled out. MRP-175 stated that localized regions in reactor internal components with structural temperatures greater than 320 °C (608 °F) and projected damage levels greater than 20 dpa (~ 1.3×10^{22} n/cm^2, E > 1.0 MeV) should be analyzed to determine the percentage increase in void fraction using the best currently available predictive equation developed by industry studies of void swelling behavior for 304 series stainless steel – Equation G-2 from MRP-175. This equation correlates the percentage increase in void concentration with temperature, dpa level, and dpa rate. If this equation yields a predicted void swelling percentage greater than 2.5 percent, then further functionality evaluations for the component are necessary.

3.9.2.4.4 Evaluation

The evaluation of AP1000 reactor internal components for potential susceptibility to IASCC and void swelling was addressed in TR-12. Section 1.2 of TR-12 provided a brief discussion of known issues of IASCC and void swelling in the currently-operating PWR fleet. The applicant indicated that reactor internal components in currently-operating Westinghouse plants have not exhibited significant IASCC or void swelling issues to date based on inservice inspections (ISIs) performed in accordance with the requirements of the ASME Code, Section XI. However, other PWR vendors have reported limited IASCC in reactor internal bolting applications for several PWR plants in Europe. Results from detailed inspections of cold-worked Type 316 stainless steel baffle bolts from Farley, Unit 1 (a the applicant three-loop design) showed no signs of cracking after 17 effective full power years (EFPY) of facility operation. The estimated neutron fluence exposure for these baffle bolts is 20 dpa.

Based on the IASCC studies and data that have been accumulated thus far, the known parameters directly affecting the onset and progression of IASCC in reactor internal structural components are peak stress level in the component and cumulative exposure to neutron radiation (neutron fluence) during plant service. For void swelling, the known parameters affecting its onset and progression are peak structural temperature in the component and neutron fluence. Therefore, screening of reactor internal components for potential susceptibility to IASCC and void swelling requires that these parameters be determined. Section 2 of TR-12 briefly discussed the calculation of these parameters for use in IASCC and void swelling screening evaluations. The applicant determined that IASCC screening would be based upon the peak stress to which a reactor internal component is subjected at full hot power. The peak stresses were said to be comprised of the “membrane stress intensity with additions due to bending and stress concentrations, steady state thermal stress additions, and high-cycle fatigue components.” The applicant stated that transients do not need to be considered for the IASCC stress calculations. The peak stress levels for each of the reactor internal components were provided in Table 2-1 of TR-12. The projected end-of-life (EOL) radiation damage levels for each of the reactor internal components were provided in Table 2-2. These damage levels were expressed in units of dpa. Table 2-3 listed the estimated structural temperatures for each of the reactor internal components during normal operation.

Section 3 of TR-12 discussed the screening of reactor internal core support structure components for potential susceptibility to IASCC. The components were evaluated through the use of a set of PWR-specific screening criteria based on stress state in the component and damage level. These screening criteria are essentially a set of threshold levels of damage level and stress, such that if the specific EOL damage level and structural stress levels for a given component are found to be below the screening criteria threshold levels, it could be concluded that IASCC would not be an applicable degradation mechanism for the component during the design life of the plant. Conversely, if the EOL damage level and structural stress levels for a component are found to be greater than or equal to the screening criteria threshold levels, IASCC is considered to be a potential degradation mechanism during the service life of the component. According to TR-12, satisfaction of the IASCC screening criteria (i.e., exceeding the stress and damage level threshold values) does not imply that IASCC will absolutely occur; rather it should be considered as a potential degradation mechanism.

The IASCC screening criteria used in TR-12 are as follows:

- For EOL damage level < 3 dpa, IASCC is not considered applicable for any stress conditions.

- For EOL damage level ≥ 3 dpa, IASCC may be applicable for specific ranges of damage level and stress. These ranges are defined as follows:

- For 3 dpa ≤ EOL damage level ≤ 10 dpa, IASCC is considered applicable if stress ≥ 427.5 MPa (62 ksi).

- For 10 dpa < EOL damage level ≤ 20 dpa, IASCC is considered applicable if stress ≥ 317.2 MPa (46 ksi).

- For 20 dpa < EOL damage level ≤ 40 dpa, IASCC is considered applicable if stress ≥ 206.8 MPa (30 ksi).

- For the three dpa ranges above, it is implied that if the component does not meet the applicable stress threshold, IASCC would not be considered applicable.

Table 3-1 of TR-12 evaluated the peak stress and EOL damage level for each of the reactor internal core support structure components against the above IASCC screening criteria to determine whether or not any of the components would be susceptible to IASCC. Although a number of components have a projected EOL damage level greater than 3 dpa, none of these components have peak stresses that exceed the IASCC threshold levels for stress listed above. It was therefore concluded that IASCC is not a potential degradation concern for the reactor internal core support structure components for the design life of the AP1000 plant.

Section 4 of TR-12 discussed the screening of reactor internal core support structure components for potential susceptibility to radiation-induced void swelling. The potential susceptibility of components was evaluated through the use of a PWR-specific screening criterion based on the structural temperature in the component during normal operation and EOL damage level. The void swelling screening criterion used in Section 4 of TR-12 is as follows:

> If the structural temperature for a component is greater than or equal to 320 °C (608 °F) during normal reactor operation, and the EOL damage level equals or exceeds 20 dpa, then void swelling has a potential to occur.

Section 4 of TR-12 invoked the criterion above to screen all reactor internal core support structure components for susceptibility to void swelling. Although several of the reactor internal core support structure components are listed as having either a structural temperature or an EOL damage level that is greater than the applicable threshold, none of the components were listed as having both structural temperature and EOL damage level greater than or equal to the above thresholds. Accordingly, the results of this screening led the applicant to the conclusion that none of the reactor internal core support structure components for the AP1000 plant are susceptible to void swelling for the design life of the plant.

Based on its initial review of the above information regarding the screening of AP1000 reactor internal components for potential susceptibility to IASCC and void swelling, the staff determined that additional information was required to complete its evaluation. In an RAI issued on January 18, 2007, the staff requested supplemental information concerning the IASCC and void swelling screening methodology. RAI questions 1, 3, 4, 5, 6, 8, 10, 11, 12, 13, and 14 addressed the IASCC screening methodology. RAI questions 2, 7, 9, and 15 addressed the void swelling screening methodology. The applicant provided responses to these RAI questions by letter dated May 2, 2007.

In RAI Question 1, part a (RAI 1a), the staff requested that the applicant clarify whether the IASCC and void swelling screening criteria were meant to be specific for the AP1000 reactor design or were meant to be applied to PWR environments, regardless of PWR design. In its response to RAI 1a, the applicant stated that the IASCC and void swelling screening criteria are generic for all PWR environments and may be applied to reactor internal components regardless of design. The staff found that this response adequately resolved RAI 1a because the applicant clarified the applicability of the IASCC and void swelling screening criteria.

In RAI 1b, the staff requested that the applicant confirm whether the IASCC screening criteria from Section 3 of TR-12 were established using the lower bound IASCC screening curve developed by EPRI in Figure B-3 of the MRP-175 report. In its response to RAI 1b, the applicant confirmed that the IASCC screening criteria in TR-12 were established using the lower bound IASCC screening curve developed by EPRI in Figure B-3 of the MRP-175 report. The staff found that this response adequately resolved RAI 1b because the applicant provided the requested statement regarding the bases for the IASCC screening criteria in Section 3 of TR-12.

In RAI 1c, the staff requested that, if the IASCC screening criteria in Section 3 of TR-12 were established based on the lower bound IASCC screening curve from Figure B-3 of the MRP-175 report, the applicant provide justification, based on environmental and material similarity, regarding how these IASCC screening criteria are applicable to reactor internal components for the AP1000. In its response to RAI 1c, the applicant stated that the materials specified for the AP1000 reactor internal components are similar to those used in the currently-operating Westinghouse three-loop extended length design. Operating parameters are also similar. IASCC screening of AP1000 reactor internal components was based on the same criteria (the lower bound IASCC screening curve from Figure B-3 of MRP-175) as those used for IASCC evaluations of reactor internal components in these operating reactors. Furthermore, the MRP-175 IASCC screening curve was developed as a generic lower bound curve for austenitic stainless steel reactor internal components in PWR environments, and its application was not intended for any specific set of material conditions (e.g., amount of cold-work, solution annealing, trace element composition). With respect to environmental similarity, the MRP-175 screening curve is based on radiation damage and stress level for the component, and according to the current understanding of IASCC, these are the two known environmental parameters directly affecting the onset and progression of IASCC behavior. Therefore, the IASCC screening curve in Figure B-3 of the MRP-175 report is applicable to the AP1000 reactor internal components, based on environmental and material similarity. Accordingly, the staff found that RAI 1c is resolved.

In RAI 1d, the staff requested that the applicant indicate whether reactor internal components that do not meet or exceed the IASCC screening criteria in TR-12 (i.e., components that do not meet or exceed the threshold stress and damage levels for IASCC) would ever be considered susceptible to IASCC. In its response to RAI 1d, the applicant stated that ongoing license renewal and life extension activities at operating Westinghouse reactors will develop new data concerning aging effects and aging management in reactor internal components. It is possible that new data may necessitate the consideration of IASCC in reactor internal components currently not considered susceptible to IASCC. However, at the present time, the IASCC screening criteria in Section 3 of TR-12 are applied for the purpose of determining whether or not a given AP1000 reactor internal component is susceptible to IASCC behavior during the operating life of the plant. Since none of the AP1000 reactor internal components have peak stress and EOL damage levels that meet or exceed the IASCC threshold levels from Section 3 of TR-12, none of the components are currently considered susceptible to IASCC. The staff found that this response adequately resolved RAI 1d because the applicant clearly stated how it applied the screening criteria for determining susceptibility to IASCC.

In RAI 2, the staff requested that the applicant confirm whether the void swelling screening criterion from Section 4 of TR-12 was established based on the void swelling screening recommendation developed by EPRI in Section G.7 of the MRP-175 report. The staff further requested in RAI 2 that the applicant provide justification, based on environmental and material similarity, regarding how the void swelling screening criterion is applicable to reactor internal components for the AP1000. In its response to RAI 2, the applicant confirmed that the void swelling screening criterion from Section 4 of TR-12 is based on the void swelling screening recommendation of MRP-175. With respect to the applicability of the MRP-175 void swelling screening recommendation to AP1000 reactor internal components, the applicant stated that the materials specified for the AP1000 reactor internal components are similar to those used in the currently-operating Westinghouse three-loop extended length design. Operating parameters are also similar. Screening of AP1000 reactor internal components for void swelling was based on the same criterion (the void swelling screening recommendation from Section G.7 of MRP-175) as that used for void swelling evaluations of reactor internal components in these operating reactors. Furthermore, the MRP-175 void swelling screening recommendation was intended to be generic for austenitic stainless steel reactor internal components in PWR environments, and its application was not intended for any specific set of material conditions (e.g., amount of cold work, solution annealing, trace element composition). With respect to environmental similarity, the MRP-175 void swelling screening recommendation is based on neutron fluence and peak structural temperature for the component, and based on the current understanding of void swelling, these are the two known environmental parameters directly effecting the onset and progression of void swelling behavior. Therefore, the void swelling screening recommendation from Section G.7 of the MRP-175 report is applicable to the AP1000 reactor internal components, based on environmental and material similarity. Accordingly, the staff found that RAI 2 is resolved.

In RAI 3, the staff requested further detail regarding how the peak stresses for the various reactor internal components in Table 2-1 of TR-12 were determined. The staff also requested, in RAI 3, that the applicant elaborate on why stresses arising from thermal transients were not considered in the peak stress calculations. In its response to RAI 3, the applicant stated that these stresses represented peak stress levels for normal operation. Finite element techniques were used in the computation of these stresses, and stress concentration factors were applied as appropriate. The reported stresses were intended to be conservative for IASCC screening of reactor internal components. With respect to consideration of thermal transients, the applicant indicated that the screening criteria stress levels (based on the MRP-175 IASCC screening curve) were developed for comparison with normal operating peak stress levels, and normal operating peak stress levels do not include stresses due to transient conditions. However, these stress levels do account for steady-state thermal stresses arising from temperature gradients within the reactor internal components during normal operation. The applicant emphasized that temperature gradients in reactor internal components are a steady-state phenomenon caused by the surrounding RCS temperatures and internal heat generation within reactor internal components due to gamma heating; these factors are known to result in steady-state temperature gradients and thermal stresses within reactor internal components during normal operating conditions. The staff found that this response adequately resolved RAI 3 because the applicant adequately clarified its methods for computing the peak stresses for the reactor internal components. Furthermore, the applicant conclusively defined these stresses as peak operating stresses that do not account for transient conditions and provided adequate justification for why transients were not considered in their computation. Therefore, the staff found that RAI 3 is resolved.

In RAI 4, the staff requested that the applicant define EOL for the projected radiation damage levels in Table 2-2 of TR-12 in terms of the total EFPY of facility operation. In its response to RAI 4, the applicant stated that EOL for the AP1000 design is considered to be 55.8 EFPY of facility operation. Therefore, the damage levels in Table 2-2 of TR-12 are projected out to 55.8 EFPY of facility operation. The staff found that this response adequately resolved RAI 4.

In RAI 5, the staff requested that the applicant discuss how ISI will be conducted for the reactor internal components during the operating life of the AP1000 plant. In its response to RAI 5, the applicant stated that ISI of reactor internal components during plant operating life will be driven by applicable codes and standards, as required by NRC regulations. At present, a VT-3 visual examination of all accessible surfaces of reactor internal core support structure components is required by the ASME Code, Section XI. These examinations must be conducted once during each 10-year ISI interval. Such visual examinations are currently performed using remotely controlled submersibles, underwater crawlers and/or pole-mounted cameras. The staff found that this response adequately resolved RAI 5 because the applicant adequately specified how ISI will be conducted for reactor internal components during the operating life of the AP1000 plant.

In RAIs 6 and 7, the staff requested that the applicant discuss how the EOL damage levels and estimated structural temperatures from Tables 2-2 and 2-3 of TR-12 were determined for the reactor internal components. In its response to RAI 6, the applicant stated that a radiation model of the reactor vessel and internal components was created and two distinct axial power distributions were utilized to determine damage levels in dpa. The higher damage level from the two core power distributions was listed for each reactor internal component in Table 2-2. In its response to RAI 7, the applicant stated that detailed finite element thermal calculations were performed to determine the structural temperatures reported in Table 2-3. These calculations accounted for the effects of gamma heating using two core power distributions. The distribution resulting in the highest component temperature was utilized and temperatures at localized regions within the components were evaluated. The highest localized temperature for the component during normal reactor operation was listed in Table 2-3. As with the peak operating stresses listed in Table 2-1, the structural temperatures listed in Table 2-3 represent peak temperatures during normal operation because the void swelling temperature threshold in Section 4 of TR-12 (based on the screening recommendation of MRP-175) was developed for comparison with normal operating temperature levels in reactor internal components. The staff found that these responses adequately resolved RAIs 6 and 7 because the applicant adequately clarified its methods for computing the EOL damage levels and structural temperatures from Tables 2-2 and 2-3 of TR-12. Furthermore, the staff found that these stated methods were appropriate for calculating temperature and damage levels for use in screening reactor internal components for IASCC and void swelling.

In RAI 8, the staff requested that the applicant discuss whether there are any localized areas within any reactor internal component that could be exposed to damage levels that exceed the IASCC screening criteria from Section 3.1 of TR-12. In its response to RAI 8, the applicant stated that the EOL damage level calculations accounted for localized areas in the reactor internal components. As such, the damage levels reported in Table 2-2 of TR-12 represent that maximum projected damage level based on the highest localized exposure in each component. Therefore, the staff found that RAI 8 is resolved.

In RAI 9, the staff requested that the applicant further explain how it screened certain reactor internal components for susceptibility to void swelling. Specifically, the staff noted that Section 4 of TR-12 concludes that void swelling is not a significant degradation mechanism for any of the reactor internal components in the AP1000 plant. This conclusion was apparently based on the fact that none of the reactor internal components met the void swelling screening criterion, as invoked in Section 4 of TR-12, which stated that if the structural temperature for a component is greater than or equal to 320 °C (608 °F) during normal reactor operation, and the EOL damage level equals or exceeds 20 dpa, then void swelling has a potential to occur. The staff reviewed the damage level projections and structural temperature levels listed in Tables 2-2 and 2-3 and noted that, while none of the components are listed as having both damage level and temperature greater or equal than the above temperature and damage level threshold values, several components are listed as having either temperature or damage level greater than the applicable threshold. Therefore, the staff requested that the applicant explain how it was determined that void swelling was not an applicable degradation mechanism for these components.

In its response to RAI 9, the applicant stated that the TR-12 void swelling screening criterion was based on the recommendations in the MRP-175 report and, as such, it requires that both temperature and damage level be greater than or equal to the above threshold levels. The staff did not agree with this interpretation of the void swelling screening recommendation from the MRP-175 report and, therefore, found that this response did not adequately resolve RAI 9. By letter dated July 11, 2007, the staff issued a second RAI on this subject in order to address screening of reactor internal components for void swelling where either temperature or damage level meet or exceed the above threshold levels. In this RAI, the staff indicated that the recommended void swelling screening criterion from the MRP-175 report was misinterpreted by TR-12 when applied to reactor internal components that met or exceeded only one of the two thresholds (temperature or damage level). The staff stated the position that void swelling may be a potential concern for reactor internal components if either temperature or damage level exceeds its applicable threshold. This position is justified because of the hypothetical situation where one of these parameters is significantly greater than the threshold, and the other is only marginally less. For such a situation, it would be unacceptable to dismiss the possibility of void swelling in the component only because just one the two thresholds had been exceeded. Therefore, the staff requested that the applicant justify why the several components that were listed in TR-12 as having either temperature or damage level greater than the applicable threshold were not deemed susceptible to void swelling.

In its second response to RAI 9, dated August 21, 2007, the applicant provided an analysis for demonstrating that there are no significant void swelling concerns for the components listed in TR-12 as having either temperature or damage level greater than the applicable threshold level. The applicant demonstrated that none of the components in question meet the hypothetical situation proposed by the staff, where one of the parameters (temperature or damage level) is significantly greater than the threshold, and the other is only marginally less. For the components with structural temperatures exceeding the 320 °C (608 °F) void swelling threshold, all of the EOL damage levels for these components are far below the 20 dpa damage threshold for void swelling, and the calculated structural temperatures are only slightly greater than the 320 °C (608 °F) threshold. One component, the core barrel inner wall, has a projected EOL damage level that is slightly greater than the 20 dpa threshold; however the calculated structural temperature is significantly less than the 320 °C (608 °F) threshold. The applicant further demonstrated that these components are extremely unlikely to experience any significant void swelling during the operating life of the plant by applying equation G-2 from MRP-175 for calculating the predicted void swelling percentage. Application of this void swelling equation to the dpa and temperature values listed in Table 2-2 and 2-3 of TR-12 and the dpa rate based on 55.8 EFPY of facility operation yields void swelling percentages of less than 0.10 percent for all of these components. MRP-175 recommended further examinations of reactor internal components for void swelling behavior are necessary only if the predicted void swelling percentage based on this equation, approaches 2.5 percent. Therefore, the applicant adequately demonstrated that void swelling is not a significant concern for any of these reactor internal components (or any other AP1000 reactor internal component) based on the current void swelling data and predictive models. Accordingly, the staff found that RAI 9 is resolved.

In RAI 10, the staff requested that the applicant reconcile differences between the 3 dpa damage threshold for IASCC susceptibility established in TR-12 and IASCC neutron fluence thresholds established in other reports. Specifically, the staff noted the IASCC neutron fluence threshold from WCAP-14577, “License Renewal Evaluation: Aging Management for Reactor Internals,” is 1×10^{21} n/cm^2 (E > 0.1 MeV). Additionally, the Babock and Wilcox report, BAW-2248, “Demonstration of the Management of Aging Effects for the Reactor Vessel

Internals," stipulates a neutron fluence threshold of 1-2 x 10^{21} n/cm^2 (E > 0.1 MeV). The staff noted in RAI 10 that, according to MRP-175, the 3 dpa threshold from TR-12 is roughly equivalent to an accumulated neutron fluence value of 2 x 10^{21} n/cm^2 (E > 1.0 MeV) for austenitic stainless steel materials. In its response to RAI 10, the applicant stated that 3 dpa was the recommended IASCC damage threshold from the MRP-175 report, and the MRP-175 screening criteria represent a consensus opinion of the EPRI MRP expert panel. The recommended 3 dpa damage threshold superseded the previous two the applicant reports. The staff found this response adequately resolved RAI 10 because MRP-175 determined that 3 dpa represents a reasonably conservative consensus value for an IASCC damage threshold for reactor internal components in PWR environments.

In RAI 11, the staff requested the applicant to discuss whether the 3 dpa damage threshold for IASCC in TR-12 was determined taking into consideration the effect of thermo-mechanical history (e.g., prior cold work, annealing, etc.) in reactor internal components that are exposed to neutron fluence levels less than 6.7 x 10^{21} n/cm^2 (E > 1.0 MeV). This question related to a statement from Section B.1.1 of MRP-175 referencing studies indicating that thermo-mechanical history may affect the onset of IASCC in reactor internal components exposed to these neutron fluence levels. In its response to RAI 11, the applicant stated the IASCC screening criteria, as applied to the reactor internal components in TR-12, are based on the screening recommendations of MRP-175. The MRP-175 IASCC screening recommendations are generic for all austenitic stainless steel materials in PWR environments. As such, the IASCC screening criteria and 3 dpa damage threshold were not developed based on any specific state of cold work (or any other prior thermo-mechanical preconditioning) in the material. While the amount of prior cold work had been shown to potentially delay the onset of IASCC at fluence levels less than 6.7 x 10^{21} n/cm^2 (E > 1.0 MeV), the applicant stated the AP1000 reactor internal components were screened using the MRP-175 screening recommendations without regard to the components' thermo-mechanical history. The applicant further stated it is not anticipated that a material's degree of cold work will necessitate screening criteria be different from the criteria recommended by MRP-175. The staff found this response adequately resolved RAI 11 because the applicant adequately explained why the MRP-175 IASCC screening recommendations were applied irrespective of the thermo-mechanical history of the components. The staff's justification for acceptance of MRP-175 recommendations for generic screening of AP1000 reactor internal components for IASCC (irrespective of the components' thermo-mechanical history) is provided below.

In RAI 12, the staff requested that the applicant discuss whether the 3 dpa damage threshold for IASCC in TR-12 was determined taking into consideration the effect of differing chemical composition for the various reactor internal components. This question related to a statement from Section B.1 of MRP-175 referencing studies indicating differences in bulk alloy composition of elements such as silicon, nickel, niobium, titanium, and boron, among various austenitic stainless steel reactor internal components can have varying effects on IASCC initiation and progression. In its response to RAI 12, the applicant stated the IASCC screening criteria, based on the generic screening recommendations of MRP-175, did not consider variations in the elemental composition among the various reactor internal components. As with the case above concerning the potential effect of components' thermo-mechanical history, the staff found this response adequately resolved RAI 12 because the applicant adequately explained why the MRP-175 IASCC screening recommendations were applied irrespective of the components' specific elemental composition. The staff's justification for acceptance of MRP-175 recommendations for generic screening of AP1000 reactor internal components for IASCC (irrespective of the components' specific elemental composition) is provided below.

In RAI 13, the staff requested that the applicant discuss whether the 3 dpa damage threshold for IASCC in TR-12 is applicable to reactor internal components fabricated from nickel-based alloys, such as alloy X-750 and Alloy 690. In its response to RAI 13, the applicant indicated IASCC studies reviewed in MRP-175 have shown that the IASCC resistance of nickel-based alloy X-750 is approximately the same as for Type 304 and 316 austenitic SSs. Furthermore, AP1000 reactor internal reactor internal components fabricated using nickel-based alloys will be exposed to a projected EOL damage level of, at most, 0.04 dpa. Since this damage level is far below the 3 dpa IASCC damage threshold, IASCC is not considered to be a relevant degradation mechanism for these components. The staff found this response adequately resolved RAI 13 because the applicant adequately addressed IASCC screening of reactor internal components fabricated from nickel-based alloys.

Studies have shown crevice corrosion may be enhanced in reactor internal components due to the production of oxidizing ions in component crevices during exposure of reactor coolant to neutron radiation. Therefore, in RAI 14, the staff requested that the applicant discuss whether the effects of crevice corrosion were taken into consideration in screening AP1000 components for IASCC. In its response to RAI 14, the applicant stated the IASCC screening criteria do not explicitly address the effects of crevice corrosion in reactor internal components. However, crevice corrosion is prevented or controlled in AP1000 reactor internal components through the use of hydrogen overpressure, which minimizes the adverse effects of any oxygen that may be present due to heat-up or cool-down of the reactor system. Furthermore, crevice locations in AP1000 reactor internal components have been designed to allow flushing to prevent stagnation, a key contributor to crevice corrosion. The staff found this response adequately resolved RAI 14 because the applicant addressed how crevice corrosion would be mitigated in AP1000 reactor internal components.

Transmutation products such as helium are known to play an important role in void swelling. In order to reduce overall interfacial energy, helium atoms will combine with vacancy clusters, thereby facilitating void nucleation and growth. Section G.1 of MRP-175 states a potentially important aspect of void swelling in PWRs arises from transmutation of trace amounts of boron, preexisting in most austenitic SSs, to produce lithium and helium. Section G.1 of MRP-175 indicates at low neutron exposure (~10^{21} n/cm^2 thermal), almost all Boron-10 (20 percent of natural boron preexisting in trace quantities in most SSs) will be converted to lithium, producing helium in the process. Since the original concentration of boron in austenitic stainless steel reactor internal components is not generally reported in certified material test reports, it is difficult to assess the concentration of helium in the reactor internal components. In RAI 15, the staff requested that the applicant address whether the void swelling screening criterion from Section 4 of TR-12 accounts for the effects of helium on void swelling in stainless steel reactor internal components. In its response to RAI 15, the applicant stated the void swelling screening criterion, based on the generic screening recommendations of MRP-175, did not explicitly consider the effects of helium. The staff found this response adequately resolved RAI 15 because the applicant explained the MRP-175 void swelling screening recommendations were applied irrespective of the components' helium content. The staff explained its acceptance of the void swelling screening evaluation for the AP1000 reactor internal components (irrespective of the components' potential helium content) in the discussion of the applicant's responses to RAI 9 above.

The acceptance of MRP-175 screening recommendations would provide a basis for setting IASCC screening criteria in TR-12. There are currently limited data to support an all-encompassing set of IASCC screening criteria that can be generally applied to reactor internal components in PWRs. Furthermore, MRP-175 has referenced studies showing variability in chemical composition, microstructural characteristics, and thermal-mechanical history between similar alloys may result in differing stress and fluence thresholds for IASCC. MRP-175 cited numerous documents both in the nuclear power industry and the open literature identifying a variety of possible threshold values for IASCC susceptibility and, therefore, a definitive, all-encompassing set of IASCC screening criteria is not likely to exist. In its response to the staff comments regarding these issues, EPRI acknowledged that exact threshold values for IASCC are expected to depend on variables, such as chemical composition, microstructural properties, and thermo-mechanical history. However, EPRI stated the IASCC screening recommendations of MRP-175 represent a consensus based on the limited amount of available data, and the IASCC screening criteria are considered to be conservative for general application to IASCC evaluations of reactor internal components in PWRs. As such, MRP-175 concluded the IASCC screening criteria were appropriate for evaluating stainless steel reactor internal components to determine their susceptibility to IASCC behavior.

The staff found the limited amount of data does support the MRP-175 conclusions regarding the conservatism of the IASCC screening criteria from Section B.3 of MRP-175. Therefore, although it may be impossible to absolutely rule out the possibility of IASCC, because reactor internal components are deemed not susceptible according to the MRP-175 screening criteria, significant IASCC behavior would not be expected for the AP1000 reactor internal components because the peak operating stresses and projected EOL damage levels for these components fall significantly below the MRP-175 screening criteria threshold levels. Furthermore, any age-related degradation of reactor internal components due to IASCC would be gradual, and the ASME Code, Section XI requirements for ISI of reactor internal components will be sufficient for capturing any age-related degradation that may occur due to IASCC phenomena.

Based on the above considerations, the staff determined that the applicant had adequately addressed the staff's concerns, as documented in the above RAIs, regarding the IASCC and void swelling screening methodologies. Therefore, the staff found the applicant had appropriately evaluated the AP1000 reactor internal components for susceptibility to IASCC and void swelling in TR-12. Furthermore, the staff agreed with the conclusions in TR-12 regarding the determination that IASCC and void swelling are not projected to be significant degradation concerns for the reactor internal components in the AP1000 plant.

The staff determined the TR-12 conclusions regarding the evaluation of reactor internal components for IASCC and void swelling meet the requirements of ASME Section III based on the MRP-175 screening criterion as reported in TR-12 and is fully represented in Sections 3.9.8.2 and 3.9.9 of the AP1000 DCD, Revision 16. Therefore, the staff found the DCD changes, as proposed by the applicant in TR-12, acceptable and AP1000 COL Information Item 3.9-2 is resolved. These DCD changes are generic and are expected for all COL applications referencing the AP1000 certified design. At this time, the NRC has not issued a COL for any AP1000 plant. Thus, the proposed changes incorporated into Revision 16 contribute to the increased standardization of the certification information in the AP1000 DCD and, thus, meet 10 CFR 52.63 (a)(1)(vii).

3.9.2.4.5 Conclusions

The staff finds the evaluation of the AP1000 reactor internal components for IASCC and void swelling meets the requirements of 10 CFR 50.55a by meeting the ASME Section III based on the MRP-175 screening criterion as reported in TR-12 and resolution of IASCC aspects of COL Information Item 3.9-2 is acceptable.

3.9.3 ASME Code Class 1, 2, and 3 Components, Component Supports, and Core Support Structures

3.9.3.1 Introduction

The staff evaluation was first performed for AP1000 DCD, Revision 16, and TR-134, Revision 5, which were issued as part of AP1000 DC amendment application. The staff subsequently included AP1000 DCD Revision 19 in its evaluation when this revision was issued by the applicant.

3.9.3.2 Evaluation

DCD Tier 2, Section 3.9.8.2, addresses the combined license information for the design specifications and reports for the major ASME Code, Section III components. In DCD Tier 2, Revision 17, COL Information Item in Section 3.9.8.2, the applicant stated the design specifications and design reports for the major ASME Code, Section III components were available for NRC audit via the TRs listed in Table 3.9-19. It is also stated that design specifications and selected design analysis information were also available for ASME Code, Section III valves and auxiliary components. The applicant's letter dated February 8, 2008, states that design specifications and design reports for most major components and auxiliary equipment and valves would be available for NRC review in July 2008. In RAI-3.9.3-EMB2-01, the staff requested that the applicant verify the schedule provided in the letter was still valid.

In a letter dated June 26, 2008, the applicant stated review of design specifications and as-designed design reports for ASME Code Section III components provides a means for the NRC to verify the design commitments in the DCD are being implemented appropriately. This review permits some level of verification during the review of the COL applications. The ultimate check on the proper implementation of design requirements for ASME Code Section III components are the ITAAC require as-built design reports for the ASME Code, Section III components. The applicant stated that it has a substantial amount of design information available for NRC review. This information was sufficient for the NRC to start its review and support the conclusion that the ASME Code, Section III components were in compliance with the commitments in the DCD. The remaining design information needed to complete the NRC verification of the design criteria and methodologies in the DCD would be available in the short term consistent with the schedule for review of the AP1000 DC amendment.

The applicant stated since the information needed to address the COL Information Item on design specifications and design reports would be complete during the review of the AP1000 Design Certification amendment there was no need for a DAC or design ITAAC on the design of ASME Code Section III components. The applicant revised its approach of resolving the component design issue, and stated the revision of the COL information item in DCD Revision 16, Section 3.9.8.2, was based on the expectation the design information available at the time was sufficient for the NRC to reach a conclusion as to the implementation of the design requirements. The applicant stated that the amount of information available for NRC review was much more developed and robust. The COL information would be revised to reflect that sufficient information would be provided to the NRC to complete its verification of the implementation of the design commitments. The applicant stated it expected that this portion of the COL information item would be satisfied and no additional information would be required of the COL applicant. The portion of the COL information item, restated as a COL holder item, is related to the as-built reconciliation of thermal cycling and stratification loadings on piping.

The applicant stated it had completed the design specifications for the major ASME Code, Section III components in the AP1000. The as-designed design reports and supporting analysis for most of the major components were also complete and available for review. The applicant stated the analyses include the use of the updated (six soils case) seismic design spectra. The components that had or will have as-designed design reports ready for review on a schedule to support the NRC preparation of the SER with open items include: reactor vessel, control rod drive mechanism, steam generator, pressurizer, passive residual heat removal heat exchanger, core makeup tank, accumulator, and reactor internals. The applicant stated all of the design specifications for valves and auxiliary equipment are now available for NRC review or will be ready in time to support the preparation of the SER. This includes the motor-operated globe and gate valves. The balance of the design specifications (expected to be one or two) will be available for review well before open items need to be cleared for the advance SER.

The staff has reviewed the above additional information provided by the applicant, and found the commitment and schedule for resolving the COL Information item to be acceptable. Pending a successful audit for the required design specifications and design reports, the staff would be able to conclude whether the COL information item is closed.

In its letter of June 28, 2008, the applicant provided a markup of the revised DCD Section 3.9.8.2, which now states the following:

> The design specification and design reports for the major ASME Code, Section III components and piping made available for NRC review are identified in APP-GW-GL-002. Design specifications for ASME Code, Section III valves and auxiliary components made available for NRC review are also identified in APP-GW-GL-TBD

In doing so, the applicant has proposed to delete Table 3.9-19 from DCD, Tier 2, which lists the TRs summarizing design specification and design reports for ASME Code Section III components and piping. The applicant also deleted references to Reference Items 22 through 32 in DCD Section 3.9.9, and placed a new Reference 22, APP-GW-GL-002, "Design Specifications and Design Reports for ASME Code, Section III Components and Piping."

The staff has reviewed the above information provided by the applicant and concludes that the additional information provided by the applicant is acceptable in responding to the staff's request of RAI-3.9.3-EMB2-01. Subsequently, the staff reviewed AP1000 DCD, Revision 17, when it became available, and verified the latest revision of DCD has incorporated all the changes as required.

During October 13 to 17, 2008, the staff conducted an onsite review of the AP1000 component design in relation to the close out of the above COL Information Item in DCD Section 3.9.8.2. The purpose of the on-site review was to verify the AP1000 component design was in accordance with the methodology and design criteria described in the DCD, and satisfies the guidance provided in NUREG-0800 Section 3.9.3 for design specifications and design reports. This includes verification the design information described in the DCD was adequately translated into documentation for each of the components designed to ASME Code Section III, Class 1, 2, and 3 requirements. A separate staff audit report, dated August 3, 2009, documents the detailed on-site review for the design of the AP1000 mechanical components, including valves. During the audit, the staff identified concerns with the reactor vessel J-groove weld design and the additional details on the containment recirculation screen design.

The staff requested in RAI-SRP-3.9.3-EMB2-05 that the applicant demonstrate how the Westinghouse methodology meets the ASME Code for the J-groove weld design.

In response to RAI-SRP-3.9.3-EMB2-05, the applicant stated it had satisfied the intent of Paragraph NB-3228.5(a) of the ASME Code, Subsection NB. According to the applicant, the purpose of the Paragraph NB-3228.5 is to limit potential excessive distortion due to incremental plasticity, sometimes referred to as stress ratcheting. The location where this applies is the J-groove weld between the piping penetration and reactor vessel head. The overstress shown in the design report is caused by the large hoop stress combined with, to a lesser degree, the axial stress. The ratcheting mechanism cannot occur as a result of the hoop stress since it is restrained by the reactor vessel head. The stresses in the radial and axial directions are well within the limits and meet the ASME Code requirements. Therefore, according to the applicant, additional plastic analysis in accordance with Paragraph NB-3228.4 was not necessary.

The staff found that the applicant's response did not resolve the issue, and again asked the applicant to provide additional information or detailed information to demonstrate the J-groove weld design meets the ASME Code requirements. The staff's concern was that the design report for the reactor vessel head penetrations split the stress components at these locations to justify the satisfaction of the Code requirements. Paragraph NB-3228 is based on stress intensities and does not allow splitting stresses for the purpose of satisfying the ASME Code.

The applicant in its response stated that the justification previously provided for meeting the requirements of NB-3228.5 is compatible with ASME Code methodology. According to the applicant, the fatigue evaluation for stresses is made for a plane of reference. The fatigue evaluation checks the range of stress intensity values for every potential plane (line) of failure and fatigue usage is determined for a point on that plane using a conservative value of primary plus secondary stress intensity range, for the purpose of determining a conservative value of Ke and, therefore, a conservative usage factor. As this conservative approach does not satisfy the limits of Paragraph NB-3228.5(a), the Code rules are used to perform a more realistic evaluation using membrane and bending stresses normal to the plane of reference. Using this approach, Paragraph NB-3228.5(a) is met with very large margin. This approach is within the Code rules specified in the Code definitions. This evaluation therefore demonstrates compliance with Paragraph NB-3228.5 and a plastic analysis is not required. The reactor vessel design report and associated stress calculation for the vessel head penetrations will be revised with this discussion.

During April 19 to 21, 2010, the staff conducted an onsite review of Open Item OI-SRP-3.9.3-EMB2-05, "Component Supports, and Core Support Structures." The applicant, in its plastic analysis of control rod drive mechanism (CRDM) and vent pipe penetrations, has demonstrated that the design of the vessel head assembly satisfies the ASME Code requirements. On this basis, the staff finds this acceptable and Open Item OI-SRP-3.9.3-EMB2-05 is closed. In a subsequent revision to the AP1000 DCD, the applicant made appropriate changes to the DCD text. In addition, APP-MV01-Z0C-015, "Detailed Analysis of Closure Head and Vessel Flange Region for AP1000 Reactor Pressure Vessel," and APP-MV01-Z0C-019, "Detailed Analysis of Closure Head Penetrations (CRDM, UMI, and Vent Pipe) for AP1000 Reactor Vessel" have been updated to include the results of the plastic analysis for the CRDM and vent pipe penetrations.

The staff reviewed the design specification and other supporting documents associated with containment recirculation screens and found several issues are not completely addressed in the design specification. In RAI-SRP-3.9.3-EMB2-08, the staff requested that the applicant address the following:

(a) According to the design specification, the supplier will provide additional design details, design drawings and requirements. Therefore, the engineering drawings (envelope drawings) of the screen assemblies were not available at the time of site audit or at the Rockville office. Provide these engineering drawings of the screen assemblies for review by the staff.

(b) Provide the following loading conditions and combinations: (i) design and service level A-D loads and load combinations, (ii) fatigue evaluation, and (iii) the origin and the basis of using ±5 psi pressure loading on the IRWST screen from sparger discharge.

(c) Justify the latent debris mass value used for the screen pressure drop component of the structural load on the IRWST and sump screens. Additionally, verify the flow rate through the screen is conservatively calculated.

During April 19 to 21, 2010, the staff conducted an onsite review of Open Item OI-SRP-3.9.3-EMB2-08. As a result of the audit, the staff identified follow-up items that required the applicant's response:

1. Screen design reports and detailed design drawings were not available, since they have not yet been provided by the responsible vendor. A set of drawings was reviewed by the staff, but these are categorized as "Envelope Drawings" and not detailed design drawings. However, AP1000 DCD, Tier 1, Table 2.2.3-4, ITAAC 5.a) was added to require review of a report verifying the as-installed screens including seismic load, post accident operating loads, head loss and debris weights.

   Subsequently, the staff confirmed the existing AP1000 DCD, Tier 1, Table 2.2.3-4, ITAAC 5.a) addressed the issue such that this ITAAC allows the staff to inspect the design reports and verify the as-installed screens including seismic load, post accident operating loads, head loss and debris weights. The staff concurred with the ITAAC approach of screen design report. The staff finds that these audit findings satisfied the staff's request for the information in part (a) RAI-SRP-3.9.3-EMB2-08 and follow-up item #1. Therefore, the follow-up item number 1 is closed.

2. The staff questioned the loading on the screen (i.e., how the 0.25 psi pressure drop loading will be added to the 34.5 kPa (5 psi) loading for the screens). Following discussion, the applicant agreed the screen head loss component of pressure loading on both the IRWST and Containment screens would be a minimum of 1.72 kPa (0.25 psi) as indicated in a Westinghouse design specification (APP-GW-GLE-002, "Impacts to the AP1000 DCD to Address Generic Safety Issue GSI-191," February 2010, p. 39). In addition, the applicant stated that it would consider augmenting this minimum head loss to allow for additional margin.

   In response to this follow-up item, documented in the applicant's response to OI-SRP3.9.3-EMB2-08, Revision 1, the applicant stated it is very unlikely that sparger actuation will occur coincident with IRWST injection as the sparger actuation comes from the ADS 1, 2, 3 discharge. IRWST injection cannot occur until the pressure in the RCS drops below the hydrostatic pressure exerted on the IRWST water due to the level in the tank. This only occurs after ADS 4 has been actuated. Therefore the 1.72 kPa (0.25 psi) debris differential pressure load is not coincident with 34.5 kPa (5 psi) loading for the screens. These two loads are not included in the same load combination. The staff finds the response satisfies the staff's request for the information in part (b)(iii) RAI-SRP3.9.3-EMB2-08 and the follow-up item number 2. Therefore, the follow-up item number 2 is closed.

3. The staff asked the applicant to confirm the applicability of the 5 psi sparger loading on IRWST screen design. The operation of the IRWST tank spargers leads to a pressure loading on the IRWST screens. An estimate of the sparger pressure loading is used as one component of the loading of both the IRWST and the containment screens. During discussions, the staff asked the applicant for a review of the available documents that support the pressure loading of ±34.5 kPa (±5 psia). The applicant responded by saying the documentation for this was not available at the time. However, the applicant stated the documentation for the magnitude of the sparger pressure loading was available, and that staff had this in their possession.

   In response of this follow-up item, documented in OI-SRP3.9.3-EMB2-08, Revision 1, the applicant stated the "Sparger Loading" is the maximum value due to actuation of the sparger. The actual shape of the pressure will be sinusoidal shape. The forces in the walls of the IRWST are bounded by a case with a uniform pressure of 5 psi applied to the walls. The actuation of the sparger will occur during discharge of ADS 1, 2, 3 valves. Tests conducted at the ENEA's VAPORE facility showed the maximum pressure exerted on the IRWST walls during a sparger actuation of 181.r kg/s (400 lbm/s) steam. The pure steam blowdown caused the highest pressures exerted on the IRWST floor directly below the sparger arm during sparger actuation. Additionally, the tests simulated a sparger steam flow of 181kg/s (400 lbm/s). This flow more than bounds the actual calculated maximum steam flow of 65.8 kg/s (145 lbm/s) for the AP1000 (APP-ME02-Z0C-001 Revision 0). The nominal hydrodynamic load exerted during the above mentioned sparger test was 34.5 kPag (5 psig). Given the steam flow was more than 2.7 times the actual design flow, this bounds the structural design requirement for DP mentioned above. The staff finds the response satisfies the staff's request for the information in part (b)(iii) of RAI-SRP3.9.3-EMB2-08.

   The staff confirmed these support documents are available for NRC review and verified the pressure loading of ±34.5 kPa (±5 psia) was acceptable by NUREG-0800 Section 6.2 evaluation. The staff concurred with the applicant's response of the pressure loading of ±34.5 kPa (±5 psia). Therefore, this follow-up item is closed.

4. The staff questioned the potential sloshing of water in the IRWST tank resulting from seismic activity and the magnitude of resulting pressure loading on the IRWST screen structures. The applicant did not have a response to whether this potential source of loading had been considered. The follow-up item for the applicant is to determine if the sloshing load on the screen should be included.

   In response to this follow-up item, documented in OI-SRP3.9.3-EMB2-08 R1, the applicant stated the sequences for the postulated accidents are such that the seismic event producing the sloshing and the actuation of the sparger are not coincident. Therefore, the sloshing loads need to be included as a load on the screen, but it is not combined with the sparger loadings. The staff finds the response satisfies the staff's request for the information in part (b)(i) of RAI-SRP3.9.3-EMB2-08. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

5. In response to part (c) RAI-SRP3.9.3-EMB2-08, documented in OI-SRP3.9.3-EMB2-08 R1, the applicant stated that the AP1000 debris inventory in containment and the development of supporting containment cleanliness programs have been reviewed by the NRC. The screen pressure drop and the flow rate through the screen have been developed in support of responding to GSI-191 issues. This information is documented in APP-GW-GLN-147, "Screen Design Report," and APP-GW-GLR-79, "Verification of Water Sources for Long Term Recirculation Following a LOCA."

The staff confirmed these support documents are available in NRC review, verified AP1000 debris inventory in containment and the development of supporting containment cleanliness programs were acceptable by NUREG-0800 Section 6.2 evaluation. The staff concurred with the applicant's response of part (c) RAI-SRP3.9.3-EMB2-08. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

The AP1000 component design has been completed to the extent that the COL Information Item in Revision 15 is not necessary, allowing the aspects of the COL information item addressing components to be eliminated, as documented in the amendment to the DCD.

Since its original DC amendment, the applicant has modified the AP1000 seismic design ground motion requirements, in order to extend the DC application to soil sites. It was expected that these revised seismic loadings would have an impact on the component designs already performed up to that point. In RAI-SRP3.9.3-EMB2-02, the staff requested that the applicant confirm that, for all the major ASME Code Section III, components already designed, all the pertinent design specifications and design reports have been updated to incorporate the effects of the newly modified seismic loadings. In a letter dated June 28, 2008, the applicant changed the design basis for the major ASME Code, Section III components to include the design spectra and seismic requirements envelope for the HR and associated with the expanded soil conditions (six soils case). These revised seismic design requirements for the six soils case are included in the design specifications for the major ASME Code components. The applicant stated the analyses supporting the as-designed design reports prepared or being completed for NRC review were in compliance with the design specifications and include these revised seismic requirements of the six soils case. Based on the above response and the confirmation obtained from the staff's onsite review, the staff found the applicant has adequately incorporated the latest revised seismic input motions for the component design. RAI-SRP3.9.3-EMB2-02 is, therefore, closed.

In APP-GW-GLR-115, Revision 2, Section 6.2.2, Tables 6.2.2-2, 6.2.2-3, 6.2.2-5 provided the resultant forces of three sample components of the primary coolant loop. The analysis of these components were to evaluate the comparison of the loads from the HRHF input to those obtained from the time history associated with the CSDRS input. For the three sample components, the applicant indicated the resultant forces due to CSDRS excitation are higher than the resultant forces caused by the HRHF excitation. Therefore, the HRHF loads will not govern the component design, but the CSDRS loads will. The staff found the loads of HRHF excitation and seismic loads to components were adequately incorporated in Revision 2 of the APP-GW-GLR-115 report and are acceptable.

The staff's review of the applicant's evaluation on the effects of high frequency seismic input on the AP1000 mechanical component design is provided in Section 3.10 of this report.

3.9.3.3 Conclusions

Based on the information provided in the applicant's responses to the RAIs, the staff finds that the application meets the guidance of RG 1.206, NUREG-0800 Section 3.9.3 and the regulations for the design of mechanical components, and is acceptable. Piping-related issues are discussed in Section 3.12 of this report.

3.9.4 Control Rod Drive Systems

In Revision 17 to the AP1000 DCD, the applicant proposed changes to the hydrostatic test pressure for the CRDM housing as well as other materials related to changes to the CRDM. This resulted in changes to the DCD in Sections 3.5.1.2.1.1, 3.9.4.1.1, 3.9.4.3, and 4.1.1. In a letter dated November 15, 2006, the applicant submitted TR-30, "AP1000 CRDM Design," APP-GW-GLN-013, Revision 0 to provide the technical justification for the proposed changes.

As stated in Revision 15 to the AP1000 DCD, Sections 3.5.1.2.1.1, 3.9.4.1.1, and 4.1.1, the specified hydrostatic test pressure for the CRDM is 150 percent of the system design pressure. In Section 3.9.4.1.1 of the DCD, the attachment of the latch assembly housing is described as a shrink-fit and partial penetration weld of the latch assembly housing. However, the latch assembly housing will be welded to the CRDM nozzle by a bi-metallic weld. Also, Section 3.5.1.2.1.1 describes the attachment of the latch assembly housing to a head adapter when in fact the latch assembly housing will be welded to an Alloy 690 nozzle. In Revision 17 to the DCD, the applicant proposed to hydrostatically test the CRDM at 125 percent of system design pressure and to describe the correct fabrication sequence and terminology for the assembly.

In addition, in Sections 3.9.4.1.2, "Control Rod Withdrawal"; 3.9.4.1.3, "Control Rod Insertion"; and 3.9.4.1.4, "Holding and Tripping of the Control Rods," the applicant proposed modifications to the sequence of events for withdrawal, insertion, holding and tripping of control rods.

The DCD was modified to clarify the classification of the CRDM latch assembly, the CRDM drive rod assembly, CRDM coil stack assembly, and the CRDM position indicator.

3.9.4.1 Evaluation

3.9.4.1.1 Hydrostatic Testing and Attachment of the Latch Assembly Housing

The applicant revised AP1000 DCD, Sections 3.5.1.2.1.1, 3.9.4.1.1, and 4.1.1 to reduce the hydrostatic test pressure for the CRDM from 150 percent to 125 percent of system design pressure. The stated reason for this change was the requirements of the ASME Code. Section III, Paragraph NB-6221 specifies that nuclear power plant components are tested at 125 percent of system design pressure. The staff finds the proposed change acceptable because the proposed hydrostatic test pressure of 125 percent of system design pressure meets the requirements of ASME Code, Section III, which the NRC had incorporated by reference in 10 CFR 50.55a.

AP1000 DCD, Revision 15, Section 3.9.4.1.1, states the attachment of the latch assembly housing to the vessel head is accomplished by a shrink-fit and partial penetration weld. The applicant determined the latch housing will be welded to the Alloy 690 nozzle with a bi-metallic weld and the nozzle will be attached to the reactor vessel head by a shrink-fit and partial penetration weld. In Revision 19 to the DCD, the applicant revised Sections 3.5.1.2.1.1, 3.9.4.1.1, and 3.9.4.3 to describe the correct fabrication sequence and correct terminology for these components. The staff finds the proposed changes are an editorial change to the AP1000 DCD and as such do not affect the design basis of the component. Furthermore, the proposed changes describe the correct fabrication sequence, uses the correct terminology and, therefore, are acceptable.

The staff reviewed the proposed changes as they relate to Revision 17 to the AP1000 DCD. The proposed changes, as identified in TR-30, have been adequately incorporated into Revision 19 to the DCD. Accordingly, these changes are generic and are expected to be used by all COL applications referencing the AP1000 certified design.

3.9.4.1.2 Control Rod Sequence of Events

In Sections 3.9.4.1.2, “Control Rod Withdrawal,” 3.9.4.1.3, “Control Rod Insertion,” and 3.9.4.1.4, “Holding and Tripping of the Control Rods,” the applicant proposed to modify the control rod withdrawal and insertion sequence order. Specifically, during control rod withdrawal the moveable gripper coil B is in the de-energized (“OFF”) state instead of the energized (“ON”) state. Furthermore, insertion of control rods initiates with the moveable gripper coil B in the de-energized (“OFF”) state instead of the lift coil C in the energized (“ON”) state.

The applicant proposed to change the DCD in Section 3.9.4.1.4 “Holding and Tripping of the Control Rods” to be in accord with the proposed change in Section 3.9.4.1.1 “Control Rod Drive Mechanism (CRDM).” The proposed change reiterates that in the holding mode both the stationary gripper coil A and the moveable gripper coil B are energized. Additionally the applicant elaborates the drive rod assembly is held in position by three latches on the stationary gripper and three latches on the moveable gripper. As a result of the proposed modification, the applicant clarifies a reactor trip occurs when power to the stationary as well as to the moveable gripper coils is cut off.

The staff finds the proposed changes to the sequence of events for control rod withdrawal, control rod insertion, and holding and tripping the control rod do not adversely affect the ability of the AP1000 CRDM to perform its safety-related functions.

3.9.4.1.3 Seismic Qualification of CRDM

The staff became aware of discussions internationally concerning the classification and qualification of the CRDM latch assembly. Based on these discussions, the staff determined the seismic qualification of the CRDM standard design may not meet requirements. GDC 2 of Appendix A to 10 CFR Part 50 states that SSCs important to safety shall be designed to withstand the effects of natural phenomena such as earthquakes, combined with appropriate effects of normal and accident conditions, without loss of capability to perform their safety functions.

In RAI-SRP3.9.4-EMB1-01, the staff requested that the applicant provide a justification to explain why the latch mechanism and coil stack assembly do not need to be seismically qualified to comply with GDC 2, or to revise the seismic classifications of the CRDM components to ensure adequate seismic qualification for the safety functions of the control rod drive system. In RAI-SRP3.9.4-EMB1-02, the staff requested further clarification on design changes discussed internationally.

The applicant provided justification for the equipment classification for the latch assembly and coil stack assembly and why they do not need to be seismically qualified. The justification is based on: 1) the design finality of the AP1000 DC; 2) the precedent of operating plants; and 3) the function of the latch assembly and coil stack assembly in the AP1000 CRDM.

The staff finds the applicant's justification for not qualifying the latch assembly using the precedent of operating plants and any postulated failure of the latch assembly results in a dropped rod and a subsequent increase in negative reactivity (justifications 2 and 3 above) unacceptable. Operating plants were licensed using a lower RRS compared to new reactors. The RRS for new reactors is much higher. Jamming of the latch mechanism is a postulated failure which results in no dropped rod and subsequently no reactivity change. Further, in the response to RAI-SRP3.9.4-EMB1-02, the applicant indicated that although international approaches to safety classification and requirements for safety class equipment may differ from the NRC requirements, it expects the design, fabrication and quality assurance requirements for the CRDM latch assemblies will remain common with the requirements for latch assemblies manufactured for U.S. applications.

In its response, the applicant referred to discussion in Chapter 15. There are only three postulated events that assume credit for reactivity control systems, other than a reactor trip to render the plant subcritical. These events are the steam-line break, feedwater-line break, and small break loss of coolant accident. The reactivity control systems in these accidents are the reactor trip system and the PXS. The probability of a common mode failure impairing the ability of the reactor trip system to perform its safety-related function is extremely low. However, analyses performed to demonstrate compliance with the requirements of 10 CFR 50.62, "Requirements for reduction of risk from anticipated transients without scram (ATWS) events for light-water-cooled nuclear power plants," demonstrate safety criteria would not be exceeded even if the control rod drive system were rendered incapable of functioning during anticipated transients for which its function would normally be expected. The evaluation demonstrates borated water from the CMT shuts down the reactor with no rods required, and the passive residual heat removal system provides sufficient core heat removal. Due to these additional safety measures, the applicant concluded the latch assembly and all other active mechanical components of the CRDM are not required to be classified as safety-related.

Based on finality, the low probability of common mode failure, and the argument that existing additional safety measures limit the safety consequence, the applicant has provided adequate justification to maintain the current classifications for the latch mechanism and coil stack assembly. Additionally, the applicant does not expect any changes to the design, fabrication and quality assurance requirements for the CRDM latch assemblies. The staff finds the responses to RAI-SRP3.9.4-EMB1-01 and RAI-SRP3.9.4-EMB1-02 acceptable and RAI-SRP-3.9.4-EMB1-02 is closed.

As a result of RAI-SRP3.9.4-EMB1-01, the applicant proposed modifications to DCD Tier 2 Table 3.2-3 to clarify the classification of the CRDM latch assembly, the CRDM drive rod assembly, CRDM coil stack assembly, and the CRDM position indicator. Additionally, DCD Tier 2, Section SR 3.1.4.3 (of the Chapter 16 TS) will be modified to include drop tests after each earthquake requiring shutdown.

The staff finds these proposed revisions acceptable. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

3.9.4.2 Conclusion

The staff further concludes the applicant's proposed changes do not adversely affect the ability of the AP1000 CRDM to perform its safety-related functions. On the basis that the AP1000 control rod drive system design continues to meet all applicable acceptance criteria and the changes are properly documented in the updated AP1000 DCD, the staff finds the changes to the CRDM design description provided in AP1000 DCD are acceptable.

3.9.5 Reactor Pressure Vessel Internals

In Revision 16 of the AP1000 DCD, the applicant added two new components (neutron panels to Section 3.9.5.1.1, and a flow skirt to Section 3.9.5.1.4) to the design of the reactor vessel internal structure. The subsequent Revision 17 of DCD Section 3.9.5 included minor changes to incorporate responses to the staff's RAIs for DCD Revision 16. DCD Revision 17 did not propose any additional new core support structure or reactor internals components requiring further technical evaluation.

3.9.5.1 Evaluation

The staff reviewed the proposed changes to the reactor vessel internals in the AP1000 DCD Revision 17 in accordance with the guidance in the NUREG-0800 Section 3.9.5, "Reactor Pressure Vessel Internals." The regulatory basis for Section 3.9.5 of the AP1000 DCD is documented in NUREG-1793. The following evaluation discusses the results of the staff's review.

3.9.5.1.1 Neutron Panels

In response to RAI-SRP3.9.5-EMB1-04 received in a letter dated June 20, 2008, the applicant stated the function of the neutron panels is to protect the reactor vessel from detrimental radiation effects by limiting the total exposure in the localized regions of the vessel wall in closest proximity to the core outer boundaries. The applicant also clarified the neutron panels are classified as internal structures, and, for conservatism, the neutron panels are analyzed in accordance with the requirements of ASME Code, Section III, Subsection NG. The neutron panels are fabricated from material complying with ASME III, NG-2000 and are designed and analyzed per ASME Code, Section III, NG-3000. The neutron panels are attached to the core barrel with threaded fasteners. The applicant also stated that the neutron panels have been sized to prevent excessive thermal loading on the bolts and to withstand flow, thermal and vibratory loading. In addition the bolts and preload of the bolts have been sized to accommodate radiation relaxation and radiation induced gamma heating such that the preload is maintained. These bolts are secured by locking devices. Oscillatory forces on the neutron panels have been calculated based on the turbulence in the annulus between the neutron panels and the reactor vessel based on the correlation with past scale model tests and CFD analysis. The analysis of the forces, as discussed was evaluated to assure the preload is maintained and design limits are achieved. The applicant also stated the AP1000 reactor vessel inside diameter has been increased by two inches over the core elevations where the neutron panels were added. This results in a net flow area increase of 4 percent in the downcomer relative to the flow area before the panels were added. Thus, the lower average downcomer velocity is expected to mitigate the potential for any adverse effects of flow-induced vibration caused by the added neutron panels.

3.9.5.1.2 Flow Skirt

The flow skirt is a perforated cylindrical ring structure attached to the reactor vessel bottom head at an elevation just below the LCSP. The flow skirt provides a more uniform distribution of inlet flow from the reactor vessel downcomer annulus to the core inlet nozzles in the LCSP. Although the flow skirt is welded to the reactor vessel, since the structure is located entirely within the pressure boundary, it is treated in the DCD as a reactor vessel internal structure. In response to RAI-SRP3.9.5-EMB1-01 received in a letter dated June 20, 2008, the applicant clarified although classified as an internal structure (as opposed to a core support structure), for conservatism the flow skirt is analyzed in accordance with the requirements of ASME Code, Section III, Subsection NG. The ASME Code jurisdictional boundary requires the attachment weld between the flow skirt and the reactor vessel flow skirt support lug to be designed and analyzed to ASME Code, Section III, Subsection NB-3200. All other design details of the flow skirt conform to ASME Code, Section III, Subsection NG-3000 requirements. The applicant also stated the flow skirt design includes flow-induced vibratory loading considerations including downcomer flow turbulence, random turbulence within the reactor vessel lower head, and vortex shedding through the flow skirt perforations. The flow skirt design specification requires the structural design qualification calculations for the flow skirt meet the requirements of ASME Code, Section III, Subsection NG-3000.

In response to RAI-SRP3.9.5-EMB1-02, dated June 20, 2008, the applicant stated the primary function of the flow skirt is to assure the distribution of flow entering the core is within prescribed limits for fuel assembly inlet flow mismatch. A CFD analysis of a reactor vessel/internals model, which included the inlet nozzle, downcomer, lower plenum (including secondary core support and vortex suppression structures), and LCSP, was performed by the applicant to determine the core inlet flow distribution. The CFD approach used in the analyses was used for analyses of similar operating reactor vessel internals geometry, and was benchmarked to scale model testing data with good agreement. The applicant performed analyses both with and without a flow skirt. Without the flow skirt the limits for uniformity of core inlet flow distribution were not met. In response to RAI-SRP3.9.5-EMB1-03, dated June 20, 2008, the applicant provided a figure of the flow skirt which clarified its form and function, and the staff considers this RAI closed.

3.9.5.1.3 Component Classification and Design Basis

The neutron panels are also classified as reactor internal structures (as opposed to core support structures), and, for conservatism, are designed according to the requirements of ASME III, Subsection NG-3000, even though ASME Code, Section III requires this approach only for internals components classified as core support structures. The flow skirt is also designed per the requirements of ASME Code, Section III, Subsection NG. As provided by ASME Code, Section III, Subsection NG-1122(b) and (c), these internal structure components must be constructed so as not to adversely affect the integrity of the core support structures, but the specific design requirements of ASME Code, Section III, Subsection NG are not required unless so stipulated by the designer. The applicant has conservatively chosen to use the requirements of Subsection NG-3000 for the design of both the flow skirt and the neutron panels.

The staff conducted a design audit at the applicant’s Energy Center in Monroeville, Pennsylvania during October 13-17, 2008. The audit included review of the ASME Code, Section III design documentation for the AP1000 RPV and the reactor internals and core support structure. The results of this audit are in an NRC letter dated December 30, 2008, Docket No. 52-006, Subject: Summary of the October 13-17, 2008, On-site Review of the AP1000 Component Design. The staff confirmed the neutron panels are part of the reactor internals design specification and design report, and the flow skirt has its separate design specification and analysis report. The audit verified the design bases for the neutron panels and flow skirt incorporate the requirements of ASME Code, Section III, Subsection NG-3000. The design analyses for the neutron panels show the results meet the design margins required by ASME Code, Section III, Subsection NG. Although the design report analysis for the flow skirt was not complete at the time of the audit, the flow skirt design specification clearly established the design requirements according to the provisions of ASME Code, Section III, Subsection NG. Therefore, the staff concluded the design methodology meets the review criteria of NUREG-0800 Section 3.9.5, and is acceptable.

In DCD Section 3.9.2.3, the applicant stated the results of the Trojan 1 reactor tests showed the lower internals vibrations are lower with neutron panels than with a circular thermal shield. Additionally, as stated above, a net flow area increase of 4 percent in the AP1000 downcomer relative to the flow area before the neutron panels were added results in a lower average flow velocity in the downcomer annulus. The lower average downcomer flow velocity will tend to mitigate the potential effects of any localized turbulence added by the neutron panels. On this basis, the staff concluded there is reasonable assurance the added neutron panels will not be adversely affected by FIV.

As indicated above, the applicant considered the flow-induced vibratory loading including downcomer flow turbulence and random turbulence for the flow skirt. The structural qualification requirements for the flow skirt and the neutron panels are consistent with the provisions of ASME Code, Section III, Subsection NG. The applicant's CFD analyses used for prediction of flow-induced vibratory loading coupled with pre-operational FIV testing (as discussed in Section 3.9.2.3 of NUREG-1793) will ensure there are no adverse effects of FIV and flow-excited acoustic resonances on the reactor vessel internal structures. On this basis, the staff finds the flow skirt and neutron panels will not cause adverse flow effects within the reactor vessel internal structures during normal operation or anticipated operational transients.

3.9.5.2 Conclusion

The applicant has met the regulatory requirements of GDC 1 and 10 CFR 50.55a by designing the neutron panels and the flow skirt to quality standards commensurate with the importance of the safety functions performed. The design criteria used for these two newly added reactor internals components are in compliance with the requirements of the 1998 Edition, including 1999 and 2000 Addenda, of ASME Code, Section III, Subsection NG-3000.

The applicant has met the regulatory requirements of GDC 2; GDC 4; and GDC 10, "Reactor Design," by designing these reactors internals components to withstand the effects of normal operation and postulated accident loadings with sufficient margin to maintain their structural integrity to assure they do not adversely affect the integrity of the safety-related reactor core support structures. The applicant has also designed these reactor internals components to assure acceptable fuel design and performance limits are met during conditions of normal operation and anticipated operational occurrences.

The staff concludes the design bases for the neutron panels and for the flow skirt meet the staff review criteria of NUREG-0800 Section 3.9.5, including the regulatory requirements of 10 CFR 50.55a, GDCs 1, 2, 4, and 10, and are, therefore, acceptable.

3.9.6 Testing of Pumps and Valves

In Revision 16 to the AP1000 DCD Tier 2, the applicant modified Section 3.9.6, "Inservice Testing of Pumps and Valves," including Table 3.9-16, "Valve Inservice Test Requirements." The applicant incorporated changes to AP1000 DCD Tier 2, Section 3.9.6, to support the description of the Inservice Testing (IST) Program required to be provided by a COL applicant.

3.9.6.1 Evaluation

In Section 3.9.6, "Testing of Pumps and Valves," of NUREG-1793, the NRC described its review of the description of the IST Program for the AP1000 design provided in AP1000 DCD Tier 2, Section 3.9.6. Other sections of the AP1000 DCD addressed the design of safety-related valves, and inservice inspection and testing of dynamic restraints. As discussed in NUREG-1793, the development of a complete plant-specific IST Program falls outside the scope of DC. At the DC stage, it is necessary to establish a baseline Code Edition and Addenda to ensure the IST requirements of the baseline ASME Code can be performed without exception, and that the design of the AP1000 systems and components provides access to permit the performance of testing pursuant to the NRC regulations specified in 10 CFR 50.55a.

AP1000 DCD Tier 2, Section 3.9.6 states inservice testing of ASME BPV Code, Section III, Class 1, 2 and 3 pumps and valves is performed in accordance with the ASME Code for Operation and Maintenance of Nuclear Power Plants (ASME OM Code) and applicable addenda, as required by 10 CFR 50.55a(f), except where specific relief has been granted by the NRC. The baseline ASME OM Code used to develop the IST plan for the AP1000 DC was the 1995 Edition and 1996 Addenda. AP1000 DCD Tier 2, Section 3.9.6 provides a general description of the IST Program to be developed for the AP1000 reactor to satisfy the requirements in 10 CFR 50.55a and the provisions of the ASME OM Code incorporated by reference in the NRC regulations. In NUREG-1793, the NRC found the IST Program description in the AP1000 DCD to be acceptable for the AP1000 DC, and that the AP1000 DCD had not taken exception to any ASME OM Code requirements established in the 1995 Edition and 1996 Addenda.

Since the issuance of NUREG-1793, the NRC has determined a COL applicant referencing the AP1000 design needs to fully describe the IST, motor-operated valve (MOV) testing and other operational programs as defined in Commission Paper SECY-05-0197, "Review of Operational Programs in a Combined License Application and Generic Emergency Planning Inspections, Tests, Analyses, and Acceptance Criteria." RG 1.206 provides guidance for a COL applicant in preparing and submitting its COL application in accordance with the NRC regulations. For example, Section C.IV.4 in RG 1.206 discusses the requirement in 10 CFR 52.79(a) for descriptions of operational programs need to be included in the FSAR in a COL application to support a reasonable assurance finding of acceptability. A COL applicant may rely on information in the applicable DC to help provide a full description of the operational programs for the COL application. At a public meeting on March 26 and 27, 2008, the applicant indicated the AP1000 DCD will address issues common to COL applicants implementing the AP1000 design. Therefore, the staff reviewed the revision to the AP1000 DCD related to the functional design, qualification, and IST programs for pumps, valves, and dynamic restraints, including DCD provisions intended to minimize the supplemental information necessary to be provided by a

COL applicant in fully describing the operational programs in support of its COL application for an AP1000 reactor. As described below, the staff concludes the revision to Section 3.9.6 of the AP1000 DCD continues to provide an acceptable description of the functional design, qualification, and IST programs for pumps, valves, and dynamic restraints sufficient for the AP1000 DC in accordance with the NRC regulations and the ASME Code requirements incorporated by reference in the NRC regulations, with provisions for the consideration of lessons learned from nuclear power plant operating experience.

A COL applicant may reference the provisions in Section 3.9.6 to the AP1000 DCD as part of its responsibility to fully describe the IST, MOV testing, and other operational programs in support of its COL application. AP1000 DCD Tier 2, Section 3.9.6 states Table 3.9-16, “Valve Inservice Test Requirements,” identifies the components subject to the preservice and IST programs, and the method and frequency of preservice and inservice testing. The staff will evaluate the full description of the IST Program provided by a COL applicant during review of the COL application consistent with RG 1.206 and NUREG-0800 Section 3.9.6, “Functional Design, Qualification, and Inservice Testing Programs for Pumps, Valves, and Dynamic Restraints.” NUREG-1482, “Guidelines for Inservice Testing at Nuclear Power Plants,” provides guidance for the preparation of IST Program documentation and tables. Following COL issuance, the NRC will evaluate development and implementation of the IST Program prior to and during plant operation.

AP1000 DCD Tier 2, Section 3.9.6.1, “Inservice Testing of Pumps,” specifies the AP1000 reactor design does not include pumps with safety functions with the exception of the coastdown of the RCPs. The proposed changes to the AP1000 DCD do not affect the use of pumps with respect to safety-related applications. Therefore, the IST Program described in the proposed revision to the AP1000 DCD does not include pumps. As determined in NUREG-1793, the NRC considers the IST Program scope for the AP1000 design with respect to pumps to be acceptable.

AP1000 DCD Tier 2 discusses the functional design and qualification of safety-related valves and dynamic restraints in several sections. For example, Section 3.9.3.2, “Pump and Valve Operability Assurance,” in AP1000 DCD Tier 2, Chapter 3, “Design of Structures, Components, Equipment and Systems,” refers to operational tests to verify the valve opens and closes prior to installation. AP1000 DCD Tier 2, Section 3.9.3.2.2 specifies cold hydro tests, HFTs, periodic inservice inspections, and periodic inservice operations to be performed in situ to verify the functional capability of the valves. Section 5.4.8, “Valves,” of Section 5.4, “Component and Subsystem Design,” in AP1000 DCD Tier 2, Chapter 5, “Reactor Coolant System and Connected Systems,” includes provisions regarding design and qualification, and preoperational testing of valves within the scope of Chapter 5, and refers to these activities for other safety-related valves. AP1000 DCD Tier 2, Section 5.4.8.3, “Design Evaluation,” states the requirements for qualification testing of power-operated active valves are based on ASME Standard QME-1-2007, “Qualification of Active Mechanical Equipment Used in Nuclear Power Plants,” as listed in AP1000 DCD Tier 2, Section 5.4.16, “References.” AP1000 DCD Tier 2, Section 5.4.9, “Reactor Coolant System Pressure Relief Devices,” includes provisions for design, testing, and inspection of relief devices in the RCS. AP1000 DCD Tier 2, Section 5.4.10, “Component Supports,” includes provisions for design, testing, and inspection of component supports in the RCS. During the public meeting on March 26 and 27, 2008, the applicant discussed its development of design and procurement specifications for safety-related valves and dynamic restraints for the AP1000 reactor design. In RAI-SRP3.9.6-CIB1-01, the staff requested that the applicant provide a schedule for the availability of the design and procurement specifications for safety-related valves and dynamic restraints to be used in the

AP1000 reactor for NRC review. In its response to this RAI, in a letter dated July 18, 2008, the applicant reported the design and procurement specifications would be made available for NRC review.

On October 14 and 15, 2008, the staff conducted an audit of design and procurement specifications for pumps, valves, and dynamic restraints to be used for the AP1000 reactor at the applicant's office in Monroeville, Pennsylvania. The staff found the applicant had included ASME Standard QME-1-2007 in its design and procurement specifications for AP1000 components. ASME QME-1-2007 incorporates lessons learned from valve testing and research programs performed by the nuclear industry and NRC Office of Nuclear Regulatory Research. In a memorandum dated November 6, 2008, the staff documented the results of the audit with the specific open items. The audit response was tracked as OI-SRP3.9.6-CIB1-01. In a letter dated January 26, 2010, the applicant provided its planned response to the audit follow-up items. First, the applicant stated a reference to ASME QME-1-2007 will be included in AP1000 DCD Tier 2, Section 3.9. Second, the applicant stated the basis for the assumptions for valve seat coefficients of friction for gate and globe valves is derived from the Joint Owners Group (JOG) Program on MOV periodic verification as a starting point for the initial actuator sizing.

The applicant indicated the final basis for the friction coefficient values will be derived in accordance with an approved methodology contained in ASME QME-1-2007. Third, the applicant stated the applicable valve design specification indicates active valves must be qualified in accordance with the ASME QME-1 standard, and the specification will be further clarified to indicate any existing testing used to demonstrate functional qualification must fully satisfy the provisions of ASME QME-1-2007. Fourth, the applicant stated the AP1000 DCD Tier 2, Figure 6.3-1, "Passive Core Cooling System Piping and Instrumentation Diagram," will be revised to include test connections to allow flow testing of Core Makeup Tank Discharge Check Valves PXS-V016A/B and V017A/B in both the forward and reverse directions. In September 2009, the NRC issued Revision 3 to RG 1.100, "Seismic Qualification of Electric and Active Mechanical Equipment and Functional Qualification of Active Mechanical Equipment for Nuclear Power Plants," which accepts the use of ASME QME-1- 2007, with certain staff positions, for the functional design and qualification of safety-related pumps, valves, and dynamic restraints.

On May 17, 2010, the staff conducted a follow-up audit at the applicant's office in Rockville, Maryland, to review the revisions to the design and procurement specifications prepared since the October 2008 audit. The staff conducted telephone conferences on May 19 and 28, and June 10, 2010, to support close-out of the audit. Based on the follow-up audit, the staff found the applicant had updated the design and procurement specifications to address NRC comments provided during the October 2008 audit. For example, the staff found the design and procurement specifications require the application of ASME Standard QME-1-2007 for the qualification of mechanical equipment to be used in an AP1000 reactor.

The design and procurement specifications also had been revised to incorporate additional comments provided by the staff during the October 2008 audit. In a memorandum dated June 15, 2010, the staff documented the results of the follow-up audit. Based on the results of the follow-up audit, OI-SRP3.9.6-CIB1-01 is closed. In Revision 19 to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

Revision 18 to the AP1000 DCD Tier 2 modified Section 6.3.2.2.8.1, "Manual Globe, Gate, and Check Valves," in Section 6.3, "Passive Core Cooling System," to remove the specification of check valves in the PXS as either piston type or swing type. In a letter dated May 21, 2010, under Change Number 4, the applicant indicated that core makeup tank discharge check valves PXS-PL-016A/B and PXS-PL-017A/B would be designed as in-line nozzle check valves rather than swing check valves as previously specified. The staff reviewed the design change for check valves PXS-PL-016A/B and PXS-PL-017A/B. The staff notes that AP1000 DCD Tier 2, Section 3.9.3.2.2, "Valve Operability," specifies that the qualification of functional capability of active valve assemblies will be performed in accordance with the requirements of ASME QME-1-2007. As noted above, the NRC staff has accepted the application of ASME QME-1-2007 in Revision 3 to RG 1.100 with certain conditions. Further, AP1000 DCD Tier 1, Table 2.2.3-1 lists check valves PXS-PL-016A/B and PXS-PL-017A/B as components to be addressed by the ITAAC specified in AP1000 DCD Tier 1, Table 2.2.3-4. Therefore, the NRC staff finds the design change for check valves PXS-PL-016A/B and PXS-PL-017A/B to be acceptable.

AP1000 DCD Tier 2, Section 3.9.2, "Dynamic Testing and Analysis," describes tests to confirm piping, components, restraints, and supports have been designed to withstand the dynamic effects of steady-state FIV and anticipated operational transient conditions. Section 14.2.9.1.7, "Expansion, Vibration and Dynamic Effects Testing," in AP1000 DCD Tier 2, Chapter 14, "Initial Test Program," states the purpose of the expansion, vibration and dynamic effects testing is to verify the safety-related, high energy piping and components are properly installed and supported such that, in addition to other factors, vibrations caused by steady-state or dynamic effects do not result in excessive stress or fatigue to safety-related plant systems. Nuclear power plant operating experience has revealed the potential for adverse flow effects from vibration caused by hydrodynamic loads and acoustic resonance on reactor coolant, steam, and feedwater systems. As part of the functional design and qualification for AP1000 components, the COL applicant will be responsible for addressing the provisions in the AP1000 DCD for consideration of potential adverse flow effects on safety related valves and dynamic restraints within the IST Program in the reactor coolant, steam, and feedwater systems from hydraulic loading and acoustic resonance during plant operation.

AP1000 DCD Tier 2, Section 3.9.6.2, "Inservice Testing of Valves," refers to the use of nonintrusive techniques to periodically assess degradation and performance of selected valves. In RAI-SRP3.9.6-CIB1-02, the staff requested that the applicant to clarify the use of nonintrusive techniques within the IST Program to support implementation of this section by a COL applicant referencing the AP1000 reactor design. In its response to this RAI, dated September 9, 2008, the applicant stated it will be the responsibility of the licensee to define the nonintrusive technique and methods for periodic assessment of check valve performance and degradation. Also in response to this RAI, the applicant modified Section 3.9.6.2 in Revision 17 to the AP1000 DCD Tier 2 to state inservice testing may incorporate the use of nonintrusive techniques to periodically assess degradation and performance of selected check valves. The staff finds that the applicant's response to this RAI and Revision 17 to the AP1000 DCD clarify the use of nonintrusive techniques referenced in the AP1000 DCD, and the COL licensee will define any nonintrusive techniques that will be implemented. Therefore, RAI-SRP3.9.6-CIB1-02 is closed.

The revision to AP1000 DCD Tier 2, Section 3.9.6.2 specifies testing of power-operated valves (POVs) used in the AP1000 reactor will utilize guidance from Generic Letter (GL) 96-05, "Periodic Verification of Design-Basis Capability of Safety-Related Motor-Operated Valves," and the JOG MOV Periodic Verification Program. The staff accepted the JOG Program on MOV periodic verification as an industry-wide response to GL 96-05 for valve age-related degradation in a safety evaluation dated September 25, 2006, and with a supplement dated September 18, 2008. In RAI-SRP3.9.6-CIB1-03, the staff requested that the applicant describe the incorporation of lessons learned from valve programs in planning the IST program for POVs other than MOVs to support implementation of this section by a COL applicant referencing the AP1000 reactor design. In its response to this RAI, in a letter dated September 9, 2008, the applicant stated AP1000 DCD Tier 2, Section 3.9.6.2 would be revised to address this RAI. As a result, Revision 17 to AP1000 DCD Tier 2, Section 3.9.6.2, states that guidance from applicable NRC generic letters and industry guidelines is reflected in the IST provisions in AP1000 DCD Tier 2, Table 3.9-16. Revision 17 to the AP1000 DCD also specifies lessons learned from GL 96-05 and the JOG MOV Periodic Verification Program are reflected in the IST Program and valve procurement testing requirements. Revision 17 to the AP1000 DCD indicates the IST Program requires periodic updating that takes into account changes to the diagnostic methods and test equipment, emergent industry issues, and equipment alignment. The staff finds the applicant response to RAI-SRP3.9.6-CIB1-03 and the provisions specified in Revision 17 to the AP1000 DCD provide an acceptable clarification as part of the AP1000 Design Certification that the lessons learned from valve operating experience and testing programs will be included in the IST and procurement programs for AP1000 nuclear power plants. RAISRP3.9.6-CIB1-03 is closed.

AP1000 DCD Tier 2, Section 3.9.6.2 states the operability test for safety-related POVs with an active function may be either a static or a dynamic (flow and differential pressure) test. In RAI-SRP3.9.6-CIB1-04, the staff requested that the applicant clarify the use of static tests for operability determinations of POVs to support implementation of this subsection by a COL applicant referencing the AP1000 reactor design. In its response to this RAI, in a letter dated September 9, 2008, the applicant stated AP1000 DCD Tier 2, Section 3.9.6.2 would be revised to address this RAI. As a result, Revision 17 to the AP1000 DCD Tier 2, Section 3.9.6.2 references Section 3.9.6.2.2 for the use of static or dynamic testing for safety-related POVs. The staff considers this clarification of Section 3.9.6.2 to be sufficient to close this RAI, but the use of static or dynamic testing for safety-related POVs will be addressed as part of RAI-SRP3.9.6-CIB1-08 discussed later in this safety evaluation. RAI-SRP3.9.6-CIB1-04 is closed.

The revision to AP1000 DCD Tier 2, Section 3.9.6.2.2 states the frequency for a position indication test will be once every 2 years unless otherwise justified. In RAI-SRP3.9.6-CIB1-07, the staff requested that the applicant clarify the need for a COL applicant to request relief from or an alternative to the ASME OM Code testing requirement with respect to position indication if the Code provisions are not satisfied. In its response to this RAI in a letter dated July 14, 2008, the applicant noted that AP1000 valves that require position indication testing, as documented in AP1000 DCD Tier 2, Table 3.9-16, are identified as having a 2 year frequency. The applicant indicated no relief is requested for position indication testing. The staff considers the position indication testing frequency in the AP1000 DCD to be consistent with the ASME OM Code. The COL applicant will need to request relief from, or an alternative to, the ASME OM Code provisions if the position indication testing frequency will not be satisfied. RAI-SRP3.9.6-CIB1-07 is resolved.

AP1000 DCD Tier 2, Section 3.9.6.2.2 discusses POV testing in a subsection titled "Power-Operated Valve Operability Tests." The revision to the AP1000 DCD specifies operability testing as required by 10 CFR 50.55a(b)(3)(ii) is performed on MOVs that are included in the ASME OM Code IST Program to demonstrate the MOVs are capable of performing their design-basis safety functions. In RAI-SRP3.9.6-CIB1-08, the staff requested that the applicant clarify the discussion of POV operability testing in the AP1000 DCD to support implementation of the DCD provisions by a COL applicant referencing the AP1000 reactor design. In response to this RAI, in a letter dated September 9, 2008, the applicant described planned changes to AP1000 DCD Tier 2, Section 3.9.6.2.2 to address this RAI. The staff determined RAI-SRP3.9.6-CIB1-08 needed to remain open until several aspects of the planned AP1000 DCD changes were clarified as discussed below for OI-SER3.9.6-CIB1-02, OI-SER3.9.6-CIB1-03, OI-SER3.9.6-CIB1-04, and OI-SER3.9.6-CIB1-05.

In OI-SRP3.9.6-CIB1-02, the staff tracked the need for the reference to static testing of valves in the AP1000 DCD to be consistent with the JOG MOV Periodic Verification Program, which might require dynamic testing based on the results of the evaluation of the MOV margin. In letters dated January 26, February 18, and March 5, 2010, the applicant provided planned changes to the AP1000 DCD Tier 2, Section 3.9.6 to specify POV testing will be consistent with the JOG MOV Periodic Verification Program, and removed the reference to static-only testing. The applicant also removed the discussion of testing of POVs outside the scope of the JOG MOV Periodic Verification Program because safety-related MOVs to be used at AP1000 plants will be within the scope of the JOG MOV Periodic Verification Program. The staff considers these planned DCD changes will resolve this portion of RAI-SRP3.9.6-CIB1-08. Therefore, OI-SRP3.9.6-CIB1-02 is closed. In Revision 19 to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

In OI-SRP3.9.6-CIB1-03, the staff tracked the need for the AP1000 DCD to specify the edition of the ASME Standard QME-1 referenced in Section 3.9 because the staff has not accepted ASME Standard QME-1 editions issued prior to 2007 as an acceptable functional qualification approach for valves. In letters dated January 26 and February 18, 2010, the applicant indicated AP1000 DCD Tier 2, Section 3.9 would be revised to reference ASME QME-1-2007. The staff considers this planned change to the AP1000 DCD will resolve this portion of RAI-SRP3.9.6-CIB1-08. In Revision 19 to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

In OI-SRP3.9.6-CIB1-04, the staff tracked the need for the planned application of ASME OM Code Case OMN-1, “Alternative Rules for Preservice and Inservice Testing of Certain Motor-Operated Valve Assemblies in Light-Water Reactor Power Plants,” within the AP1000 IST Program to be consistent with the edition of Code Case OMN-1 accepted in RG 1.192, “Operation and Maintenance Code Case Acceptability, ASME OM Code,” or to indicate the need for the submission of a request to implement an alternative to the ASME OM Code. In letters dated January 26, February 18, and March 5, 2010, the applicant provided a planned revision to AP1000 DCD Tier 2, Section 3.9.6 that will specify use of ASME OM Code cases must be consistent with RG 1.192. The staff considers this planned revision to the AP1000 DCD to be acceptable. A COL applicant or licensee planning to use an ASME OM Code case not accepted in RG 1.192 will need to submit a request to implement an alternative to ASME OM Code as required by 10 CFR 50.55a. The staff considers this planned change to the AP1000 DCD will resolve this portion of RAI-SRP3.9.6-CIB1-08. Therefore, OISRP3.9.6-CIB1-04 is closed. In Revision 19 to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

In OI-SRP3.9.6-CIB1-05, the staff tracked the need for the TS and TS Bases to be revised to be consistent with the ASME OM Code, such as in paragraph d of TS Section 5.5.3, and in References 4 and 5 to TS Bases for Surveillance Requirement 3.7.1.1. In its letter dated January 26, 2010, the applicant provided a planned revision to the AP1000 DCD TS and TS Bases to be consistent with the ASME OM Code. The staff considers these planned changes to the AP1000 DCD will resolve this portion of RAI-SRP3.9.6-CIB1-08. Therefore, OI-SRP3.9.6-CIB1-05 is closed. In Revision 19 to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

AP1000 DCD Tier 2, Section 3.9.6.2.2 discusses check valve testing in a subsection titled "Check Valve Exercise Tests." The revision to the AP1000 DCD Tier 2 indicates check valves must be exercised in the open and closed directions. In RAI-SRP3.9.6-CIB1-09, the staff requested that the applicant clarify the discussion of the AP1000 IST Program to support implementation of the AP1000 DCD provisions for check valves by a COL applicant referencing the AP1000 reactor design. In its response to this RAI, in a letter dated September 9, 2008, the applicant specified the acceptance criteria for assessing individual valve performance will be based on full open (full disk lift or achieving design accident flow rates) and valve closure verification using differential pressure/backflow tests. The applicant stated it is anticipated that Appendix II, "Check Valve Condition Monitoring Program," of the ASME OM Code will be implemented after sufficient operational data are obtained for the AP1000 check valves. The staff considered the RAI response to be acceptable, but the AP1000 DCD needed to include the specified acceptance criteria for check valve testing. The staff tracked this item as OI-3.9.6-CIB1-06. In letters dated January 26 and March 5, 2010, the applicant provided planned changes to AP1000 DCD Tier 2, Section 3.9.6 and Table 3.9-16 to include the check valve test acceptance criteria and to identify those check valves that will need to have a mechanical exerciser installed in lieu of flow testing. The staff considers that these planned changes to the AP1000 DCD will resolve RAI-SRP3.9.6-CIB1-09. Therefore, OISRP3.9.6-CIB1-06 is closed. In Revision 19 to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

The section titled "Pressure/Vacuum Relief Devices," in AP1000 DCD, Tier 2, Section 3.9.6.2.2 addresses the IST Program for pressure and vacuum relief devices. In RAI-SRP3.9.6-CIB1-10, the staff requested that the applicant provide additional information in specific areas regarding the IST Program for safety and relief valves. In response to this RAI, in a letter dated September 9, 2008, the applicant stated RCS pressure relief devices are discussed in AP1000 DCD Tier 2, Section 5.4.9. Pressure relief devices for other ASME Code systems are described with the applicable system in the AP1000 DCD. All safety and relief valves included in the IST Program will be tested to the rules of Appendix I, "Inservice Testing of Pressure Relief Devices in Light-Water Reactor Nuclear Power Plants," of the ASME OM Code. ASME Code Class 1, 2, and 3 pressure relief valves are identified in AP1000 DCD Tier 2, Table 3.9-16. The staff considers this clarification of the applicable provisions for safety and relief valves to be consistent with the ASME OM Code. RAI-SRP3.9.6-CIB1-10 is resolved.

AP1000 DCD Tier 2, Table 3.9-16 lists the valves in the IST Program with their valve and actuator type, safety-related missions, safety functions, ASME Class and IST Category, and IST type and frequency. In RAI-SRP3.9.6-CIB1-11, the staff requested that the applicant update Note 31 of Table 3.9-16, which addresses operability testing of various POVs to reflect changes to the AP1000 DCD. In its response to this RAI, in a letter dated July 18, 2008, the applicant stated the MOV and air-operated valve (AOV) programs are expected to incorporate attributes for a successful POV periodic verification program as discussed in Regulatory Issue Summary (RIS) 2000-03, "Resolution of Generic Safety Issue 158: Performance of Safety-Related Power-Operated Valves under Design Basis Conditions." The applicant provided a planned revision to Note 31 of Table 3.9-16 stating the applicable valves are subject to operability testing per the NRC regulations in 10 CFR 50.55a. The staff considered Note 31 needed to be clarified to be consistent with the JOG MOV Periodic Verification Program, and to include the expectation indicated by the applicant in the RAI response that the MOV and AOV programs will incorporate attributes for a successful POV periodic verification program as discussed in RIS 2000-03. The staff tracked this item as Open Item OI-SRP3.9.6-CIB1-07. In its letter dated January 26, 2010, the applicant provided a planned revision to Note 31 in Table 3.9-16, which will specify valve test frequencies will be established in accordance with the results of the JOG MOV Periodic Verification Program. The planned Note 31 revision will also state the JOG approach will be applied to all actuator types and the attributes of the POV programs will include lessons learned as delineated in RIS 2000-03. The staff considers these planned changes to the AP1000 DCD will resolve RAI-SRP3.9.6-CIB1-11. Therefore, OI-SRP3.9.6-CIB1-07 is closed. In Revision 19 to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

The revision to the AP1000 DCD includes changes to several notes in Table 3.9-16. In RAI-SRP3.9.6-CIB1-12, the staff requested that the applicant discuss the basis for the changes specified to Table 3.9-16. In its response to this RAI, in a letter dated September 9, 2008, the applicant stated Note 2 addressing valve safety functions includes such cases where normal valve operator action moves the valve to the open or closed position by de-energizing the operator electrically, by venting air, or both, then the exercise test will satisfy the fail-safe test requirements and an additional test for fail-safe testing will not be performed. Note 20 indicates the MSIVs and main feedwater isolation valves (MFIVs) will not be exercised during power operation to avoid a potential plant transient and reactor trip consistent with the guidance in NUREG-1482. Note 33 applies to fuel transfer tube isolation manual valve FHS-PL-V001 that will be tested consistent with 10 CFR 50.55a(b)(3)(vi) at a 2 year interval. Note 38 applies to main control room emergency habitability system (VES) pressure regulating valves that are exempt from the ASME OM Code, but the applicant stated it would revise the note in Table 3.9-16 to clarify the testing for these valves. As a result, Revision 17 to the AP1000 DCD, Section 3.9.6 modifies Note 38 to state exercise stroke tests for the VES pressure regulating valves will consist of a pressure drop test across the valve using the downstream test connection to ensure adequate testing of the valves. The staff finds the applicant’s response to RAI-SRP3.9.6-CIB1-12, and Revision 17 to the AP1000 DCD, Section 3.9.6 adequately clarify the testing for the valves described in the applicable notes in Table 3.9-16 discussed in this RAI to be consistent with the ASME OM Code and the NRC regulations. RAI-SRP3.9.6-CIB1-12 is closed.

The revision to the AP1000 DCD Tier 2 modifies Section 3.9.6.2.2 in a section titled “Remote Valve Position Indication Inservice Tests” to state position indication testing requirements for passive valves are identified in Table 3.9-16. In RAI-SRP3.9.6-CIB1-13, the staff requested that the applicant clarify this modification. In its response to this RAI, in a letter dated July 24, 2008, the applicant stated passive valves with remote position indication will be locally observed to verify the remote position indication accurately reflects valve position. All valves requiring position indication verification will be exercised during the position indication test such that the open and closed positions can be verified. The frequency of this test will be once every 2 years. All passive valves with test requirements are included in AP1000 DCD Tier 2, Table 3.9-16. The staff considers the incorporation of passive valves with test requirements in Table 3.9-16 to be consistent with the requirements of the ASME OM Code, Subsection ISTC-3700, “Position Verification Testing.” RAI-SRP3.9.6-CIB1-13 is resolved.

Section 3.9.6.2.2 of the AP1000 DCD Tier 2 under Manual/Power-Operated Valve Tests states the IST requirements for measuring stroke time for valves in AP1000 reactor will be completed in conjunction with a valve exercise test, and the stroke time test is not identified as a separate test. In RAI-SRP3.9.6-CIB1-14, the staff requested that the applicant clarify the stroke time testing provisions in the AP1000 DCD. In its response to this RAI, in a letter dated July 24, 2008, the applicant stated each POV is stroke-time tested when the full stroke exercise test is performed. The stroke time open or closed will match the safety-related mission (i.e., transfer open or closed) as identified in AP1000 DCD Tier 2, Table 3.9-16. The staff considers the IST description for stroke-time testing specified in Table 3.9-16 to be consistent with the ASME OM Code. RAI-SRP3.9.6-CIB1-14 is resolved.

Section 3.9.6.2.2 of the AP1000 DCD Tier 2 under Manual/Power-Operated Valve Tests states safety-related valves that fail to the safety-related actuation position to perform the safety-related missions are subject to a valve exercise inservice test. In RAI-SRP3.9.6-CIB1-15, the staff requested that the applicant clarify the discussion of fail safe testing. In its response to this RAI, in a letter dated July 24, 2008, the applicant stated the exercise test will satisfy the fail safe test requirements in cases where normal valve operator action moves the valve to the open or closed position by de-energizing the operator electrically, by venting air, or both. The applicant indicated remote position indication is used as applicable to verify proper fail safe operation, provided the indication system for the valve is periodically verified in accordance with ASME OM Code, Subsection ISTC-3700. The valves listed in Table 3.9-16 with an Active to Failed Safety Function are designed for only one safety-related mission direction with the fail position being the transfer open or transfer close position. The staff considered the reference to ASME OM Code, Subsection ISTC-3700, needed to be clarified to confirm the exercise test frequency requirements specified in the ASME OM Code for these valves will be satisfied. This item was tracked as Open Item OI-SRP3.9.6-CIB1-08. In its letter dated January 26, 2010, the applicant noted the Position Indication Verification Test is separate and independent of the Fail Safe Test. The applicant provided a planned revision to AP1000 DCD Tier 2, Table 3.9-16 to indicate a separate Fail Safe test for the applicable valves with fail safe functions. The staff considered these planned changes to the AP1000 DCD would resolve RAI-SRP3.9.6-CIB1-15. Therefore, OI-SRP3.9.6-CIB1-08 is closed. In Revision 19 to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

The revision to Section 3.9.6.2.2 of the AP1000 DCD Tier 2 under Check Valve Exercise Tests states, if exercise testing during a refueling outage is not practical, then another method is applied, such as nonintrusive diagnostic techniques or valve disassembly and inspection. In RAI-SRP3.9.6-CIB1-16, the staff requested that the applicant clarify the revision to the AP1000 DCD for check valve exercise testing. In its response to this RAI, dated July 24, 2008, the applicant stated no check valves for which exercise tests are recommended have been identified, which cannot be full stroke exercised. As a result, neither nonintrusive techniques nor disassembly/inspection is required as part of the AP1000 certified design. If check valves are identified for which exercise tests are recommended but not practical due to operational issues or changes to the ASME OM Code, the applicant stated it will be the responsibility of the licensee to define the types of nonintrusive diagnostic techniques to be used. To clarify this provision, Revision 17 to AP1000 DCD Tier 2, Section 3.9.6.2.2, specifies the check valves included in the IST Program outlined in Table 3.9-16 do not require another means as an alternate to exercise testing based on the ASME OM Code used to develop the IST plan for the AP1000 Design Certification. The staff finds that the applicant’s response to RAI-SRP3.9.6-CIB1-16 and Revision 17 to the AP1000 DCD provide an acceptable clarification of the exercise testing for check valves. RAI-SRP3.9.6-CIB1-16 is closed.

Section 3.9.6.2.2 of the AP1000 DCD Tier 2 under Pressure/Vacuum Relief Devices states the frequency for this inservice test is every 5 years for ASME Class 1 and main steam safety valves, or every 10 years for ASME Classes 2 and 3 devices. The ASME OM Code also requires 20 percent of the valves from each valve group be tested within any 24 month interval for Class 1 and main steam safety valves, and within any 48 month interval for Class 2 and 3 devices. In RAI-SRP3.9.6-CIB1-18, the staff requested that the applicant discuss the requirement to test 20 percent of each valve group within the interval required by the ASME OM

Code. In response to this RAI, in a letter dated July 24, 2008, the applicant indicated that AP1000 DCD Tier 2, Table 3.9-16 includes the provision for 20 percent of the valves from each group to be tested. Further, Revision 17 to the AP1000 DCD Tier 2, Section 3.9.6.2.2, clarifies the provision that 20 percent for the valves from each group will be tested within any 24 month interval for Class 1 and main steam safety valves and within any 48 month interval for Class 2 and 3 devices. The staff finds the applicant's response to RAI-SRP3.9.6-CIB1-18 as incorporated into AP1000 DCD Revision 17 provides an acceptable clarification to ensure the IST activities are consistent with the ASME OM Code. RAI-SRP3.9.6-CIB1-18 is resolved.

The revision to the AP1000 DCD Tier 2 modifies Section 3.9.6.2.3 to state the sample disassembly examination program shall group check valves of similar design, application, and service condition, and shall require a periodic examination of one valve from each group. In RAI-SRP3.9.6-CIB1-19, the staff requested that the applicant clarify its plans for the disassembly examination program for check valves. In its response to this RAI, in a letter dated July 24, 2008, the applicant stated all check valves in the AP1000 IST Program outlined in AP1000 DCD Tier 2, Table 3.9-16 are capable of being full stroke exercise tested based on the ASME OM Code (1995 Edition and 1996 Addenda) used to develop the IST plan for the AP1000 Design Certification. The applicant indicated it will be the responsibility of the licensee to define requirements of a disassembly and inspection program if check valves are identified for which exercise tests are recommended, but are not practical due to operational issues or changes in the ASME OM Code. The provisions in the AP1000 DCD for check valve exercise tests are consistent with ASME OM Code and, therefore, are acceptable. RAI-SRP3.9.6-CIB1-19 is resolved.

The revision to AP1000 DCD Tier 2 modifies Table 3.9-16 to identify valve type, operator, class and category for valves in the AP1000 IST Program. In RAI-SRP3.9.6-CIB1-20, the staff requested that the applicant clarify several items in Table 3.9-16. In its response to this RAI, in a letter dated September 9, 2008, the applicant discussed each specific RAI item and planned changes to the AP1000 DCD. For example, the applicant provided a modification to Table 3.9-16 (incorporated in Revision 17 to the AP1000 DCD) that includes a provision for full stroke exercising during refueling outages for service air supply containment isolation valve CAS-PL-V205. The applicant stated that the chemical volume and control system (CVS) containment isolation valves CVS-PL-V045, CVS-PL-V047, CVS-PL-V090, CVS-PL-V091, CVSPL-V092, and CVS-PL-V094 will receive only a leakage test in accordance with 10 CFR Part 50, Appendix J, “Primary Reactor Containment Leakage Testing for Water-Cooled Power Reactors.” The applicant clarified that the air operator for RCS purification return line stop valve CVS-PL-V081 does not perform a safety function, and the valve will act as a simple check valve upon loss of power. The applicant provided a modification to Table 3.9-16 (incorporated in AP1000 DCD, Revision 17) that specifies full stroke exercise tests during refueling outages for demineralized water supply containment isolation check valve DWS-PL-V245 and fire water containment supply isolation check valve FPS-PL-V052.

The applicant provided a correction to Table 3.9-16 (incorporated in AP1000 DCD, Revision 17) to reflect the 2 year test frequency and IST Category C for ADS discharge header vacuum relief valve RCS-PL-V010A and V010B. The applicant clarified that the main control room emergency habitability system pressure regulating valves VES-PL-V002A and V002B are pressure regulating valves that are not part of the ASME OM Code IST Program, and provided a modification to Table 3.9-16 (incorporated in AP1000 DCD, Revision 17) to specify these valves are part of an augmented inspection program. The applicant stated Note 3 in Table 3.9-16 would be revised to remove the discussion of PRA for the ADS valves. The applicant stated the leak testing for valves CVS-PL-V001, V002, V080, V081, V082, V084, and V085 described in

Note 32 is beyond the ASME OM Code IST program, and is part of an augmented testing program. The applicant provided a modification to Table 3.9-16 (incorporated in AP1000 DCD, Revision 17) to correct the categorization of these CVS valves from Category A to Category B or C, which do not require OM Code leak testing.

The staff determined several aspects of this RAI response needed to be clarified and tracked this item as OI-SRP3.9.6-CIB1-09. The applicant addressed this open item in its letter dated January 26, 2010. First, the applicant stated CVS valves CVS-PL-V045, V047, V090, V091, V092, and V094 have a safety function to transfer closed for containment isolation and do not serve an RCS pressure boundary function. The applicant provided a planned revision to AP1000 DCD Tier 2, Table 3.9-16 to correct the function indication for these valves. Second, the applicant provided a planned revision to Note 3 in Table 3.9-16 to ensure consistency with RAI response. Third, the applicant clarified its response regarding the categorization of the CVS valves discussed in Note 32. The staff considers the clarifications and the planned changes to the AP1000 DCD will resolve RAI-SRP3.9.6-CIB1-20. Therefore, OI-SRP3.9.6-CIB1-09 is closed. In Revision 19 to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

Section 3.9.6.2.2 of the AP1000 DCD Tier 2 under Check Valve Low Differential Pressure Tests identifies low differential pressure testing as an inservice test is performed in addition to exercise inservice tests once each refueling cycle. In RAI-SRP3.9.6-CIB1-17, the staff requested that the applicant clarify the discussion of low differential pressure testing. In its response to this RAI, in a letter dated July 24, 2008, the applicant stated the low differential pressure testing is part of an augmented test activity similar to that established for the AP600 reactor design during staff review of that design certification. As a result, Revision 17 to AP1000 DCD Tier 2, Section 3.9.6.2.2, indicates the low differential pressure testing is not required by the ASME OM Code, but is part of an augmented inspection program. In its RAI response, the applicant indicated AP1000 DCD Tier 2, Table 3.9-16 will be revised to specify this test will be performed once every refueling cycle. The staff finds the applicant's response to RAI-SRP3.9.6-CIB1-17 adequately clarifies the AP1000 test activities to be consistent with the AP600 certified design. However, the planned changes to Table 3.9-16 for the applicable check valves did not appear to be included in Revision 17 to the AP1000 DCD. In Revision 19 to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

The revision to AP1000 DCD Tier 2 includes a new Section 3.9.3.4.4, "Inspection, Testing, Repair and/or Replacement of Snubbers," which specifies a program for inservice examination and testing of dynamic supports (snubbers) to be used in the AP1000 reactor will be prepared in accordance with the requirements of ASME OM Code, Subsection ISTD. AP1000 DCD Tier 2, Section 3.9.3.4.4 indicates details of the snubber inservice examination and testing program, including test schedules and frequencies, will be reported in the inservice inspection and testing plan included in the IST Program required by AP1000 DCD Tier 2, Section 3.9.8.3, "Snubber Operability Testing." AP1000 DCD Tier 2, Section 3.9.8.3 states a COL applicant referencing the AP1000 design will develop a program to verify operability of essential snubbers. The staff finds the provision in the AP1000 DCD for application of the ASME OM Code, Subsection ISTD, in the examination and testing of dynamic supports to be acceptable for the AP1000 Design Certification. The COL applicant will be responsible for satisfying the COL Information Item in AP1000 DCD Tier 2, Section 3.9.8.3.

The staff reviewed the revisions to the AP1000 DCD with respect to the functional design, qualification, and IST programs for pumps, valves, and dynamic restraints to be used at an

AP1000 nuclear power plant. The staff finds the changes are generic and are expected to be applicable to all COL applications referencing the AP1000 certified design.

3.9.6.2 Conclusion

The staff concludes the revision to the AP1000 DCD continues to support the design aspects for the functional design, qualification, and IST programs for safety-related valves and dynamic restraints in the applicable NRC regulations for the AP1000 DC. The revision to the AP1000 certified design provides sufficient information to satisfy 10 CFR Part 50 and 10 CFR Part 52 for the design aspects of the functional design, qualification, and IST programs for safety-related valves and dynamic restraints to be used in the AP1000 reactor. The staff will review the operational program aspects regarding the functional design, qualification, and IST programs for safety-related valves and dynamic restraints in a COL application referencing the AP1000 certified design as part of the COL application review process.

3.9.7 Integrated Head Package

The integrated head package (IHP) provides the ability to rapidly disconnect cables including the CRDM power cables, digital rod position indication cables, and in-core instrument cables from the IHP components. The rapid disconnection of these cables provides the ability to move the IHP components as an assembly to permit the expedited lifting and removal of the reactor vessel head. In addition, the IHP provides support for the vessel head stud tensioner/detensioner during refueling. The IHP includes a lifting rig, seismic restraints for CRDMs, and support for the following IHP components: reactor head vent piping, cable bridge, power cables, cables and guide tubes for in-core instrumentation, cable supports, and shroud assembly.

By letter dated November 14, 2006, the applicant submitted TR-61, “AP1000 Integrated Head Package,” APP-GW-GLN-014. The purpose of TR-61 was to address changes in the IHP described in Revision 15 to the AP1000 DCD as reviewed by the staff in NUREG-1793.

Following a preliminary review, the staff requested additional information in a March 29, 2007 letter, via questions RAI-TR61-01 through RAI-TR61-04. By letter dated April 13, 2007, the applicant provided responses to the staff’s questions. It should be noted much of the staff’s focus in the review of TR-61 was associated with the change in the IHP design related to the removal of the CRDM cooling fans from the IHP to a separate structure and the resulting questions related to the adequacy of CRDM cooling.

The applicant subsequently submitted Revisions 16 and 17 to the DCD. In Section 3.9.7 of Revision 17 to the DCD, the applicant, again, proposes to attach the CRDM cooling fans to the IHP. In addition, the following changes are proposed:

- In the first paragraph of Section 3.9.7, the cable bridge is included in the IHP description but the guide tubes for in-core instrumentation are excluded.

- In Section 3.9.7.1, the shroud and CRDM seismic support plate, are no longer in the list of components which are required to provide seismic restraint for the CRDM and the valves and piping of the reactor head vent. The CRDM and the valves and piping of the reactor head vent still require seismic restraints. These components are AP1000 equipment Class C, seismic Category I and are designed in accordance with the ASME Code, Section III, Subsection NF requirements.

- The instrumentation guide tubes and the instrumentation support structure are excluded from those components function as part of the lifting rig and are required to be capable of lifting and carrying the total assembled load of the IHP.

- The components of the in-core instrumentation system (IIS) that interface with the IHP are the QuickLoc stalk assembly and the IIS cables and connectors. These have been excluded from the IHP description.

- The shroud assembly is required to provide radiation shielding of the CRDMs but the conduit for in-core instrumentation when the instrumentation is withdrawn into the conduit is not required to provide shielding. The radiation level at the exterior surface of the shroud during refueling with the in-core instrument thimble withdrawn is excluded from the discussion in the radiation levels discussed in Section 12.2.

- The description of the IHP in Section 3.9.7.2 excludes the In-core Instrumentation support structure.

- The description of the lifting system is modified. The lifting system attaches to the CRDM seismic support structure. The lift lugs transfer the head load during a head lift from the head attachment lugs; however, the attachment is no longer through the CRDM seismic support structure to the lift rig.

- In the description of the mechanism seismic support structure has been modified to reflect minor, proposed changes in the support structure.

- The description of the in-core instrumentation-support structure (IISS) has been changed to discuss the in-core instrumentation. The following statements related to the support structure have been deleted:

  – The in-core instrumentation support structure is used during refueling operations. This support structure is used for withdrawing the in-core instrumentation thimble assemblies into the integrated head package. It protects and supports the thimble assemblies when they are in the fully withdrawn position.

  – Also, the in-core instrumentation support structure includes a platform which provides access to the in-core instrumentation during maintenance and refueling and to attach the lifting system to the crane hook.

3.9.7.1 Evaluation

The staff reviewed the proposed changes related to Section 3.9.7 of AP1000 DCD Revision 17, including TR-61. The AP1000 IHP continues to meet all applicable acceptance criteria and requirements, as discussed below. The components of the IHP, which provide seismic support including the CRDM seismic support and the shroud, are designed using the ASME Code, Section III, Subsection NF which satisfies the limit on deflection of the top of the CRDM rod travel housing. The components of the IHP included in the load path of the lifting rig are designed to satisfy the requirements for lifting of heavy loads in NUREG-0612, “Control of Heavy Loads at Nuclear Power Plants,” July 1980. The criteria of ANSI N14.6-1978, “Standard for Special Lifting Devices for Shipping Containers Weighing 10,000 Pounds or More for Nuclear Materials," are used to evaluate the loads and stresses during a lift.

Those cables and connectors for the IIS are required to meet Class 1E requirements are evaluated for environmental conditions including normal operation and postulated accident conditions.

Components required to provide seismic restraint for the CRDMs and the valves and piping of the reactor head vent are AP1000 equipment Class C, seismic Category I and are designed in accordance with the ASME Code, Section III, Subsection NF requirements.

The loads and loading combinations due to seismic loads for these components are developed using the appropriate seismic spectra.

The structural design of the IHP is based on a design temperature consistent with the heat loads from the vessel head, the CRDMs, and electrical power cables. The design also considers changes in temperature resulting from plant design transients and loss of power to the cooling fans.

Components required to provide cooling to the CRDMs are non-safety-related AP1000 equipment Class E. Section 4.6 of the DCD Revision 17, offers a discussion of the effect of failure of cooling of the CRDMs.

Those components that function as part of the lifting rig are required to be capable of lifting and carrying the total assembled load of the IHP which includes the vessel head, CRDMs, CRDM seismic supports, shroud, cooling ducts, and insulation. The lifting rig components are required to meet the guidance for special lifting rigs, in NUREG-0612. The lifting rig components are non-safety-related, AP1000 equipment Class E.

The electrical cables and connectors, within the IHP, for the IIS are AP1000 equipment Class C, Class 1E. The other cables within the IHP, including power cables and cables for the digital rod position indicator system, are not Class 1E. The cable support provides seismic support and maintains separation for instrumentation and power cables.

3.9.7.2 Conclusion

The components of the IHP, which provide seismic support including the CRDM seismic support and the shroud, are designed using the ASME Code, Section III, Subsection NF. The IHP satisfies the limit on deflection of the top of the CRDM rod travel housing. The components of the IHP included in the load path of the lifting rig are designed to satisfy the requirements for lifting of heavy loads in NUREG-0612. The criteria of ANSI N14.6 are used to evaluate the loads and stresses during lifting.

Those cables and connectors for the IIS are required to meet Class 1E requirements are evaluated for environmental conditions including normal operation and postulated accident conditions. Accordingly, the staff concludes the AP1000 IHP design meets the requirements of 10 CFR Part 50, Appendix A, GDC 1; GDC 2; and GDC 30, "Quality of Reactor Coolant Pressure Boundary"; and 10 CFR Part 50, Appendix S; therefore, the proposed changes to Section 3.9.7 of the AP1000 DCD are acceptable.

3.10 Seismic and Dynamic Qualification of Seismic Category I Mechanical and Electrical Equipment

In Revision 17 of the DCD, Section 3.10, the applicant proposed some editorial and technical changes and clarifications. A summary of the major changes is described below.

One of the significant changes from DCD Revision 15 to DCD Revision 17 is that the applicant decided not to use Experience-Based Qualification Method for seismic qualification of AP1000 mechanical and electrical equipment. Therefore, all statements related to the experience-based qualification have been deleted or revised. For example, Section 3.10.6 and Item E.7 of Attachment E of Appendix D have been deleted.

In the introductory statements for Section 3.10 of AP1000 DCD Revision 17, a new paragraph was added to address the CSDRS exceedance in the high frequency spectrum region at some CEUS rock sites. A new Reference 3 was added to DCD Revision 17 and this new Reference 3 (Not "Reference 5" as indicated in the new paragraph) is related to the "AP1000 Design Control Document High Frequency Seismic Tier 1 Changes." The Tier 2 material related to the high frequency seismic input is provided in AP1000 DCD Revision 17, Appendix 3I.

Appendix 3I of AP1000 DCD addresses the effect of HRHF seismic input. The AP1000 HRHF evaluation study is reported in TR-115, which is referenced in AP1000 DCD Revision 17. In the course of reviewing TR-115, staff generated a list of RAIs, which is applicable to DCD Appendix 3I of AP1000 DCD Revisions 16 and 17.

3.10.1 Evaluation

The staff reviewed the major changes to Section 3.10 of the AP1000 DCD Revision 17 in accordance with the guidance in: (1) NUREG-0800 Section 3.10, "Seismic and Dynamic Qualification of Mechanical Electrical Equipment"; (2) DC/COL-ISG-1, "Interim Staff Guidance on Seismic Issues Associated with High Frequency Ground Motion in Design Certification and Combined License Applications," May 19, 2008; and (3) SECY-93-087, including SRM93-087 issued on July 21, 1993. The regulatory basis for Section 3.10 of the AP1000 DCD is documented in NUREG-1793.

The changes in Appendix 3I related to Section 3.10 are mainly provided in Section 3I.6.4. The changes involve editorial clarifications and technical revisions. The results of the staff's review of the list of RAI responses are described below.

In RAI-SRP3.10-EMB-01, the staff requested that the applicant describe the screening process for potential high frequency sensitive mechanical and electrical equipment and components, and to provide a list of equipment including the justification for screening in or screening out. The detailed response to this RAI was initially submitted in a letter dated May 28, 2008, and later, a revised response was provided dated August 21, 2008. The applicant stated the AP1000 screening process for potential high frequency sensitive equipment is consistent with the NRC requirements in Section 4.0, "Identification and Evaluation of HF Sensitive Mechanical and Electrical Equipment/Components," of DC/COL-ISG-1, and guidelines identified in the EPRI White Paper, "Considerations for NPP Equipment and Structures Subjected to Response Levels Caused by High Frequency Ground Motions," transmitted to the NRC on March 16, 2007.

The goal of the AP1000 HRHF screening program is to identify those safety-related equipment and components are potentially HRHF-sensitive and show them to be acceptable for their specific application (screened-out). The AP1000 HRHF screening program is a two-step process; the first step is a HRHF susceptibility review to identify potential high frequency sensitive safety-related equipment. The second step is the screened-out equipment process to demonstrate its acceptability for the HRHF seismic excitation. Evaluation of screened-in equipment as defined in DC/COL-ISG-1 is not performed because all safety-related equipment is screened-in will be eliminated or shown to be acceptable through a design change process. Additional information is provided in Appendix 3I.6.4 of AP1000 DCD, Revision 17.

The staff reviewed the applicant's response related to the criteria and procedure for the AP1000 HRHF screening program as described above, and finds the response to be acceptable. The staff considers RAI-SRP3.10-EMB-01 to be closed.

In RAI-SRP3.10-EMB-02, the staff requested that the applicant explain, with respect to TR-115 Section 6.4.5, "Screening Process," its justification for using 50 Hz as the cut-off natural frequency for the Group No. 1 rugged equipment in the screening process, and to explain whether the electrical/electronic equipment/devices with natural frequencies greater than 50 Hz are considered as rugged equipment. The staff also requested that the applicant provide justification for not requiring additional evaluation for high frequency seismic inputs for equipment.

In Section 6.4.5 of TR-115 for the Screening Process, the applicant concluded safety-related equipment may be screened and grouped as follows: Group No.1 – Rugged equipment with dominant natural frequencies above 50 Hz; Group No. 2 – Cabinets and other equipment which exhibit dominant natural frequencies below HRHF exceedance range; and Group No. 3 – safety-related equipment which exhibit dominant natural frequencies in HRHF exceedance range. For Group No. 1 and Group No. 2 equipment, no additional evaluation for high frequency seismic input is necessary. For Group No. 3 equipment, the equipment will be subjected to supplemental high frequency seismic evaluation to verify acceptability.

In response to RAI-SRP3.10-EMB-02, dated May 28, 2008, the applicant stated that for AP1000, the frequency range of interest in the screening process is 25 Hz to 50 Hz. This range coincides with the peak region of the HRHF ground motion. Since the AP1000 plant building structure's dominant natural frequencies are considerably lower than 50 Hz, the horizontal and vertical GMRS above 50 Hz will not be amplified significantly and their response will dissipate quickly as it travels through the building structure. The worst case seismic loading will occur when the fundamental frequencies of the potential HRHF-sensitive equipment coincide with the peak of the response spectra. In addition, the applicant noted from review of AP1000 HRHF ISRS generated from the HRHF ground motions above 50 Hz, the ZPA regions of the response spectra are being approached. The applicant further stated equipment designs with dominant natural frequencies above 50 Hz are inherently rugged. The highly unlikely case of HRHF-sensitive equipment with a natural frequency of 55 Hz, for example, is a special class and would require combining screening process Groups Nos. 1 and 3. For this condition, the Group No. 3 process would govern and the equipment would be subjected to a supplemental HRHF seismic evaluation/screening test.

The staff concludes that, in general, 50 Hz is adequate to be used as the cut-off frequency for rugged equipment in screening process if the ZPA of the HRHF ISRS approaches 50 Hz. The staff considers RAI-SRP3.10-EMB-02 to be closed.

In RAI-SRP3.10-EMB-03, the staff requested that the applicant provide justifications for not performing additional low level testing (5 OBEs) for equipment identified as potentially sensitive to high frequency motion is located in an area with potential for high frequency seismic input motions. OBE testing requirements of Institute of Electrical and Electronics Engineers (IEEE) Std. 344-1987, "IEEE Recommended Practice for Seismic Qualification of Class 1E Equipment for Nuclear Power Generating Stations," and NUREG-0800 Section 3.10 must be satisfied. The NRC's policy and staff's technical positions related to OBE issues are clearly delineated in SECY-93-087. The detailed response to RAI-SRP3.10-EMB-03 was initially submitted in a letter dated May 28, 2008, and later, a revised response was provided under the applicant's letter dated August 21, 2008. In the May 28, 2008, response, the applicant stated the HRHF screening test is not considered to be a qualification test. The HRHF screening test is intended as a supplemental test to the required seismic qualification performed in accordance with IEEE 344. As a result of further discussion with the staff, the applicant submitted its revised response on August 21, 2008. The applicant stated its HRHF screening test will be in compliance with the seismic test input requirements in IEEE Std. 344-1987 and Interim Staff Guidance defined in DC/COL-ISG-1. The five OBE (one-half SSE) and a minimum of one SSE AP1000 CSD ISRS test runs preceding the HRHF screening test are performed in compliance with IEEE Std. 344-1987. All of these test runs can be used to address seismic aging (fatigue) of the safety-related equipment in the high frequency exceedance region. Each test run will produce a number of peak stress magnitudes, which will have fatigue damage potential. OBE testing in the HF exceedance region was not significant because the cyclic fatigue of equipment (ten peak stress cycles per event) for equipment is more damaging in the frequency range below the HF exceedance region. The acceleration response in the HF exceedance region will produce very small displacements and lower number of high-stress cycles resulting in the overall equipment accumulative fatigue being less than or equal to that experienced during qualification testing.

The applicant's response to this RAI was partially acceptable. The applicant did not demonstrate OBE testing requirements of IEEE Std. 344-1987 and NUREG-0800 Section 3.10 (including SECY-93-087) were satisfied. Therefore, the staff followed up with RAI-SRP3.10-EMB-10 to continue resolution of the staff concerns. The staff's evaluation of the applicant's response to RAI-SRP3.10-EMB-10 is described later in this report. The staff considered RAI-SRP3.10-EMB-03 to be closed.

In RAI-SRP3.10-EMB/EEB-04, the staff requested that the applicant confirm battery chargers and inverters with digital components are included in the high frequency seismic screening process. The detailed response to this RAI was initially submitted in a letter dated May 28, 2008, and later, a revised response was provided under the applicant's letter dated August 21, 2008. The applicant stated electronic components such as those found in battery chargers, inverters, and solid state and microprocessor-based components are listed in Table 6.4.5-1, "Potential Sensitive Equipment List," of TR-115. The applicant further stated Table 3.11-1 of AP1000 DCD Revision 16 was reviewed to verify all potential high frequency (HF) sensitive AP1000 safety-related equipment were included in APP-GW-GLN-144 (TR-144) Table A-1, "Potential High Frequency Sensitive AP1000 Safety-Related Equipment." As a result of its review, the applicant identified additional equipment may be potentially HF-sensitive. Table 3I.6-2 of AP1000 DCD Revision 17 and Table A-1 of TR-144 have been updated to include the following additional equipment types: batteries, neutron detectors, radiation monitors and hot leg sample isolation limit switches. The remaining AP1000 safety-related equipment not high frequency sensitive is defined in APP-GW-GLN-144 Table A-2, "List of AP1000 Safety-Related Electrical and Mechanical Equipment Not High Frequency Sensitive." Table 3I.6-3 of AP1000 DCD Revision 17 and Table A-3 of TR-144 include justifications for classifying the equipment as not HF-sensitive.

The staff has verified those electronic components in question are included in the tables mentioned above. The staff considers RAI-SRP3.10-EMB/EEB-04 closed.

In RAI-SRP3.10-EMB-05, the staff requested that the applicant provide justification for the conclusions addressing the use of existing test data in Section 6.4.7 (Summary and Conclusions) of TR-115. The detailed response to this RAI was initially submitted in a letter dated May 28, 2008, and later a revised response was provided under the applicant's letter dated August 21, 2008. The applicant stated the conclusions reached were based on the information presented in TR-115, Section 6.4.4 (Review of Existing Seismic Test Data). The test data in TR-115 represents existing the applicant seismic test data reviewed as part of the study to confirm seismic qualification to the AP1000 certified design ISRS envelops the HRHF seismic inputs for most applications. The applicant further stated that power spectral density (PSD) and other acceptable evaluation methods as defined in IEEE Std. 344-1987 are ways of determining energy content within a seismic test run. When available, PSD plots were used to evaluate seismic test data reported in Section 6.4.4 of TR-115. For the test data reported, energy content in the 25 Hz to 50 Hz frequency range was demonstrated by meeting at least one of the following criteria:

1. Test reports stated the seismic time history inputs were developed with content in the frequency range up to 50 Hz as a minimum.

2. The test response spectra (TRS) were shown to be amplified in the 25 Hz to 50 Hz frequency and were not caused by impact or test unit rattling.

3. PSD plots indicate energy content in the high frequency region.

Figures 1 through 6 of the applicant's response provide examples of test data that demonstrate frequency content in the 25 Hz to 50 Hz range.

The staff has examined Figures 1 through 6 and concluded that, for the existing test data reported, energy content in the 25 Hz to 50 Hz frequency range was demonstrated by meeting at least one of the criteria described above. Therefore, the staff considers RAI-SRP3.10-EMB-05 to be closed.

In RAI-SRP3.10-EMB-06, the staff requested that the applicant provide detailed evaluation comparisons for the reactor vessel internals response to the HRHF and CSDRS seismic input motions, and, also, the seismic anchor motion effects of the high frequency input motion. The detailed response to this RAI was submitted in a letter dated June 6, 2008. The applicant provided a comparison between the CSDRS results and HRHF results for various support (interface) loads within the reactor internals system model. The comparison indicates these support loads are reduced for HRHF evaluation when compared to the CSDRS analysis. The comparison also indicates CSDRS would control the cyclic loading demand. The applicant further stated the seismic anchor motion effects are included in the high frequency input motion study and, therefore, included in the evaluation.

The staff finds the applicant's response to be adequate in resolving its concerns relating to the comparison of the pertinent stress analysis results for the reactor internals system under the CSDRS and HRHF seismic input excitations. The applicant has also included the cyclic loading and seismic anchor motion effects in the HRHF evaluations. The staff considers RAI-SRP3.10-EMB-06 to be closed.

In RAI-SRP3.10-EMB-07, the staff requested that the applicant provide justification for concluding the reactor internals are representative of the primary mechanical components such that all others can be screened out, and also provided quantitative evaluation result for mechanical component other than reactor vessel internals to substantiate the justification. The detailed response to this RAI was submitted in a letter dated June 6, 2008. The applicant stated the mechanical components listed in Table 3.2-3 of the AP1000 DCD, Tier 2 must be designed for the SSE are those classified as Seismic Category, I and II. Among those equipment and components, the applicant stated many mechanical components and equipment that are safety-related are not high frequency sensitive as is some electrical equipment. Therefore, it is only necessary to evaluate a representative sample of mechanical components and equipment. The applicant stated the reactor vessel is representative of a mechanical component with complex internals that was evaluated as part of the HRHF evaluation. The seismic response of this component is considered representative of other mechanical components. The reactor internals were chosen for evaluation because this is an important component related to safety, and the reactor internals are representative of other component internals. It is, therefore, not necessary to perform further analysis of other mechanical components and equipment for the HRHF earthquake excitations.

The staff concludes reactor internals are relatively complex and contain broader natural frequencies than other mechanical components. The staff considers the applicant's response adequate in justifying that reactor internals can be considered as representative of ASME safety-related mechanical components and the equipment for high frequency evaluation. Therefore, the staff considers RAI-SRP3.10-EMB-07 to be closed.

In RAI-SRP3.10-EMB-08, the staff requested that the applicant justify the use of the required input motion (RIM) curve of IEEE Std. 382-1996, "IEEE Standard for Qualification of Actuators for Power-Operated Valve Assemblies With Safety-Related Functions for Nuclear Power Plants," for qualification of line-mounted equipment (e.g., valves) for HRHF response spectra with exceedance, or to provide methodologies would be acceptable for the case of HRHF excitation. The detailed response to this RAI was initially submitted in a letter dated May 28, 2008, and later Revision 1 response was provided in a letter dated August 21, 2008. Revision 2 of the applicant's response was submitted in a letter dated May 27, 2009. The applicant stated it was performing seismic qualification of safety-related SSCs based on AP1000 CSDRS. The HRHF screening is a functional verification test in compliance with Interim Staff Guidance defined in COL/DC-ISG-1 to verify potential high frequency sensitive safety-related equipment will perform its function as required under HRHF seismic demand response spectra. The HF screening is a supplemental evaluation to the required seismic qualification methods performed in accordance with IEEE Std. 344-1987 for those plants that have potentially high frequency sensitive equipment and components with high frequency exceedance of their CSDRS.

The applicant stated in those instances where the seismic qualification of line-mounted equipment (e.g., valves and their appurtenances) are potential HRHF-sensitive components, seismic testing performed in compliance with Figure 6 (RIM curve) of IEEE Std. 382-1996 will be extended out for one additional octave to 64 Hz.

AP1000 DCD Tier 2, Section 3.7.3.5.1 defines rigid components such as rigid valves as the following: "A rigid component (fundamental frequency >33 hertz), whose support can be represented by a flexible spring, can be modeled as a single degree of freedom model in the direction of excitation (horizontal or vertical directions)." When dealing with HRHF sites we should refrain from using the wording rigid equipment or rigid components because it can differ between the AP1000 CSRDS and HRHF sites. Seismic qualification of safety-related equipment by analysis will be addressed over the range of interest up to the cutoff frequency of the AP1000 certified design ISRS. In most instances a dynamic analysis or a static coefficient analysis using the peak of the applicable response spectra at the mounting location of the equipment will be used.

The applicant further noted in its Revision 2 Response, dated May 27, 2009, AP1000 DCD Tier 2, Appendix 3I, Table 3I.6-3 includes a list of AP1000 safety-related equipment and mechanical equipment not high frequency sensitive. Notes 1 and 2 of the table identify the requirement for performing seismic RIM testing of line-mounted equipment out to 64 Hz.

Based on the review of the applicant's documents, DPC/NRC2144, DCP/NRC2235, and DCP/NRC2503, the staff determined the applicant has adequately addressed the questions raised in this RAI. The staff has also verified the conclusion of the applicant's response to this RAI has been documented in Notes 1 and 2 of Table 3I.6-3 in Tier 2 document Appendix 3I of AP1000 DCD Revision 17. Therefore, the staff considers RAI-SRP3.10-EMB-08 to be closed.

In RAI-SRP3.10-EMB-09, staff requested that the applicant discuss the basis for deleting references to dampers in Section 3.10. In several locations in Section 3.10 of AP1000 DCD and Revision 17, the applicant has replaced the reference to safety-related dampers with a reference to safety-related valves; Section 3.10.2.2 is an example. The applicant's response to this RAI was submitted in a letter dated May 28, 2008. The applicant stated for the AP1000 design, there are no safety-related dampers. The term "dampers" was used in error. Changes were made in Section 3.10 of AP1000 DCD and Revision 17 to correctly identify the subject equipment as safety-related valves. The staff considers the applicant's response to be acceptable. Therefore, RAI-SRP3.10-EMB-09 is closed.

In the revised response to NRC RAI-SRP3.10-EMB-03 dated August 21, 2008 (ADAMS Accession Number ML082390116), the applicant indicated the five OBE (one-half SSE) and a minimum of one SSE AP1000 CSD ISRS test runs preceding the HRHF screening test were performed in compliance with IEEE Std. 344-1987. The staff understands the same specimen is used for all these test runs. The applicant also indicated all of the CSDRS test runs can be used to address seismic aging of the equipment in the high frequency exceedance region.

In RAI-SRP3.10-EMB-10, as a follow-up to the August 2008 response to RAI-SRP3.10-EMB-03, the staff requested that the applicant provide justifications including the results from calculations that show seismic qualification of electrical/electronic equipment by tests for AP1000 CSDRS design spectra can be considered as equivalent to or more than 5 OBE peak stress cycles for HRHF spectra. This should be done using bounding AP1000 ISRS generated from CSDRS and bounding ISRS generated from HRHF Spectra and following the guidelines as delineated in Annex D of IEEE 344-1987. The staff also requested that the applicant document the conclusion of the comparison result of CSD ISRS and HRHF ISRS peak stress cycles in DCD Section 3I.6.4. In its response dated October 17, 2008 and March 5, 2009, the applicant stated that the AP1000 safety-related equipment will be seismically- qualified to the AP1000 CSD ISRS associated with the mounting location of the equipment as a minimum. Seismic qualification testing will consist of five AP1000 ISRS OBEs followed by one SSE as a minimum. The OBE level will be at least one-half the SSE level. The OBE testing is used to account for vibration aging and address low-cycle fatigue of equipment prior to SSE testing. The applicant stated cyclic fatiguing of equipment for the HRHF exceedance area can be adequately addressed by performing five AP1000 ISRS OBE (one-half the SSE) and a minimum of one

SSE seismic test runs in compliance with IEEE Std. 344-1987 prior to performing the supplemental HRHF screening test.

The applicant has performed an evaluation to demonstrate OBE testing in the high frequency exceedance range is adequately addressed by AP1000 CSD ISRS seismic qualification testing (5 OBE and 1 SSE). The evaluation compared the peak stress cycles resulting from five one-half SSE events from AP1000 HRHF ISRS to the peak stress cycles resulting from five one-half SSE events and one full SSE event from AP1000 CSD ISRS using the guidelines defined in Annex D of IEEE Std. 344-1987. The applicant's evaluation of AP1000 CSD ISRS peak stress cycles to the AP1000 HRHF ISRS peak stress cycles is documented in Westinghouse Calculation CN-EQT-08-35/APP-GW-S2C-002. The evaluation of AP1000 CSD ISRS peak stress cycles to the AP1000 HRHF ISRS peak stress cycles was performed for two AP1000 plant elevations; the AP1000 NI Auxiliary and Shield Building (ASB) at or below 135 feet elevation and the AP1000 CIS at or below 40.9194 m (134.25 ft) El.

The peak stress cycles in each direction were determined based on the ZPA of the 1/2 SSE HRHF ISRS and the 1/2 SSE and SSE CSD ISRS acceleration time histories normalized to the same ZPA value to demonstrate equivalency of results. Results of the cycle counting in compliance with guidelines defined in Annex D of IEEE Std. 344-1987 are summarized in Table 1 of the applicant's letter.

The applicant concluded that the completed evaluation has demonstrated the peak stress cycles resulting from five one-half SSE events using the AP1000 HRHF ISRS are equivalent to or enveloped by the peak stress cycles resulting from five one-half SSE events and one full SSE event using the AP1000 CSD ISRS.

The staff has reviewed the applicant's responses as stated above. The staff concludes the applicant has adequately demonstrated by calculations that the peak stress cycles resulting from five one-half SSE events using the AP1000 HRHF ISRS are equivalent to or enveloped by the peak stress cycles resulting from five one-half SSE events and one full SSE event using the AP1000 CSD ISRS. The applicant's response also included the proposed revision to the DCD. The staff finds the proposed revision acceptable. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

In RAI-SRP3.10-EMB-11, the staff pointed out that the applicant's evaluations from the envelope response spectra (ERS) for the Central and Eastern U. S. rock sites (HRHF foundation response spectra exceeds CSDRS for frequencies above about 15 Hz) presented in TR-115, Revision 2, indicated some resulting FRS are higher than those presented in Revision 0 and Revision 1. Some resulting HRHF FRS exceeds the CSDRS FRS significantly in the frequency range from 6 Hz to 60 Hz. The applicant is requested to demonstrate all AP1000 safety-related mechanical and electrical equipment (not limited to HF-sensitive equipment only) are seismically qualified to the RRS at the equipment/device locations to meet the requirements of GDC 2 as a result of TR-115, Revision 2.

The detailed response to this RAI was initially submitted in a letter dated August 6, 2010, and later, Revision 1 response was provided under the applicant's letter dated August 23, 2010. The applicant stated the equipment seismic qualification information provided in Revision 2 of TR-115 was developed using the latest revision of the CSDRS and HRHF. The equipment will be qualified to the latest AP1000 CSDRS applicable to its mounting location. Potential HRHF sensitive equipment will be subjected to a high frequency screening test consistent with the guidance in ISG-1 after completion of CSDRS testing. Appendix 3I of the AP1000 DCD provides two tables that separate the AP1000 safety related electrical and mechanical equipment into two categories: (1) Table 3I.6-2 includes equipment that is potentially high frequency sensitive and (2) Table 3I.6-3 contains equipment not high frequency sensitive. The applicant stated seismic qualification for both categories is performed using the current revision of the CSDRS ISRS associated with the mounting locations of equipment based on the guidance of IEEE Std. 344-1987. After completing CSDRS ISRS seismic qualification testing, the potential high frequency sensitive equipment will be subjected to a HRHF screening test to the HRHF ISRS associated with the mounting location of the equipment as a minimum. To demonstrate acceptability for both CSDRS and HRHF testing, the test response spectra must envelop the CSDRS ISRS with margin over the frequency range of interest in compliance with IEEE Std. 344-1987. If the HRHF screening test cannot demonstrate the equipment to be acceptable, then the safety related equipment will be removed or modified and additional testing or justification will be required.

The applicant noted that, at locations where HRHF response spectra show exceedance of the CSDRS for category (2) equipment (not high frequency sensitive) in Table 3I.6-3 of AP1000 DCD, further evaluations would be performed to verify the existing qualification is adequate. The applicant further stated that, in the event that the CSDRS and/or HRHF response spectra would be revised after the qualification program had been completed, a reconciliation effort were performed to verify the CSDRS and HRHF testing was still valid. The reconciliation effort may result in re-qualification activities and qualification documentation revisions.

The seismic qualification testing for both CSDRS and HRHF spectra for AP1000 safety-related equipment will be documented in equipment qualification document packages as described in Appendix 3D of the AP1000 DCD. These qualification document packages will be used to satisfy the equipment's seismic Category I ITAAC described in Tier 1 of the AP1000 DCD. The applicant's response to RAI-SRP3.10-EMB-11 also included the proposed revision to the DCD (Section 3I.6.4, "Electrical and Electro-mechanical Equipment").

Based on the aforementioned response, the staff finds the applicant's response to RAI-SRP3.10-EMB-11 and the proposed revision to AP1000 DCD is acceptable. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

3.10.2 Conclusion

The staff reviewed the proposed changes related to Section 3.10 of AP1000 DCD, including Appendix 3I to the DCD. On the basis that the AP1000 mechanical and electrical equipment continue to meet all applicable acceptance criteria and procedures for seismic qualification of mechanical electrical equipment in accordance with the guidance of NUREG-0800 Section 3.10, RG 1.100, SECY-93-087, and DC/COL-ISG-1, the staff finds the changes to Section 3.10 of AP1000 DCD are acceptable. The staff finds the AP1000 design provides adequate assurance that AP1000 seismic Category I equipment will function properly under the effects of earthquake motions, and the acceptance criteria for the AP1000 design meet the requirements of 10 CFR Part 50, Appendix A, GDC 1, 2, and 30; and 10 CFR Part 50, Appendix S.

3.11 Environmental Qualification of Mechanical and Electrical Equipment

In Revision 17 to the AP1000 DCD Tier 2, the applicant modified Section 3.11, "Environmental Qualification of Mechanical and Electrical Equipment." The objective of environmental qualification (EQ) is to reduce the potential for common failure due to specified environmental conditions and seismic events, and to demonstrate the equipment within the scope of the EQ Program is capable of performing its intended design safety function under all conditions including environmental stresses resulting from design bases events.

3.11.1 Evaluation

In Section 3.11, "Environmental Qualification of Mechanical and Electrical Equipment," of NUREG-1793, the staff described its review of the description of the EQ Program for the AP1000 design. The regulatory basis for the NRC review of the design certification information is documented in NUREG-1793. The regulatory basis for the proposed changes to the AP1000 DCD is the same as specified in NUREG-1793.

In NUREG-1793, the staff concluded the program described for environmentally qualifying electrical equipment important to safety and safety-related mechanical equipment in support of the AP1000 DC complied with the requirements for 10 CFR 50.49, "Environmental qualification of electric equipment important to safety for nuclear power plants," and other relevant requirements and criteria.

Since the issuance of NUREG-1793, the NRC has determined a COL applicant referencing the AP1000 design needs to fully describe EQ and other operational programs as defined in SECY-05-0197. RG 1.206 provides guidance for a COL applicant in preparing and submitting its COL application in accordance with the NRC regulations. For example, Section C.IV.4 in RG 1.206 discusses the requirement in 10 CFR 52.79(a) for descriptions of operational programs that need to be included in the FSAR in a COL application to support a reasonable assurance finding of acceptability. A COL applicant may rely on information in the applicable DC to help provide a full description of the operational programs for the COL application. At a public meeting on March 26 and 27, 2008, the applicant indicated its intent to revise the AP1000 DCD to resolve issues common to COL applicants implementing the AP1000 design. Therefore, the staff reviewed Revision 17 to the AP1000 DCD, Section 3.11, including DCD changes intended to minimize the supplemental information necessary to be provided by COL applicants in fully describing their operational programs in support of the COL applications. As described below for specific review areas, the staff finds the revision to the AP1000 DCD continues to provide an acceptable description of the EQ Program sufficient for the AP1000 Design Certification in accordance with the NRC regulations.

A COL applicant referencing the AP1000 design will be responsible for fully describing the EQ operational program in support of its COL application. A COL applicant may reference the provisions in the AP1000 DCD as part of its responsibility to fully describe the EQ operational program. The staff will evaluate the full description of the operational EQ Operational Program provided by a COL applicant during review of the COL application consistent with RG 1.206 and NUREG-0800 Section 3.11, "Environmental Qualification of Mechanical and Electrical Equipment."

Section 3.11, "Environmental Qualification of Mechanical and Electrical Equipment," in AP1000 DCD Tier 2 presents information to demonstrate the mechanical and electrical portions of plant safety systems are capable of performing their designated functions while exposed to applicable normal, abnormal, test, accident, and post-accident environmental conditions. AP1000 DCD Tier 2, Appendix 3D, "Methodology for Qualifying AP1000 Safety-Related Electrical and Mechanical Equipment," describes the methodology to be used to qualify equipment for nuclear power plants with the AP1000 reactor design. During the March 26 and 27, 2008, public meeting, the applicant stated procurement specifications were being prepared for safety-related equipment to be used in the AP1000 reactor design. In RAI-SRP3.11-CIB1-01, the staff requested that the applicant describe the implementation of the methodology for environmental qualification of safety-related mechanical equipment to be used in the AP1000. In its response to this RAI, in a letter dated May 30, 2008, the applicant described its EQ Program for safety-related mechanical equipment. The applicant stated safety-related functions of mechanical equipment shall be shown to be acceptable under the required operating conditions and environmental parameters. Further, the AP1000 harsh and mild environmental conditions will be supplied to the vendor in the design and qualification specifications.

On October 14 and 15, 2008, the staff conducted an audit of design and procurement specifications, including environmental qualification, for pumps, valves, and dynamic restraints to be used for the AP1000 reactor at the applicant office in Monroeville, Pennsylvania. The staff found the applicant had included ASME Standard QME-1-2007 in its design and procurement specifications for AP1000 components, including ASME QME-1-2007, Appendix QR-B, “Guide for Qualification of Nonmetallic Parts.” Further, AP1000 DCD Tier 2 (Revision 17), Section 5.4.8.3, “Design Evaluation,” states the requirements for qualification testing of power-operated active valves are based on ASME Standard QME-1-2007 as listed in AP1000 Tier 2, Section 5.4.16, “References.” In a memorandum dated November 6, 2008, the staff documented the results of the audit with specific open items. In a letter dated January 26, 2010, the applicant discussed its plans to address the October 2008 audit findings. Resolution of the audit findings were tracked as Open Item OI-SRP3.11-CIB1-01. In a letter dated February 23, 2010, the applicant provided its response to Open Item OI-SRP3.11-CIB1-01. In particular, the applicant stated the valve design specifications indicate active valves will be qualified in accordance with ASME Standard QME-1-2007. The applicant also provided planned changes to the AP1000 DCD to ensure consistency in the EQ provisions and tables.

As discussed in Section 3.9.6 of this SER, the staff conducted a follow-up audit at the applicant’s office in Rockville, Maryland, on May 17, 2010, to review the revisions to the design and procurement specifications prepared since the October 2008 audit. Based on the May 2010 audit, the staff found the applicant has updated the design and procurement specifications to address NRC comments provided during the October 2008 audit. For example, the staff found the design and procurement specifications require the application of ASME Standard QME-1-2007 for the qualification of mechanical equipment to be used in an AP1000 reactor. Further, the staff found the equipment qualification specification mandates non-metallic components be environmentally qualified using the provisions of Appendix QR-B to ASME Standard QME-1-2007. Based on the follow-up audit, Open Item OI-SRP3.11-CIB1-01 is closed. In Revision 19 to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

Section 3.11.5, “Combined License Information Item for Equipment Qualification File,” in Revision 17 to the AP1000 DCD states the COL holder will define the process and procedures for which the equipment qualification files will be accepted from the applicant and how the files will be retained and maintained in an auditable format for the period that the equipment is installed and/or stored for future use in the nuclear power plant. In RAI-SRP3.11-CIB1-02, the staff requested that the applicant specify the necessary actions for the COL applicant to establish the process and procedures for accepting, maintaining, and storing equipment qualification files. In its response to this RAI in a letter dated May 30, 2008, the applicant stated it will act as the agent for the COL holder during the equipment design phase, equipment selection and procurement phases, equipment qualification phase, plant construction phase, and ITAAC inspection phases. The applicant indicated the COL applicant will provide supplemental information to fully describe the process for retention and maintenance of the EQ documentation for the operational life of the plant. The staff considers the RAI response clarifies the role of the applicant in the EQ process; RAI-SRP3.11-CIB1-02 is closed.

The staff reviewed the revisions to the AP1000 DCD with respect to the EQ Program for electrical equipment important to safety and safety-related mechanical equipment. The staff finds the changes are generic and are expected to be applicable to all COL applications referencing the AP1000 certified design.

3.11.2 Conclusion

The staff concludes that the proposed changes to the AP1000 DCD continue to satisfy the NRC regulations for electrical and mechanical equipment within the scope of the EQ Program for the AP1000 design. The revision to the AP1000 DCD provides sufficient information to satisfy 10 CFR Part 50 and 10 CFR Part 52 for the EQ Operational Program for electrical and mechanical equipment to be used at an AP1000 nuclear power plant and are, therefore, acceptable. Further, the staff concludes the AP1000 DCD changes related to the EQ Operational Program are generic and are expected to apply to all COL applications referencing the AP1000 DC.

3.12 Piping Design

The AP1000 DCD, Revision 15 was approved by the staff in the certified design. In the AP1000 DCD Revision 17, the applicant proposed the completion of Design Specification and Reports which is COL Information Item 3.9.2 in Sections 3.9.3.1.4, 3.9.3.1.5, 3.9.3.4 and 3.9.8.2 and 3.9.8.6 of the DCD. In addition, COL Information Item 3.9-6 would be closed in Section 3.9.8.6.

In Appendix 3I, the applicant proposed to address HR sites that show higher amplitude at high frequency than the CSDRS. In Appendix 3C, the applicant proposed to remove the containment interior building structure and the surge line piping from the original reactor coolant loop (RCL) model and provided more accurate description for the RCL model and analysis methods.

In Section 3.9.3.1.2, the applicant revised piping lines connected to the RCS from not susceptible to thermal stratification, cycling or striping (TASCS) to susceptible to TASCS. The applicant added clarification to Sections 3.9.3.1.4 and 3.9.3.1.5. The applicant proposed changes to the requirement for the welded connections of ASTM A500 Grade B tube steel members as described in Section 3.9.3.4. In Section 3.9.3.4, the pipe support deflection limit and pipe support stiffness values used in the piping analysis were clarified. Clarification was added in Section 3.9.8.6 to address COL information item related to piping benchmark program. Lastly, the applicant proposed changes in Section 3.9.8.2 to remove piping DAC from the DCD.

3.12.1 Evaluation

The staff reviewed the proposed changes to the piping design in the AP1000 Revision 17 in accordance with the guidance in the NUREG-0800 Section 3.12, "ASME Code Class 1, 2, and 3 Piping System, Piping Components and their Associated Supports." The regulatory basis for Section 3.12 of the AP1000 DCD is documented in NUREG-1793.

3.12.1.1 Design Specification and Reports

In Section 3.9.8.2 the applicant stated "COL holder referencing the AP1000 design will have available for NRC audit the design specifications and as-designed reports prepared for major ASME Section III components and ASME Code, Section III piping." The statement implied the COL applicant may not complete the piping design prior to issuance of a COL.

On February 8, 2008, the applicant issued a letter related to schedule for piping design document review. In this letter, the applicant stated "It is the intention of Westinghouse that design documents related to DAC and COL Information Item will be available for NRC review during the period scheduled for the NRC review of the design certification amendment. It is expected information will be available for NRC review to permit the resolution, closure, or removal of the DAC and COL Information Item."

In RAI-SRP3.12-EMB-4, the staff questioned whether the applicant would complete the as-designed piping analyses and design reports by December 2008 as stated in the February 8, 2008, letter. The staff requested that the applicant revise the DCD to reflect the design completion or propose a method and schedule to resolve the piping DAC issue and update the DCD to reflect the proposed alternative.

By letter dated June 20, 2008, the applicant responded that it intended to have the design documents for the risk-significant piping packages identified by the NRC available during the review of the design certification amendment. The DCD would be revised to reflect the expected completion of the piping design. It was also expected the NRC's review of these documents would permit the resolution, closure, or removal of the DAC and the COL Information Item. The staff reviewed the applicant's response and its follow-up letter, which indicated the schedule for the risk-significant piping packages would be completed by June 30, 2009, in order to resolve the piping DAC.

By letter dated April 1, 2010, the applicant stated that it would not be able to complete the piping analysis for the previously specified risk significant piping packages to support the DC amendment. In this letter, the applicant revised DCD Sections 3.9.8.2 and 3.9.8.7 to address all aspects related to as-designed piping design specification, design reports, and analysis. Additionally, the applicant revised Section 14.3.2.2 of DCD to address DAC/ITAAC closure process for OI-SRP3.12-EMB-04.

The applicant proposed the piping DAC become COL Information Item 3.9-7 in the DCD for the DC amendment. COL Information Item 3.9-7 would state the COL applicant needs to complete the as-designed piping analysis for the identified risk significant piping packages to close the piping DAC. The COL information item may be addressed by the COL applicant in a manner that complies with NRC guidance provided in RG 1.215, and outlined in Appendix 14.3A of the DCD. The applicant's use of piping DAC was previously approved and certified in Revision 15 of the DCD and documented in NUREG-1793. The staff finds this acceptable.

By letter dated August 23, 2010, the applicant provided a Revision 2 response to OI-SRP3.12-EMB-04 to address RAI-SRP3.12-EMB1-09 that is documented in Section 3.12.1.3 of this SER. In this letter, the applicant revised Sections 3.9.8.2 and 3.9.8.7 to further clarify as-designed design specifications, design reports, and analysis will be the responsibility of the COL applicants. The applicant also clarified the availability of the piping design information and design reports will be identified to the NRC. The staff has determined these clarifications for the COL applicants' activities are acceptable. In that letter, the applicant added a Table 3.9-20, which describes piping packages chosen to demonstrate piping design for piping DAC closure (in addition to Class 1 lines larger than (2.54 cm (1 in) in diameter). The staff reviewed this table and concluded these piping packages and Class 1 lines do represent the Class 1, 2, and 3 piping packages and would be able to demonstrate piping design for piping DAC closure. Therefore, the staff finds this acceptable.

In this letter, the applicant also provided a markup of Section 14.3A of the DCD for DAC/ITAAC closure process as follows:

> 14.3A Design Acceptance Criteria / ITAAC Closure Process
>
> DAC (Design Acceptance Criteria) are a set of prescribed limits, parameters, procedures, and attributes upon which the NRC relies, in a limited number of technical areas, in making a final safety determination to support a DC. DAC are to be objective (measurable, testable, or subject to analysis using pre-approved methods), and must be verified as a part of the ITAAC performed to demonstrate the as-built facility conforms to the certified design. (SECY-92-053, "Use of Design Acceptance Criteria during 10 CFR Part 52 Design Certification Reviews")
>
> There are three process options for DAC/ITAAC resolution:
>
> - Resolve through amendment to design certification
> - Resolve as part of COL review
> - Resolve after COL is issued
>
> In the first two options, the applicant will submit the design information and the NRC will document its review in a safety evaluation. In the third option, the COL holder notifies the NRC of availability of design information and the staff will document its review in an inspection report.
>
> Should the third option be implemented for the first standard AP1000 plant, subsequent COL applicants may reference the first standard plant closure documentation and close the DAC/ITAAC under the concept of "one issue, one review, one position," identified in NRC guidance.
>
> Additionally, the applicant may submit licensing topical reports for NRC review of the material supporting the DAC/ITAAC closure and request the NRC to issue a safety evaluation in conjunction with a closure letter or inspection report concluding the acceptance criteria of the DAC/ITAAC have been met. Subsequent COL applicants may reference these reports and NRC closure documents in effort to close the DAC/ITAAC.
>
> For technical areas where DAC/ITAAC applies in the DC rule, COL applicants will provide an ITAAC and associated closure schedule indicating the approach to be applied.
>
> For subsequent COL applicants following the first standard AP1000 plant, the application could reference the existing DAC/ITAAC closure documentation for the first standard plant.

NRC guidance for DAC/ITAAC is provided in RG 1.206, Section C.III.5. Further information on the staff's position of DAC/ITAAC being used as part of the 10 CFR Part 52 review process is provided in SECY-92-053.

The staff reviewed and evaluated the applicant's letter addressing OI-SRP3.12-EMB-4. On the basis that the applicant-proposed position provides no change from the approved design (the use of Piping DAC had been approved in DCD Revision 15) and better defines a plan for closure later in the construction period, the staff finds this acceptable. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

In RAI-SRP3.12-EMB-5, the staff questioned how the COL holder would complete verification of the thermal cycling and stratification loading considered in the stress analysis as discussed in Section 3.9.3.1.2 prior to fuel load. The applicant had not provided a specific monitoring program for verification of thermal cycling and stratification loading condition of the automatic depressurization Stage 4 lines and the passive residual heat removal line. These two lines are susceptible to thermal stratification as described in Section 3.9.3.1.2 of DCD. If verification could not be completed prior to fuel load, the applicant was requested to provide alternatives.

In a letter dated June 20, 2008, the applicant responded that Section 3.9.8.2 deals with design specifications and design reports and the requirement to perform a reconciliation/analysis for the as-built piping. The intent of the phrase in parenthesis (verification of the thermal cycling and stratification loading considered in the stress analysis discussed in Section 3.9.3.1.2) was to verify "dimensional/layout/support differences" identified in an as-built walk-down were considered in thermal cycling/stratification as well as the standard portion of the piping analysis. The monitoring program identified in Section 3.9.8.5 was a one-time requirement for the surge line and was not related or applicable to Section 3.9.8.2. Thermal cycling and stratification loading were to be evaluated by analysis and if the as-built dimensions, layout, or supports on the piping lines changed as the result of construction, a reconciliation of the stratification analysis was to be performed. The staff reviewed the clarification provided in the response and determined it was acceptable.

3.12.1.2 Closure of COL Information Item 3.9-6 (Piping Benchmark Program)

The original COL information item commitment stated the COL applicant will implement a benchmark program as described in Section 3.9.1.2 if a piping computer program other than the one used for design certification is used. The piping benchmark problems identified in Reference 20 for the Westinghouse AP600 are also representative of AP1000 and can be used for the AP1000 piping benchmark program if required.

In Section 3.9.8.6, the applicant proposed to close out the COL Information Item 3.9-6. The applicant stated the combined license information requested in this subsection had been completely addressed in TR-15, "Benchmark Program for Piping Analysis Computer Programs," APP-GW-GLR-006, March 2006, and no additional work was required by the combined license applicant to address the combined license information requested in this subsection.

The staff reviewed TR-06, which stated all piping analysis performed for AP1000 was being completed using only programs that had already been benchmarked to NRC's satisfaction. PIPESTRESS, GAPPIPE, WECAN and ANSYS require no additional benchmarking by the COL Applicant. On the basis that the above mentioned computer codes have been accepted by the staff and other analysis codes are not being used for piping analysis, the staff finds this change acceptable and COL Information Item 3.9.6 is closed.

3.12.1.3 Evaluation for High Frequency Seismic Input

The staff reviewed the applicant's Appendix 3I of DCD Revision 17, and its supporting document, TR-115. However, the seismic input has been identified in Section 3.7.3 as inadequate due to mathematical model error. The applicant revised TR-115 with adequate seismic input. The staff reviewed the revised document, TR-115, Revision 2.

TR-115, Revision 2 states the HRHF exceeds the CSDRS for frequencies above about 15 HZ and the representative piping considered is based on high frequency participation as indicated in Section 6.3.1 of TR-115.

The staff noted the floor response spectra exceedances were in the region for frequencies around 6-12 Hz as shown in Figure 6.3.2.2-1 through 6.3.2.2-3 of TR-115. The staff identified the selected representative piping systems only addressed high frequency piping systems. TR-115 failed to address all other piping packages related to the FRS exceedances for frequencies around 6-12 Hz. The staff reviewed sample piping system selection criteria and determined the selection criteria was not adequate. The staff also noted TR-115, Revision 2 did not address support load increase due to the response spectra exceedance. The staff issued OI-SRP3.12-EMB1-09 to ask the applicant to address all piping packages for the FRS exceedances around 6-12 Hz and piping support load increases.

In a letter dated August 17, 2010, the applicant provided the following response:

> HRHF GMRS effects on ASME Class 1, 2 and 3 piping systems will be evaluated as part of the Piping DAC, captured as COL Information Item 3.9-7 in the DCD (See response to Open Item OI-SRP3.12-EMB-4 R1 in Letter No. DCP_NRC_002845).
>
> Areas of exceedance of the CSDRS will be addressed for the entire frequency range.
>
> The following will be considered in the evaluation:
> - Piping Qualification
> - Support Loads
> - Valve Accelerations
> - Valve End Stresses
> - Equipment Nozzle Loads
>
> Impacts on the following evaluations will be considered:
> - Pipe Rupture Hazards Analysis
> - LBB
> - Piping and Component Fatigue Analysis"

The applicant also provided a markup of revised Table 3.9-19 and revised Appendix 3I to state ASME Class 1, 2 and 3 piping systems will be evaluated for the HRHF GMRS and this evaluation is within the scope of the piping DAC.

The staff reviewed the applicant's response and identified COL Information Item 3.9-7 is not listed in the Table 1.8-2 of DCD. The staff requested that the applicant address COL Information Item 3.9-7 (as-designed piping analysis). In a letter dated August 23, 2010, the applicant provided a markup of revised Table 1.8-2 by adding this COL Information Item to address staff's concern. In this letter, the applicant also revised its DAC/ITAAC closure process. The evaluation of DAC/ITAAC closure process is documented in Section 3.12.1.1.

In the markup of revised Appendix 3I of DCD, the applicant stated the COL will evaluate the HRHF GMRS effects of the piping systems by changing the piping system screening criteria from at least 2 piping analysis package to all ASME Code Class 1, 2, and 3 piping systems. The staff determined the revised position meets design requirements of GDC 2. Therefore, the staff finds this acceptable. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

3.12.1.4 Reactor Coolant Loop Analysis Methods

The staff reviewed the proposed change in Appendix 3C of DCD Revision 17, and its supporting document TR-13, "Safety Class Piping Design Specifications and Design Reports Summary," APP-GW-GLR-013, Revision 1, May 2007. The proposed change would remove the containment interior building structure and the surge line piping from the reactor coolant loop model description. The staff also reviewed the applicant's proposed change related to time history analysis in Section 3.9.3.1.4 of DCD Revision 17. The applicant clarified that unless appropriate time-history seismic input from the building is provided at multiple supported locations, the containment internals structure is included in the system-coupled model in the time-history analysis. The staff agreed that a containment interior building structure is not required because the seismic inputs to the RCL model are provided at all of the building attachments to the RCL.

TR-13 identifies that pressurizer surge-line piping is to be analyzed in APP-RCS-PLR-040 as listed in Table 2. In RAI-SRP3.12-EMB-6, the staff noted that the RCL analysis did not couple the branch lines such as the pressurizer surge line. Section 3.7.3.8.1 of the DCD states that "if the ratio of the run piping outside diameter to the branch piping outside diameter (nominal pipe side) exceeds or equals 3.0, the branch piping can be excluded from the analysis of the run piping." Several branch lines do not meet this ratio, and therefore, should be included in the RCL piping analysis. The staff requested that the applicant explain this discrepancy and take action to address this DCD conformance issue.

In a letter dated December 23, 2008, the applicant responded as follows:

> The branch piping has been excluded from the reactor coolant loop analysis because the criteria in Subsection 3.7.3.8.1 do not apply to the hot and cold leg piping. Just as attached piping is excluded from primary equipment models, the branch piping of the surge line, automatic depressurization system Stage 4 (ADS4), RNS suction line, and several smaller lines are excluded from the analysis of the hot and cold leg piping.
>
> The reactor coolant loop (APP-RCS-PLA-050) is unique in that the stiffness and mass characteristics are closer to that of equipment than a typical piping analysis package. With the relatively short run length, comparatively large pipe diameter and pipe thickness, both the cold and hot legs have much less flexibility than a typical run length of pipe. The large interplay of the hot and cold leg piping with the reactor pressure vessel and steam generator extends the boundary of the piping analysis package to include primary equipment as well as primary loop piping.

> No non-conformance exists because the reactor coolant loop piping is treated as a rigid piece of equipment (fundamental frequency greater than 33 Hz) and not a flexible pipe.

In this letter, the applicant also submitted the DCD revision for Section 3.7.3.8.1 and Appendix 3C to reflect that the branch piping is excluded from the RCL analysis.

The staff reviewed the RCL layout configuration, which showed a total length of the 95.25 cm (37.5 in) outside diameter hot leg pipe to be approximately 6.09 m (20 ft), which should conform to a rigid body motion. On the basis that the applicant has performed a calculation to demonstrate that AP1000 RCL piping is rigid and has a fundamental frequency much higher than 33 Hz, the staff finds this acceptable.

On the basis of above discussion, the staff found that the proposed change is acceptable to reflect the RCL model used in the loop analysis.

3.12.1.5 Remove Piping Design Acceptance Criteria (DAC)

The staff reviewed the proposed changes in the introduction of DCD Revision 17 and related Tier 2 Section 3.9.8.2 and Table 3.9-19. The staff determined that risk-significant piping design packages would have to be completed in order to resolve or remove reference to piping DAC.

DCD Section 3.9.8.2 was revised to reflect the design completion by indicating that as-designed design specifications and design report for the major ASME Code, Section III components and piping are available for NRC review.

During the period October 20-24, 2008, the staff performed an on-site review, at the applicant's headquarters, of ASME Code Class 1 piping and support design with the intent to resolve piping DAC. During this review, the staff found that the applicant had not completed risk-significant ASME Class 1 piping analysis packages. On the basis that the risk-significant piping analyses had not been completed, the staff cannot remove piping DAC at this time. The onsite review summary is documented in a letter dated December 30, 2008.

In a letter dated January 19, 2009, the applicant submitted AP1000 piping DAC Analysis Schedule. In this letter, the applicant stated that the AP1000 ASME Code, Section III, Class 1, 2, and 3 piping analysis packages are rescheduled to be completed by June 30, 2009. The applicant will inform the staff when it is ready for another on-site review for Class 1, 2, and 3 risk-significant piping analysis to complete resolution of the piping DAC. This is Open Item OI-SRP3.12-EMB-4.

In a letter dated April 1, 2010, the applicant stated that it would not be able to complete the piping analysis for the previously specified risk significant piping packages to support the DC amendment. The resolution and evaluation are discussed and evaluated in Section 3.12.1.1 of this report.

3.12.1.6 Change Component and Piping Support Weld Connections Requirement

The staff reviewed the proposed changes in Tier 2 Section 3.9.3.4 of DCD Revision 17. Section 3.9.3.4 stated that the welded connections of ASTM 500 Grade B tube steel members satisfy the requirements of the AISC "Load and Resistance Factor Design (LRFD) Specification for Steel Hollow Structure Sections," dated November 10, 2000. NUREG-0800 Section 3.8.3, "Concrete and Steel Internal Structures of Steel or Concrete Containments," Acceptance Criteria 2, identified applicable steel structure codes, standard, and specifications. The applicant proposed LRFD Specification is not listed as acceptable. NUREG-0800 proposed "ANSI/AISC N690-1994, including Supplement 2 (2004)" as an acceptable specification. ANSI/AISC N690-1994 including Supplement 2 (2004) has been accepted by the NRC as ASME Code Case N-570-2. The later LRFD version of AISC N690, ASME Code Case N-721, has not been accepted by the NRC. The staff noted that the NRC's current acceptable specification is based on allowable stress design (ASD) specification. Further, the LRFD method has not been approved for use in the design of new reactor nuclear facilities. In RAI-SRP3.12-EMB-8, the staff requested that the applicant identify differences between the two methods and show equivalency with respect to NUREG-0800 acceptable specification or provide alternatives to satisfy the acceptance criteria.

In a letter dated July 30, 2009, the applicant stated that the AP1000 component and piping support designs satisfy the requirements of the ASME Code Section III, Subsection NF and the requirements in the DCD on the welding of members fabricated on tube steel are in addition to the requirements in Subsection NF. These requirements are not considered to be an alternative to the Subsection NF requirements. On the basis that the applicant meets the requirements of ASME Code Section III, Subsection NF, any additional requirements imposed by the applicant shall provide additional level of quality and safety. Therefore, the staff finds this acceptable. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

3.12.1.7 Revision of RCS Lines from Not Susceptible to TASCS to Susceptible to TASCS

The staff reviewed the applicant's proposed change related to piping lines susceptible to TASCS in Section 3.9.3.1.2 of DCD Revision 17. The staff reviewed piping and instrument drawings for these lines identified by the applicant and determined these lines are susceptible to TASCS. Therefore, the staff finds this acceptable.

3.12.1.8 Piping Design Methods

The staff reviewed the applicant's proposed change related to piping design methods and criteria in Section 3.9.3.1.5 of DCD Revision 17. The applicant summarized the methods and criteria used in design and analysis of the ASME Code Classes 1, 2, and 3 in Table 3.9-19. The staff reviewed Table 3.9-19 and determined that the applicant's summarization is acceptable.

3.12.1.9 Pipe Support Deflection Limit and Pipe Support Stiffness

The staff reviewed the applicant's proposed change related to pipe support design in Section 3.9.3.4 of DCD Revision 17. The applicant's change from dynamic loading to dynamic combined faulted loading is for clarification and considered an editorial change. The editorial change for support stiffness also provides clarification. The staff finds these editorial changes for clarification acceptable.

3.12.2 Conclusion

Based on its review of the information provided in the AP1000 Amendment, the staff concludes that supports of piping systems important to safety are designed to quality standards commensurate with their importance to safety. Section 3.12.1.1 of this report discusses the path to completion of piping analysis, including piping supports. The staff also concludes that the applicant satisfies the following:

- The requirements of GDC 1 and 10 CFR 50.55a by specifying methods and procedures for the design and construction of safety-related pipe supports in conformance with general engineering practice.

- The requirements of GDC 2 and GDE 4 by designing and constructing the safety-related pipe supports to withstand the effects of normal operation, as well as postulated events such as LOCAs and dynamic effects resulting from the SSE.

- 10 CFR Part 50 requirements by identifying applicable codes and standards, design and analysis methods, design transients and load combinations, and design limits and service conditions to assure adequate design of all safety-related piping and pipe supports in the AP600 for their safety functions.

- 10 CFR Part 52 requirements by providing reasonable assurance that the piping systems will be designed and built in accordance with the certified design. Through the performance of the ITAAC, the COL holder will verify the implementation of these preapproved methods and satisfaction of the acceptance criteria. This will assure that the as-constructed piping systems conform to the certified design for their safety functions.

- 10 CFR Part 50, Appendix S, requirements by designing the safety-related piping systems with a reasonable assurance that they will withstand the dynamic effects of earthquakes with an appropriate combination of other loads of normal operation and postulated events with an adequate margin for ensuring their safety functions.

4. REACTOR

4.1 Introduction

In Revision 17 of the AP1000 design control document (DCD), Westinghouse Electric Company, LLC (Westinghouse or the applicant) proposed changes related to the reactor core and fuel design. In a letter dated October 31, 2006, to the U.S. Nuclear Regulatory Commission (NRC), Westinghouse submitted Westinghouse Commercial Atomic Power (WCAP)-16652-NP, Revision 0, APP-GW-GLR-059, “AP1000 Core & Fuel Design Technical Report” (technical report (TR)-18), to justify the proposed changes. Various sections of DCD Chapter 4, Revision 17, incorporate the majority of these proposed changes. The NRC staff’s evaluation of the proposed changes for each section of Chapter 4 of the AP1000 DCD is addressed in the corresponding section of this safety evaluation. This particular section describes the staff’s evaluation of the proposed changes to DCD Section 4.1, “Summary Description.”

In its letter of May 26, 2007, regarding its application to amend the AP1000 design certification (DC) rule, Westinghouse referred to the criterion of Title 10 of the *Code of Federal Regulations* (10 CFR) 52.63(a)(1)(vii)), “Finality of standard design certifications” and noted that these proposed changes contribute to increased standardization of the certification information.

4.1.1 Evaluation

General Design Criterion (GDC) 10, “Reactor Design,” of Appendix A, “General Design Criteria for Nuclear Power Plants,” to 10 CFR Part 50, “Domestic licensing of production and utilization facilities,” requires that the reactor core and associated coolant, control, and protection systems be designed to assure that the specified acceptable fuel design limits (SAFDLs) are not exceeded during any condition of normal operation, including anticipated operational occurrences (AOOs). GDC 13, “Instrumentation and Control,” requires that instrumentation be provided to monitor variables and systems over their anticipated ranges for normal operation, AOOs, and accident conditions. GDC 26, “Reactivity Control System Redundancy and Capability,” requires that two independent reactivity control systems of different design principles be provided to ensure that SAFDLs are not exceeded and that the reactor core can be held subcritical under cold conditions. GDC 27, “Combined Reactivity Control Systems Capability,” requires that the reactivity control systems be designed to have a combined capability, in conjunction with poison addition by the emergency core cooling system (ECCS), of reliably controlling reactivity changes to ensure that, under postulated accident conditions and with appropriate margins for stuck rods, the capability to cool the core is maintained. GDC 28, “Reactivity Limits,” requires that the reactivity control systems be designed with appropriate limits on the potential amount and rate of reactivity increase to ensure that the effects of postulated reactivity accidents will not result in damage to the reactor coolant pressure boundary (RCPB) or sufficiently disturb the core, its support structures, or other reactor pressure vessel internals to impair significantly the capability to cool the core. Various sections of Chapter 4 of the AP1000 DCD pertaining to the reactor core, fuel design, nuclear design, thermal-hydraulic design, and reactivity control system design describe compliance with these GDC.

DCD Section 4.1, “Summary Description,” describes the AP1000 reactor core and fuel design. The staff reviewed the proposed changes to DCD Section 4.1 and other sections in Chapter 4 for compliance with these GDC. In DCD Revision 17, the applicant proposed the following changes to DCD Tier 2, Section 4.1, related to the AP1000 reactor core and fuel design: (1) clarification of the fuel protective grid design and modification of the top nozzle design nomenclature; (2) modification of the gray rod cluster assembly (GRCA) design; (3) modification of the values of several parameters in DCD Section 4.1.1 and Table 4.1-1 for consistency; and (4) addition of four neutron panels on the thermal shield.

The current DCD Section 4.1 states that the top and bottom grids of the fuel assembly design do not contain mixing vanes. In DCD Revision 17, the applicant revised this sentence to state that the top and bottom grids and the protective grid do not contain mixing vanes. This clarification specifically states that the protective grid also does not contain mixing vanes. In DCD Table 4.1.1, the applicant revised the number of grids per fuel assembly to specifically identify one protective grid. This is a clarification of the design, not a design change, and is, therefore, acceptable.

In DCD Revision 17, the applicant proposed to change “integral clamp top nozzle (ICTN)” to “Westinghouse integral nozzle (WIN)” in the fuel assembly design. In TR-18, the applicant stated that the change from a reconstitutable ICTN to WIN in the fuel assembly is a nomenclature change. The WIN design is a proven enhancement to the ICTN design and is currently in use in the Westinghouse fleet. Both the ICTN and WIN designs eliminate the need for the top nozzle spring screws and spacer clamps. There is no significant design difference between the ICTN and WIN. The applicant described the design refinements of WIN, as compared to the ICTN, in a letter dated April 19, 2004, regarding the fuel criterion evaluation process (FCEP) notification of the WIN design (proprietary and nonproprietary) (Agencywide Documents Access and Management System (ADAMS) Accession Nos. ML041120331 and ML041120332). The staff finds that the applicant developed the WIN design using the fuel criteria evaluation process described in WCAP-12488. Therefore, the change as presented in DCD Revision 17 is acceptable.

In DCD Revision 17, the applicant proposed to change the GRCA design from 4 rodlets (out of 24) containing silver-indium-cadmium (Ag-In-Cd) to 12 rodlets containing Ag-In-Cd with reduced diameter, as described in DCD Section 4.2.2.3.2. The applicant revised DCD Table 4.1-1 to reflect this change. As discussed in Section 4.2 of this report, the staff finds the change to the GRCA design acceptable.

In DCD Section 4.1.1, the applicant changed the calculated core average power limit in the principal design requirement from 18.73 kilowatts per meter (kW/m) (5.71 kilowatts per foot (kW/ft)) to18.76 kW/m (5.718 kW/ft). The value of 18.73 kW/m (5.71 kW/ft) is a truncation of the actual value of 18.76 kW/m (5.718 kW/ft). DCD Tables 4.1-1 and 4.3-2 round the core average linear power to 18.77 kW/m (5.72 kW/ft). Therefore, the staff finds the change in Section 4.1.1 to 18.76 kW/m (5.718 kW/ft) acceptable. The applicant also revised several parameters in DCD Table 4.1-1. The effective reactor coolant flow area of heat transfer, the average velocity along the fuel rods, and the average mass velocity were revised slightly to be consistent with DCD Table 4.4-1 and the revised definition of core flow area and the core bypass flow described in DCD Section 4.4. Section 4.4 of this report addresses the revision to the core flow area and bypass.

The applicant revised DCD Table 4.1-1 to include four neutron panels on the thermal shield. The applicant made this revision to be consistent with the reactor internals design changes, which call for the addition of four neutron panels to reduce the reactor vessel fluence at the circumferential locations that have the highest fluence values, along with the addition of a flow skirt in the lower reactor vessel head, as described in WCAP-16716-NP, Revision 2, “AP1000

Reactor Internals Design Changes" (TR-29). Since these changes could affect the core inlet flow distribution and the flow area and flow resistance in the reactor vessel downcomer and lower plenum, the staff requested that the applicant provide an evaluation of the impacts of these proposed changes on the analysis results of each of the transients and accidents described in DCD Chapter 15, "Accident Analyses."

In response to request for additional information (RAI)-TR29-SRSB-01, the applicant presented the results of the evaluation and safety analyses of the reactor vessel internals design changes. This evaluation also included the pressurizer changes described in TR-36, APP-GW-GLR-016, Revision 0, "AP1000 Pressurizer Design." (In its letter of July 18, 2008, in response to RAI-SRP10.3-SBPA-02, the applicant also stated that the evaluation of the limiting Chapter 15 event analyses provided in RAI-TR29-SRSB-01 included the revised main steam safety valve setpoints and capabilities.) The applicant concluded that these reactor internals changes have minimal impact on the fluid volume, metal masses, pressure drop through the reactor vessel, and the design reactor coolant system (RCS) flow rates used in the safety analyses. The applicant performed the evaluation or analyses on the limiting event of each of the event categories discussed in DCD Chapter 15. The analysis results for these events demonstrate that the applicable acceptance criteria for each event are met or that the existing analysis is bounding.

In its June 30, 2008, letter, the applicant provided APP-GW-GLE-026, Revision 0, "Application of ASTRUM Methodology for Best Estimate Large Break Loss of Coolant Accident Analysis for AP1000." Subsequently, the applicant, in a letter dated February 3, 2009, submitted APP-GW-GLE-026, Revision 1. This TR describes a reanalysis of a large-break loss-of-coolant accident (LOCA) using the NRC-approved uncertainty treatment method, Automatic Statistical Treatment of Uncertainty Method (ASTRUM). This large-break LOCA reanalysis includes the reactor vessel internals design changes discussed above. The results of this large-break LOCA analysis with the design changes to date show compliance with the acceptance criteria of 10 CFR 50.46, "Acceptance criteria for emergency core cooling systems for light-water nuclear power reactors." In the review of large-break LOCAs, Section 15.2.6.5 of this report addresses the staff evaluation of this TR.

DCD Section 4.1.1, "Principal Design Requirements," lists the criteria, or principal design requirements, that must be met by the mechanical design and physical arrangement of the reactor components, together with the corrective actions of the reactor control, protection, and emergency cooling systems. These principal design criteria are designated Tier 2* information, which indicates that staff approval will be required before implementation of any change to this information. Various sections of Chapter 4 of this report describe other Tier 2* information related to the reference core design. In Section 4.1 of NUREG-1793, "Final Safety Evaluation Report Related to Certification of the AP1000 Standard Design," the staff states that the following sections in DCD Tier 2, Chapter 4, include Tier 2* information:

- WCAP-12488-A, "Westinghouse Fuel Criteria Evaluation Process," issued October 1994

- Principal Design Requirements

- Maximum Fuel Rod Average Burnup of 62,000 Megawatt-Days per Metric Ton of Uranium (MWDF/MTU)

- Table 4.3-1, Reactor Core Description (First Cycle)

- Table 4.3-2, Nuclear Design Parameters (First Cycle)

- Table 4.3-3, Reactivity Requirements for Rod Cluster Control Assemblies

In DCD Revision 16, the applicant proposed to reclassify all Tier 2* information throughout Chapter 4 as Tier 2 information to allow future changes to this information to be implemented without prior NRC approval. However, in response to RAI-SRP4.2-SRSB-01, the applicant stated that it would withdraw the request that Tier 2* items be reassigned to Tier 2 status in Chapter 4. Therefore, all Tier 2* items in DCD Chapter 4, including the principal design requirements, remain Tier 2* items. In DCD Revision 17, all Tier 2* information currently identified in DCD Revision 15 is restored to Tier 2*. In DCD “Introduction,” Table 1-1, “Index of AP1000 Tier 2 Information Requiring NRC Approval for Change,” these Tier 2* items, which were included in DCD Revision 15 but deleted in Revision 16, have been restored. The staff finds this acceptable.

4.1.2 Conclusion

Based on this evaluation, the staff concludes that the changes to DCD Section 4.1 continue to meet the requirement of GDCs 10, 13, 26 and 28 as described above. In addition, the results of the large break LOCA analysis with these design changes comply with the acceptance criteria of 10 CFR 50.46. Therefore, the proposed changes are acceptable.

4.2 Fuel System Design

Revision 17 of the AP1000 DCD includes the following changes to Section 4.2 (as compared to Revision 15): (1) reference changes; (2) densification value; (3) control rod descriptions; (4) burnable absorber rod design; (5) debris protection package description; (6) top nozzle nomenclature; and (7) grid fabrication description.

The staff based its review of the AP1000 fuel design on the information in the DCD and the TRs referenced by the applicant. The review was limited in scope to the changes to DCD Revision 15, as presented in Revision 17. The staff conducted its review in accordance with the guidelines provided in NUREG-0800, “Standard Review Plan [SRP] for the Review of Safety Analysis Reports for Nuclear Power Plants,” Section 4.2, “Fuel System Design,” which prescribes acceptance criteria to ensure that certain requirements of 10 CFR Part 50 are met. In particular, the AP1000 fuel design must meet the following GDC:

- GDC 10
- GDC 27
- GDC 35, “Emergency Core Cooling”

The fuel design must also meet the requirements of 10 CFR Part 100, “Reactor site criteria.” Thus, in reviewing the AP1000 fuel system design, the staff’s objective was to ensure that the design fulfills the following criteria:

- The fuel system will not be damaged during any condition of normal operation, including the effects of AOOs.

- Fuel damage during postulated accidents will not be severe enough to prevent control rod insertion when required.
- The number of fuel rod failures for postulated accidents is not underestimated.
- Coolability is always maintained.

The term “will not be damaged” means that the fuel rods will not fail, the fuel system’s dimensions will remain within operational tolerances, and the functional capabilities will not be reduced below those assumed in the safety analysis. These objectives address GDC 10, and the design limits that accomplish these objectives are referred to as SAFDLs. In a “fuel rod failure,” the fuel rod leaks and the first fission product barrier (i.e., the fuel cladding) is breached. The applicant must account for fuel rod failure in the dose analysis for postulated accidents required by 10 CFR Part 100. The radiological dose consequences criteria given in 10 CFR 50.34(a)(1), “Contents of applications; technical information,” are referenced in 10 CFR 100.21, “Non-seismic siting criteria.” Compliance with dose consequence criteria in 10 CFR 50.34(a)(1), with the site parameters postulated for the design, is discussed in Section 15.3 of this report.

“Coolability,” which is sometimes termed “coolable geometry,” is the ability of the fuel assembly to retain the geometrical configuration of its rod bundle with adequate coolant channel spacing for removal of residual heat. GDC 27 and GDC 35 specify the general requirements for maintaining control rod insertability and core coolability. In addition, 10 CFR 50.46 establishes specific requirements for the performance of the ECCS following postulated LOCAs. Compliance with 10 CFR 50.46 is discussed in Section 15.2.6.5 of this report.

4.2.1 Evaluation

The applicant made various reference changes in Revision 17. When needed, the applicant included additional references. In other cases, the applicant replaced references to correct erroneous references found in Revision 15. For example, the applicant deleted an erroneous reference for the integral fuel burnable absorber design in Section 4.2.2.1. In RAI-SRP4.2-SRSB-04, the staff requested that the applicant include the correct reference instead of simply removing the incorrect reference. In its response, the applicant committed to add a reference to WCAP-12610-P-A to the conclusion of Section 4.2.2.1. DCD Section 4.2.6 includes this report as Reference 5. The staff has reviewed these changes and finds them acceptable.

Throughout Section 4.2, the applicant revised the description of the control rod assemblies to clarify that the control rod clusters consist of both rod cluster control assemblies (RCCA) and gray rod cluster assemblies (GRCA). The term gray rod refers to clusters of neutron absorber rods with reduced rod worth relative to that of an RCCA. The GRCAs are used in load follow maneuvering to provide a mechanical shim reactivity mechanism to eliminate the need for changes to the concentration of soluble boron. Additionally, the applicant changed the GRCA design. Specifically, the applicant increased the number of rodlets from 4 to 12 and correspondingly reduced the diameter, such that the overall worth of the GRCA is essentially the same, as explained in the applicant’s response to RAI-SRP4.2-SRSB-05, but the assembly power profile is more even. The change in the GRCA provides a more distributed absorber material within the assembly. By reducing the diameter of the absorber material, and dispersing the absorber over more rodlets, the reactivity worth of the GRCAs is maintained while lessening the local power perturbation. DCD Revision 17 does not present the impact of these GRCAs on determining the worst-case scenarios for accident analyses. The applicant's response to RAI-SRP4.2-SRSB-05 indicated that the Chapter 15 analyses remain bounding because the use of the newer GRCA design results in a more uniform rod power throughout the affected assemblies and does not affect the worst-case assumptions used in the accident analyses. The NRC staff found this acceptable based on the RAI response and the nonsafety status of the GRCAs.

The applicant changed the burnable absorber rod design from wet annular burnable absorbers (WABAs) to borosilicate glass. However, the reference for the borosilicate design presented (WCAP-7113) is from 1967 and does not appear to have been previously approved by the NRC.

Additionally, the DCD continues to list the WABA design as an alternative. The staff issued RAI-SRP4.2-SRSB-02, RAI-SRP4.2-SRSB-03, and RAI-SRP4.2-SRSB-07 regarding these items. The applicant's response pointed out previous NRC approval of Reference Safety Analysis Reports (RESARs), that used the same reference (WCAP-7113), covering borosilicate glass RCCAs, but the applicant did not provide a specific RESAR reference. The applicant also referred to operational experience with the borosilicate glass rodlets, including a single failure of a rodlet that became detached and remained in the guide tube. In response to RAI-SRP4.2-SRSB-07, the applicant states that borosilicate burnable absorbers were used previously in a Westinghouse core design with a 14-ft core and a feed fuel enrichment of 4.4 percent. This is very similar to the AP1000 core. The response further explained that there are no changes to rodlet diameter and no changes to boron concentration for the AP1000 design as compared with the previously approved design. Based on the responses to RAI-SRP4.2-SRSB-02, RAI-SRP4.2-SRSB03, and RAI-SRP4.2-SRSB-07, the staff concludes that the use of borosilicate glass burnable absorbers is acceptable.

The applicant provided further description of the debris mitigation package in DCD Sections 4.2.2 and 4.2.2.1. Specifically, the applicant explicitly listed the parts of the debris mitigation package that include a zirconium oxide coating on the bottom section of the fuel cladding.

The applicant changed the top nozzle design in Section 4.2 (and other sections) from "Integral Clamp Top Nozzle (ICTN)" to "Westinghouse Integral Nozzle (WIN)." As described in Section 4.1.1 of this safety evaluation report (SER), the staff found this change to be acceptable.

The applicant further explained the grid fabrication process in Section 4.2.2.2.4. This information did not appear to change the grid design from that presented in DCD Revision 15 and is, therefore, acceptable.

In accordance with TR-119, APP-GW-GLR-119, "AP1000 Design Control Document Chapter 4 Tier 2* Information," the applicant edited DCD Revision 16 to remove Tier 2* designation from various fuel-related items. The applicant argued, in TR-119, that these items would be provided in a future "core reference report" and as such they could be reclassified as Tier 2. In RAI-SRP4.2-SRSB-01, the staff expressed concern that the reclassification could theoretically be interpreted to allow changes to the affected items after the core reference report was approved. In response, the applicant stated that it would withdraw the request for reclassification of all items presented in TR-119 and restore, in DCD Revision 17, all Tier 2* information currently identified in DCD Revision 15. The staff verified that Section 4.2 of Revision 17 includes all of the items designated as Tier 2* in Revision 15. In addition, Revision 17 for Table 1-1 of the DCD "Introduction" also includes these Tier 2* items, which require NRC approval for change. This staff finds this acceptable.

In Revision 15 of the DCD, Sections 4.2.5, 4.3.4, and 4.4.7 state that combined license (COL) applicants referencing the AP1000 certified design will address changes to the reference design presented in the DCD to the fuel burnable absorber rods, RCCAs, or initial core design. DCD Tier 2, Table 1.8-2, lists these COL applicant actions as COL Information Items 4.2-1, 4.3-1, and 4.4-1. In DCD Revision 17, the applicant proposed to revise Sections 4.2.5, 4.3.4, and 4.4.7.1 to state that: (1) APP-GW-GLR-059 completely addressed the COL information requested in these sections; (2) the DCD incorporated applicable changes; and (3) no additional work is required by the COL applicant to address the COL information requested in this section. In DCD Revision 17, the applicant revised Table 1.8-2 to require no COL applicant action for COL Information Items 4.2-1, 4.3-1, and 4.4-1. These COL information items intend for the COL applicant to provide information regarding the changes to the referenced reactor core design in the AP1000 DC. To increase standardization of the certified design, the applicant submitted APP-GW-GLR-059, which provides information that addresses changes to the reference design of the fuel burnable absorber rods, RCCAs, or initial core design in Revision 15 of DCD. DCD Revision 17 incorporates the applicable changes.

Based on the evaluation discussed in this report, the staff concludes that COL Information Items 4.2-1, 4.3-1, and 4.4-1 associated with DCD Revision 15 have been completed, and Revision 17 of DCD Sections 4.2.5, 4.3.4, and 4.4.7.1 is acceptable. It should be noted that the referenced design of the fuel burnable absorber rods, RCCAs, and initial core design parameters described in DCD Chapter 4 are classified as Tier 2* information, as described in Section 4.1.1. It is likely that future advancements in the design of these items could occur and COL applicants might desire these improved designs. Any change to the Tier 2* information will require prior approval by the NRC.

4.2.2 Conclusion

The staff concludes that the AP1000 fuel system, as defined by the DCD Revision 17 changes to the approved design, has been designed so that: (1) the fuel system will not be damaged as a result of normal operation and AOOs; (2) fuel damage during postulated accidents will not be severe enough to prevent control rod insertion when it is required; and (3) core coolability will always be maintained, even after severe postulated accidents, thereby meeting the related requirements of 10 CFR 50.46; GDC 10, 27, and 35; and 10 CFR Part 50.34.

The applicant provided sufficient information indicating that the changes to the approved design, as detailed in the DCD, meet the guidance provided in NUREG-0800 Section 4.2.

4.3 Nuclear Design

The staff reviewed Section 4.3 in Revision 17 of the AP1000 DCD. The staff conducted its evaluation in accordance with the guidelines provided in NUREG-0800 Section 4.3, "Nuclear Design."

In DCD Revision 17, Section 4.3, "Nuclear Design," the applicant proposed changes to the following areas related to the AP1000 nuclear design: (1) online monitoring of power distribution; (2) gray rod assembly design; (3) criticality design method outside the reactor, including soluble boron credit methodology; (4) deletion of a specific value for the moderator temperature change that accounts for the control system deadband; and (5) typical control bank worth for the initial cycle. In support of these changes, the applicant submitted APP-GW-GLR-059. The applicant originally proposed in DCD Revision 16 to reclassify the Tier 2* information in DCD Section 4.3 to Tier 2. However, in DCD Revision 17, the applicant rescinded this proposal and restored this information to its original Tier 2* designation.

4.3.1 Evaluation

DCD Tier 2, Section 4.3, “Nuclear Design,” presents the design bases for the AP1000 nuclear design. The nuclear design must ensure that the SAFDLs will not be exceeded during normal operation, including AOOs, and that the effects of postulated reactivity accidents will not cause significant damage to the RCPB or impair the capability to cool the core.

Section 4.3 of NUREG-0800 outlines relevant requirements of Commission regulations for this area of review and the associated acceptance criteria, which include the following:

- GDC 13 requires a control and monitoring system to monitor variables and systems over their anticipated ranges for normal operation, AOOs, and accident conditions.

- GDC 26 requires, in part, a reactivity control system capable of holding the reactor subcritical under cold conditions.

- GDC 28 requires, in part, that the reactivity control systems be designed to limit reactivity accidents so that the RCS boundary is not damaged beyond limited local yielding.

In Section 4.3.2.2.6, the applicant modified the text to state, “Online monitoring system is not a required element for a short term reactor operation,” and added the statement, “Limits are placed on the axial flux difference so that the heat flux hot channel factor (FQ) is maintained within acceptable limits.” In Section 4.3.2.2.9, the applicant modified the text to state, “the in-core and ex-core detector systems provide adequate monitoring of power distributions when the online monitoring system is out of service.”

During the review, the staff requested additional information on why online monitoring system outage is not a required element for a short-term operation. In response to RAI-SRP4.3-SRSB-01, the applicant stated the following:

> in the unlikely event that the Online Power Distribution Monitoring System (OPDMS) should become inoperable, reactor operation can continue with shutdown margin and power distribution controls established by bounding analyses and implemented by Technical Specification Limiting Conditions for Operations (LCOs) 3.1.5, 3.1.6, 3.2.1, 3.2.2, 3.2.3 and 3.2.4. These LCOs become applicable immediately or as otherwise specified in the associated Technical Specification applicability statements, when the OPDMS is inoperable.

The staff agrees with the RAI response and finds the proposed change acceptable. In Section 4.3.2.2.6 of the DCD, the phrase “short-term” refers to the time needed to restore the online power distribution monitoring system to operable status.

In the event that the online monitoring system is out of service for a short time, the in-core and ex-core detectors provide the operator with the necessary information regarding the power distribution based on the bounding and precalculated analysis. Therefore, the online monitoring system is not a required element. The staff finds the proposed change acceptable. The applicant provided a clarification change to Sections 4.3.2.2.4, 4.3.2.2.6, and 4.3.2.2.9 regarding the axial, limiting power distribution, and monitoring instrumentation. The clarification states that, in the event the online monitoring system is out of service, limits placed on axial flux differences are designed so that the heat flux hot channel factor and departure from nuclear boiling ratio (DNBR) are maintained within acceptable limits. The staff finds this clarification to be acceptable.

In Section 4.3.2.4.13, the applicant proposed to change the number of GRCA Ag-In-Cd rodlets from 4 to 12 reduced-diameter rodlets and to change the stainless steel (SS) rodlets from 20 to 12. The total number of rodlets is unchanged at 24. The applicant made a related change to the description of the GRCAs in DCD Section 4.3.2.2.2, Figure 4.3-8 and Figure 4.3-11. Specifically, the applicant changed the gray bank from M0 to MA+MB. This change also applies to the corrections made to the titles of Figures 4.3-8 and 4.3-11. In Section 4.3.2.4.16, the applicant added the statement, “Gray rod operation is a Condition I event which includes the periodic exchange of gray rod banks.”

The term “gray rod” refers to the reduced reactivity worth relative to that of an RCCA. The GRCAs are used in load follow maneuvering to provide a mechanical shim reactivity mechanism to eliminate the need for changes to the concentration of soluble boron. The change in the GRCA provides a more distributed absorber material within the assembly. By reducing the diameter of the absorber material, and dispersing the absorber over more rodlets, the reactivity worth of the GRCAs is maintained while lessening the local power perturbation.

This change affects information in Sections 4.3 and 4.3.2.4.13, as well as Table 4.3.1. This change is not expected to impact the conclusion of Chapter 15 and is, therefore, acceptable. Condition I comprises normal operation and operational transients that are accommodated with margin between any plant parameter and the value of that parameter requiring either automatic or manual protective action. The staff agrees with categorizing GRCA operation as a Condition I event and finds the proposed addition of the statement, “gray rod operation is a Condition I event which includes the periodic exchange of gray banks,” to Section 4.3.2.4.16 acceptable.

In Section 4.3.2.6.1, “Criticality Design Method Outside the Reactor,” the applicant deleted the formula describing the total uncertainty of the criticality calculation, and added the soluble boron credit methodology to Section 4.3.2.6.2. The methodology used in soluble boron credit analysis references WCAP-14416-P (Reference 63). This WCAP is not approved by the NRC; therefore, this proposed change is not acceptable and requires further review by the NRC staff. The staff identified the issue in RAI-SRP4.3-SRSB-03. Since this issue was also identified in RAI-SRP9.1.1-SRSB-05 pertaining to the spent fuel storage rack criticality analysis, the staff designated this as Open Item OI-SRP9.1.1-SRSB-01. In response to RAI-SRP9.1.1-SRSB-05, which also serves as the response to RAI-SRP4.3-SRSB-03, the applicant indicated that it has completely revised the AP1000 spent fuel pool (SFP) criticality analysis in APP-GW-GLR-029, Revision 0, “Spent Fuel Storage Racks Criticality Analysis,” with a new methodology that meets 10 CFR 50.68 requirements. The new analysis is APP-GW-GLR-029, Revision 1, “AP1000 Spent Fuel Racks Criticality Analysis” which is a complete rewrite to supersede Revision 0. In addition the applicant has stated that the new method and models replace specific shortcomings that the NRC identified as being no longer reliable as “approved methodology.” In a letter dated September 29, 2009, the applicant submitted APP-GW-GLR-029, Revision 2, which is identical to Revision 1, except for minor updates to include pyrex insert burnable absorber design among other burnable absorbers. These new efforts include evaluation of soluble boron. The applicant also proposed to revise DCD Sections 4.3.2.6.1 and 4.3.2.6.2 to be consistent with the methodology described in APP-GW-GLR-029, Revision 2. The staff evaluation of spent fuel criticality analysis of APP-GW-GLR-029, Revision 2, is addressed in Section 9.1.2.2.4 of this report. The staff confirmed that DCD Sections 4.3.2.6.1 and 4.3.2.6.2 were revised in a subsequent revision to the DCD.

In Section 4.3.2.4.2, the applicant proposed to delete the specific value of the Δ2.22 °Celsius (C) (Δ4 °Fahrenheit (F)) moderator temperature increase that accounts for the control system deadband. The shutdown margin control requirements calculation accounts for the control system deadband and measurement uncertainties by assuming that the moderator temperature is at its maximum possible value before plant trip. This conservatively increases the change in moderator temperature when going from hot full power to hot zero power after plant trip, thereby increasing the shutdown margin control requirement. The uncertainty is based on conservative engineering judgment and includes both instrument errors and deadband. The AP1000 analyses used a preliminary T_{avg} uncertainty, which is provided in the DCD. The applicant revised Section 4.3.2.4.2 to reflect that the allowance for deadband and measurement errors is not set at a fixed value of Δ2.22 °C (Δ4 °F). This change does not affect the conclusion of Chapter 15; therefore, it is acceptable.

The applicant revised Tables 4.3-1 and 4.3-2 and Sections 4.3.2.2.7, 4.3.4, and 4.3.5 to reflect the DCD Chapter 15 accident analysis input assumptions and its results. The applicant revised the fuel assemblies' diameter of guide thimbles and lower part to be consistent with the other dimension values given in the table. The applicant revised the nuclear design parameters, reactivity coefficient, and doppler coefficients in Table 4.3-2 to correctly refer to Figure 15.0.4-1 and to be consistent with the DCD Chapter 15 accident analysis. The applicant revised Section 4.3.4 to reflect COL information updates. The applicant also updated Sections 4.3.2.2.7 and 4.3.5 to correct, delete, and add new references. These changes provide consistency with other DCD sections and do not impact the conclusion of Section 4.3 or Chapter 15; therefore, they are acceptable.

In Table 4.3-2, the applicant provided first-cycle values for the typical hot channel factors and bank worth from beginning of life to end of life. The changes to these values represent first-cycle updated results of the in-core fuel management scheme and are acceptable.

In Section 4.3.2.4.16, the applicant revised mechanical shim load follow and base load operations (including the gray rod bank insertion sequence exchanges) to establish a more negative value than the axial offset associated with all-rods-out condition. The staff considers this to be a conservative change and it is, therefore, acceptable.

The applicant revised Section 4.3.4 to state that APP-GW-GLR-059 (Reference 64) completely addresses the COL information requested in this section, and the DCD incorporates applicable changes. No additional work is required by the COL applicant to address the COL information requested in this section. This change is acceptable as discussed in Section 4.2 of this report.

Revision 17 of DCD Section 4.3 includes numerous editorial and clarification changes concerning specifications that are covered in the core operating limits report, general formatting changes to the references, and clarifications to the variable units used in Section 4.3 of the DCD. The staff finds these clarifications to be acceptable.

4.3.2 Conclusion

The staff reviewed the changes to DCD Revision 17 that demonstrate that sufficient control rod and burnable poison worth exist to provide safe shutdown of the plant. Furthermore, the control rod system is designed to ensure that reactivity accidents do not result in damage to the RCPB. Therefore, the staff finds that the proposed DCD changes comply with the requirements of GDC 13, 26, and 28 and are acceptable. The staff expects the above changes to apply to all COL applications referencing the AP1000 DC.

4.4 Thermal-Hydraulic Design

In Revision 17 to the AP1000 DCD, the applicant proposed changes related to the reactor core thermal-hydraulic design. In a letter dated October 31, 2006, the applicant submitted TR-18, which provides rationale and justification for the proposed changes related to the reactor core and fuel design. In TR-108, APP-GW-GLN-019, "AP1000 Standard Combined License Technical Report, Fluid System Changes," the applicant proposed revisions to the AP1000 fluid systems, including the digital metal impact monitoring system (DMIMS). DCD Revision 17, Section 4.4, includes the proposed changes that affect the reactor core thermal-hydraulic design.

In its letter of May 26, 2007, regarding its application to amend the AP1000 DC rule, the applicant referred to the criterion of 10 CFR 52.63(a)(1)(vii) and stated that these proposed changes contribute to increased standardization of the certification information.

4.4.1 Evaluation

DCD Section 4.4, "Thermal and Hydraulic Design," describes the AP1000 reactor core thermal-hydraulic design to ensure adequate heat removal to prevent fuel damage during normal operation and transients. In Revision 17 of the AP1000 DCD, the applicant proposed the following changes to Section 4.4 related to the AP1000 core thermal-hydraulic design: (1) revision of the core bypass flow; (2) change of the maximum rod bow penalty for DNBR calculation from less than 1.5 percent DNBR to less than about 2 percent DNBR; (3) change of the hydraulic loads calculation from the mechanical design flow to the best estimate flow; (4) change of the peak linear power resulting from overpower transient/operator errors from 73.82 kW/m (22.5 kW/ft) to less than or equal to 73.65 kW/m (22.45 kW/ft); (5) change of the term "canned motor pump" to "reactor coolant pump"; (6) revision of the description of the DMIMS; (7) changes of the values of several parameters in Table 4.4-1; (8) addition of WCAP-15063-P-A, Revision 1; (9) addition of Reference 87 (WCAP-16652-NP); and (10) division of Section 4.4.7, "Combined License Information," into Sections 4.4.7.1 and 4.4.7.2, with revisions to each section.

GDC 10 specifies that the reactor core and the associated coolant, control, and protection systems must be designed with appropriate margin to ensure that SAFDLs are not exceeded during any condition of normal operation, including the effects of AOOs. In its review of the AP1000 DCD changes related to DCD Section 4.4, the staff used the guidance of NUREG-0800 Section 4.4, "Thermal and Hydraulic Design," which sets forth the acceptance criteria used by the staff to evaluate the thermal-hydraulic design of the reactor core for compliance with the relevant requirements of GDC 10. The following discusses the evaluation of these changes.

DCD Section 4.4.1.3.1, "Design Basis," identifies the core bypass flow (which is not considered effective for heat removal) as the coolant flow through the thimble tubes and the leakage from the core barrel shroud region into the core. Revision 17 revised the core bypass flow as the coolant flow through the thimble and instrumentation tubes and the leakage between the core barrel and core shroud, head cooling flow, and leakage to the vessel outlet nozzles. In TR-18, the applicant indicated that it made this change to accurately describe the core cavity flow area caused by a change from the core baffle-former design to a welded core shroud design, which eliminates the need for bolts in the high fluence regions immediately adjacent to the reactor core. The revision to DCD Section 4.4.1.3.1 clarifies the regions of the core bypass flow that are not effective for core heat transfer. The shroud core cavity flow is considered to be active flow that is effective for fuel rod cooling. Therefore, the applicant deleted Item E in Section 4.4.4.2.1 from a core bypass flow path to be consistent with core bypass flow design basis detailed in Section 4.4.1.3.1. This revision results in slight changes in the effective core flow area, average velocity along the fuel rods, and average mass velocity, as reported in Tables 4.1-1 and 4.4-1, from 3.85 square meters (m^2) (41.5 square feet (ft^2)), 4.85 meters per second (m/s) (15.9 feet per second (ft/s)), and 3268.5 kilograms per second-square meter (kg/s-m^2) (2.41×10^6 pounds per hour-square feet) (lbm/hr-ft^2)) to 3.88 m^2 (41.8 ft^2), 4.82 m/s (15.8 ft/s), and 3458.4 kg/s-m^2 (2.55×10^6 lbm/hr-ft^2), respectively.

DCD Section 4.4.4.2.1 states that calculations using drawing tolerances in the most conservative direction and accounting for uncertainties in the pressure losses show the core bypass to be no greater than the 5.9-percent design value. The maximum value of 5.9 percent allotted as bypass flow and the thermal design flow of 94.1 percent of the thermal flow rate assumed for the core cooling evaluations, as stated in DCD Sections 4.4.1.3.2 and 4.4.1.3.1, respectively, remain unchanged. Thus, the change in the core bypass flowpaths has insignificant effects on the core cooling calculation and is, therefore, acceptable. The change in the average mass velocity reflects a correction to the coolant temperature used in the calculation of the core average flow rate from the core average temperature to the core inlet temperature. This is acceptable because the calculation with higher water density of the core inlet temperature results in a higher mass velocity with the same volumetric flow rate.

In DCD Revision 17, the applicant added Reference 88 to Sections 4.4.1.2.1 and 4.4.8 (the reference section). Reference 88 addresses the NRC approval of the maximum burnup limit of 62,000 MWD/MTU for WCAP-10444-P-A, WCAP-12610-P-A, WCAP-12488-A, and WCAP-15063-P-A, all of which are referenced in Section 4.4.8. The applicant added Reference 88 for completeness, and the staff finds this addition acceptable.

In DCD Revision 17, the applicant added Reference 82a to Sections 4.4.2.2.1 and 4.4.8. Reference 82a addresses the application of an adjustment factor to the WRB-2M critical heat flux correlation described in Reference 82, which is used in the AP1000 thermal-hydraulic design calculations. The applicant added Reference 82a for completeness, and the staff finds this addition acceptable.

Section 4.4.2.2.5 states that the maximum rod bow penalties accounted for in the design safety analysis are based on an assembly average burnup of 24,000 MWD/MTU and indicated that the maximum rod bow penalty is less than 1.5 percent DNBR. In Revision 17, the applicant changed the maximum rod bow penalty of “less than 1.5 percent DNBR” to “less than about 2 percent DNBR.” In TR-18, the applicant stated that it made this change for consistency with the basis used for 3-D flow-accelerated corrosion (FAC) analysis. Because the change of the maximum penalty from 1.5 percent to about 2 percent DNBR is a more conservative change, and the actual value of the rod bow penalty used in the safety analysis will be calculated based on actual fuel design and assembly burnup of 24,000 MWD/MTU, the staff concludes that the change is acceptable.

Section 4.4.2.6.2 states that the hydraulic loads at normal operating conditions are calculated considering the mechanical design flow and account for the minimum core bypass flow based on manufacturing tolerances. In Revision 17, the applicant changed the mechanical design flow to the best estimate flow. As stated in TR-18, the applicant changed the mechanical design flow to the best estimate flow for the hydraulic calculation to achieve consistency with the current design procedures. Therefore, the staff finds the change to be acceptable.

In DCD Revision 17, Section 4.4.2.7.1, the applicant corrected a typographic error in the Dittus-Boelter correlation for the force convection heat transfer coefficients calculation. However, the staff found that the correction still includes editorial errors. The applicant stated, in response to a telecom of November 17, 2008, that it will correct these errors in a follow up version of DCD Section 4.4.2.7.1. In a subsequent revision to the DCD, the applicant made appropriate changes to DCD Section 4.4.2.7.1, which resolves this issue.

In Section 4.4.2.11.6, the applicant changed the peak linear power resulting from overpower transient or operator errors from 73.82 kW/m (22.5 kW/ft) to less than or equal to 73.65 kW/, (22.45 kW/ft). This change ensures consistency with the reactor design value specified in Tables 4.1-1 and 4.4-1 and is, therefore, acceptable.

In Section 4.4.4.6, the applicant changed the term “canned motor pump” to the more generic term, “reactor coolant pump.” This editorial change does not affect the negative slope for the pump head-capacity curve as a generic reactor coolant pump characteristic and is, therefore, acceptable.

In Section 4.4.6.4, the applicant made changes to the description of the DMIMS. In TR-103, APP-GW-GLN-019, Revision 2, “AP1000 Standard Combined License Technical Report, Fluid Systems Changes,” the applicant stated that it made these changes to correct a misinterpretation of the required number of sensors and to correct and delete incorrect information. The requirement for loose parts monitoring system sensors was incorrectly interpreted as requiring four, rather than two, sensors per collection region. This correction results in the removal of the term “redundancy” regarding sensors at each RCS location and instrumentation channel. The applicant made other changes to the descriptions of the DMIMS performance tests method and the technique used to minimize false impact detection. The applicant made these changes to accurately represent the DMIMS design, and they do not result in a change of the design. The DMIMS design continues to conform to system design aspects of Regulatory Guide (RG) 1.133, Revision 1, “Loose-Part Detection Program for the Primary System of Light-Water-Cooled Reactors.”

In Table 4.4-1, the applicant changed the values of several parameters to be consistent with Table 4.1-1. In Footnote j, the applicant revised the theoretical density of the fuel from 95 percent to 95.5 percent for AP1000 (95 percent for others). The applicant modified Footnote f, which is associated with heat transfer, by changing the phrase, “based on 157 fuel assemblies and hot densified fuel length” to “based on densified active fuel length.” The applicant rounded the value for AP1000 to 18.77 kW/m (5.72 kW/ft). The changes regarding the theoretical density are acceptable as they are consistent with DCD Section 4.2.3.2.

In Section 4.4.2.11, the applicant added Reference 85, WCAP-15063-P-A, Revision 1, “Westinghouse Improved Performance Analysis and Design Model (PAD 4.0).” This report presents an NRC-approved fuel rod design methodology. The addition of a reference to this topical report reflects the NRC's approval of the methodology. Therefore, this addition is acceptable.

DCD Revision 16, Section 4.4, proposed to change Reference 9, WCAP-12488-A, from Tier 2* information to Tier 2. As discussed in Section 4.1 of this report, in response to RAI-SRP4.2-SRSB-01, the applicant stated that it would withdraw the request that this Tier 2* item be reassigned to Tier 2 status in Chapter 4. In DCD Revision 17, the applicant restored all Tier 2* information identified in DCD Revision 15, including WCAP-12488-A, to Tier 2*. The staff finds this acceptable.

In Revision 17, the applicant revised Section 4.4.7.1 to state that APP-GW-GLR-059 (Reference 87) completely addressed the COL information requested in this section and the DCD incorporated applicable changes; therefore, no additional work is required by the COL applicant to address the COL information requested in this section. The staff finds this revision to be acceptable, as discussed in Section 4.2 of this report.

In DCD Revision 17, Section 4.4.7.2 states the following:

> Following selection of the actual plant operating instrumentation and calculation of the instrumentation uncertainties of the operating plant parameters as discussed in Subsection 7.1.6, and prior to fuel load, the Combined License holder will calculate the design limit DNBR values. The calculations will be completed using the RTDP with these instrumentation uncertainties and confirm that either the design limit DNBR values as described in Section 4.4, "Thermal and Hydraulic Design," remain valid, or that the safety analysis minimum DNBR bounds the new design limit DNBR values plus DNBR penalties, such as rod bow penalty.

This is a change from DCD Revision 15, Section 4.4.7, "Combined License Information." The applicant has changed the "combined license applicant" who will calculate the design limit DNBR values to the "combined license holder" who will calculate the design limit DNBR values before fuel load. In response to RAI-SRP4.4-SRSB-02, the applicant stated that the design limit DNBR depends on the selection of the actual plant operating instrumentation, as well as on calculation of the instrumentation uncertainties of the operating plant parameters. The applicant further stated the following:

> The actual calculated instrumentation uncertainties will be used, when available, to recalculate the RTDP [revised thermal design procedures] DNBR design limits. If these recalculated DNBR design limits are less than those given in DCD 4.4.1.1.2, then the DCD values are conservatively high and will not be revised. If the calculated values are higher than the values in the DCD, then the design limits will be revised. Note that since conservatively high values of the instrumentation uncertainties were used in the calculations, we do not expect the design limits to change.

The staff agrees that the actual design limit DNBR can only be calculated after the selection of actual plant operating instrumentation and, therefore, the change from "the combined license applicant" to the "combined license holder" who will calculate actual design limit DNBR values is acceptable. It should be noted that in NUREG-1793, Appendix F, "Combined License Action Items," Item 4.4-1 reiterated DCD COL Information Item 4.4-2. Therefore, this same change in COL Information Item 4.4-2, as described in DCD Section 4.4.7.2, is applied to NUREG-1793

Item 4.4-1. Also, in Revision 17 of the DCD, the applicant revised Table 1.8-2, “Summary of AP1000 Standard Plant Combined License Information Items,” to be consistent with the changes to Section 4.4.7.2 to indicate that COL Information Item 4.4-2 is an action required by the COL holder. This is acceptable to the staff.

4.4.2 Conclusion

The staff has reviewed the changes to DCD Section 4.4. Based on the evaluation discussed above, the staff concludes that the core thermal-hydraulic design continues to meet the requirements of GDC 10 and is, therefore, acceptable.

4.5 Reactor Materials

4.5.1 Control Rod Drive System Structural Materials

4.5.1.2.1 Material Specification

In Revision 16 to the AP1000 DCD, the applicant proposed changes to Section 4.5.1 to include austenitic SS Types 304, 304L, 316, and 316L for parts of the control rod drive mechanisms (CRDMs) and control rod drive (CRD) line exposed to reactor coolant, including pressure-boundary components. TR-33, APP-GW-GL-009, “Pressure Boundary Material Change,” Revision 1, submitted in a letter dated May 24, 2007, identified and justified these changes.

In addition, the applicant revised DCD Tier 2, Section 4.5.1, to include the use of a cobalt alloy or qualified substitute to fabricate CRDM latches and links. The applicant also modified the nickel-chromium-iron alloy (Alloy 750) specification used for CRDM springs from Aerospace Material Specification (AMS) 5698E and AMS 5699E to AMS 5698 and AMS 5699. TR-106, APP-GW-GLN-106, “AP1000 Licensing Design Changes for Mechanical Systems and Component Design Updates,” Revision 1, submitted in a letter dated September 28, 2007, identified and justified the aforementioned changes.

4.5.1.2.2 Evaluation

4.5.1.2.2.2 Changes to Control Rod Drive Mechanism Stainless Steel Materials (TR-33)

GDC 1, “Quality Standards and Records,” requires structures, systems, and components (SSCs) important to safety to be designed, fabricated, erected, and tested to quality standards to ensure a quality product in keeping with the required safety function. GDC 4, “Environmental and Missile Dynamic Effects Design Bases,” requires that SSCs important to safety be appropriately protected against environmental and dynamic effects, including the effects of missiles that may result from equipment failure. The staff review of the AP1000 DCD changes related to this section ensures that the materials for the CRD system meet the American Society of Mechanical Engineers (ASME) Code requirements and are compatible with the reactor coolant environment to ensure a quality product commensurate with its importance to safety.

DCD Tier 2, Section 4.5.1, describes the materials used to fabricate components of the CRDM and CRD line. The parts of the CRDMs and CRD line exposed to reactor coolant are made of materials designed to resist the degradation mechanisms of the reactor environment.

DCD Tier 2, Section 4.5.1, describes the materials used to fabricate components of the CRDM. The parts of the CRDM exposed to reactor coolant are made of materials designed to resist the degradation mechanisms of the reactor environment. Currently, DCD Section 4.5.1.1 and the corresponding Table 5.2-1 in Section 5.2.3 include SS Types 304LN and 316LN, which have high resistance to sensitization. Therefore, these materials are more resistant to stress-corrosion cracking (SCC) because of their low carbon content. The applicant revised DCD Tier 2, Section 4.5.1, to include austenitic SS Types 304, 304L, 316, and 316L, as discussed in TR-33. TR-33, which provides the basis for the change, states that the addition of these materials will enhance manufacturing flexibility, reduce costs, and reduce risk relative to material availability. The applicant submitted changes to the AP1000 DCD, as proposed in TR-33, pursuant to 10 CFR 52.63(a)(1)(vii) on the basis that the proposed changes contribute to increased standardization of the certification information.

SS Types 304 and 316 (higher carbon content) are less resistant to sensitization due to heat treatment or welding. In addition, NRC Information Notice 2006-27, "Circumferential Cracking in Stainless Steel Pressurizer Heater Sleeves of Pressurized Water Reactors," and numerous requests for relief from the ASME Code concerning repairs to leaking CRDM canopy seal welds discuss emerging issues involving SS Types 304 and 316. These instances of SCC are occurring in stagnant or dead end pressurized-water reactor (PWR) coolant environments. Since Type 304 and 316 SS materials are more susceptible to intergranular stress-corrosion cracking (IGSCC) and transgranular stress-corrosion cracking than the low-carbon SS Types 304L, 304LN, 316L, and 316LN, the use of Types 304 and 316 materials may affect the integrity of the CRD components (including the RCPB portions of the latch housing and rod travel housing). Specifically, the use of these materials can affect the structural integrity of CRD components that are subjected to stagnant water (trapped oxygen), dead legs, or areas prone to increased levels of oxygen.

Therefore, the staff requested, in RAI–SRP4.5.1-CIB1-01, that the applicant delete the proposed addition of SS Types 304 and 316 from the AP1000 DCD or provide further justification addressing the acceptability of the proposed addition of these materials.

In a letter dated May 30, 2008, the applicant provided further justification concerning the acceptability of the proposed addition of SS Types 304 and 316 in components subjected to stagnant water. The applicant stated that all austenitic SSs are procured in the solution annealed condition and that controls are established in Section 5.2.3.4 of the AP1000 DCD to avoid sensitization due to heat treatment or welding and prevent susceptibility to intergranular attack as addressed by RG 1.44, "Control of the Use of Sensitized Stainless Steel," issued May 1973. In addition, cleaning procedures and contamination preventative measures are implemented to prevent the presence of detrimental impurities that could contribute to SCC. The AP1000 CRDM design uses only one canopy seal (CRDM to the rod travel housing) in lieu of the three canopy seals in current designs. In addition, this canopy seal weld was redesigned with a larger radius and thicker wall to reduce stress levels, and the design includes a vent and drainpath for the canopy seal volume to prevent fully stagnant conditions. The number of occurrences of cracking in SS components exposed to PWR operating environment is small considering the number of SS components used in PWR applications. Most of these failures have occurred as a result of adverse conditions (trapped oxygen in stagnant water) and high stresses.

The staff agrees that using the guidance in RG 1.44 and proper cleaning techniques limits the amount of sensitization of Types 304 and 316 SS, which in turn reduces the susceptibility to SCC. In addition, the redesign of the CRDM reduces the stresses and adverse environment (vent and drainlines to minimize the presence of an oxygenated environment) that is a major contributor to the susceptibility of the SS to SCC. Therefore, the staff finds that Types 304 and 316 SS can be used, in addition to Types 304L, 304LN, 316L, and 316LN (which are less susceptible to sensitization) previously approved by the staff in NUREG-1793 because the applicant's design changes will reduce the number of canopy seal welds to one per CRDM, reduce the stresses in the canopy seal weld, eliminate the presence of an oxygenated environment using vent and drainlines, and follow the guidance in RG 1.44. However, these design changes (reduced number of welds, reduced stresses, and use of vent and drainlines) and the use of RG 1.44 are critical in preventing the occurrence of SCC in these components. However, the staff concluded that the applicant should add these design changes and the use of RG 1.44 for the CRDM components, including the canopy seal welds, to the DCD. It should be noted that DCD Section 4.5.1.2 applies the controls on preventing SCC, including the guidance in RG 1.44 for the austenitic SS pressure-housing components of the CRDM. The canopy seal welds may not be considered a pressure-housing component since they only provide a leakage barrier. The staff identified this issue as Open Item OI-SRP4.5.1-CIB1-01. In a letter dated May 13, 2009, the applicant provided a marked-up copy of the DCD, which included the design changes and the use of RG 1.44 as requested by the staff. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

The identified added materials and the additional information on grades, types, or classes meet the requirements of GDC 1, GDC 4, and the ASME Code, Sections II and III, in accordance with the guidance of NUREG-0800 Section 4.5.1. Therefore, the addition of the identified materials and the additional information on grades, types, or classes presented in TR-33, Revision 1, is acceptable.

The staff reviewed the proposed material changes to the AP1000 DCD. The applicant has incorporated the proposed changes, as identified in TR-33, Revision 1, into the AP1000 DCD. Therefore, the staff finds that the DCD changes that address material changes, as proposed by the applicant in TR-33, Revision 1, are acceptable.

The proposed changes contribute to the increased standardization of the certification information in the AP1000 DCD and are acceptable.

4.5.1.2.2.3 Changes to Control Rod Drive Mechanism Latches, Links, and Springs (TR-106)

GDC 26 requires that one of the reactivity control systems use control rods, preferably with a positive means for inserting the rods, and be capable of reliably controlling reactivity changes for assurance that fuel design limits are not exceeded under conditions of normal operation, including AOOs.

The staff reviewed the AP1000 DCD changes related to this section to ensure that the materials for the CRDMs will perform adequately throughout the design life of the plant. The CRDM latches, links, and springs are not RCPB components and are, therefore, not required to be fabricated from materials meeting ASME Code, Section III. DCD Tier 2, Section 4.5.1, describes the materials used to fabricate CRDM components.

The applicant revised DCD Tier 2, Section 4.5.1, to include a cobalt alloy or qualified substitute to fabricate CRDM latches and links. Previously, the applicant intended to fabricate latches and links from SS hard faced with Stellite.™ The applicant also deleted its requirement that all cobalt alloy material be ordered in the solution-treated, cold-worked condition. In addition, the applicant modified the nickel-chromium-iron alloy (Alloy 750) specification used for CRDM springs. The applicant also changed the specification from AMS 5698E and AMS 5699E to AMS 5698 and AMS 5699.

In TR-106, the applicant stated that the previous design of the CRDM in Section 4.5 of Revision 15 of the AP1000 DCD was based on a design utilized in past Westinghouse plants to achieve a design life of 3 million steps. The applicant modified the design to meet a design life of 8 million steps, which required a material change for CRDM latches and links. The redesigned latches have also been modified to a double tooth design constructed of solid Stellite™ in lieu of the previous design, which utilized a single tooth design and was constructed of SS hard faced with Stellite. ™

In response to RAI-TR106-CIB1-02, dated October 5, 2007, the applicant provided additional information regarding the use of solid Stellite™ components in PWR CRDMs. The applicant stated that cast single-tooth latches constructed from solid Stellite™ have been used extensively in the Combustion Engineering (CE) fleet and all CE units in Korea. CE has used single-tooth cast Stellite™ to construct latches for the past 30 years in its units. Electricite de France (EDF) has used double-tooth hardfaced latches. The AP1000 cast latches will be based on AMS 5387.

AMS 5387 (similar to Stellite™ 6) is a cast cobalt-based alloy that provides adequate resistance to wear and corrosion in the reactor coolant environment. The staff is unaware of any failures or degradation issues associated with the use of cast Stellite™ in CRDM components. Based on the corrosion resistance and mechanical properties of this material, as well as the favorable operating experience in currently operating plants, the staff finds the applicant’s use of AMS 5387 to fabricate latches and links acceptable. The applicant’s elimination of required solution heat treatment and cold-working for cobalt alloys used in the CRDMs is acceptable because the AMS 5387 used for latches and links requires that components fabricated to this specification are used in the as-cast condition. It is the staff’s understanding that cobalt alloy link pins will still be delivered in the solution treated, cold-worked condition because these components are not cast.

In addition to the modifications to DCD Tier 2, Section 4.5.1.3, discussed above, the applicant changed the specification for CRDM springs (Alloy 750) from AMS 5698E or AMS 5699E to AMS 5698 or AMS 5699. This modification does not change the materials that the staff previously approved. The modification to specifications listed for CRDM springs allows current versions of AMS 5698 and AMS 5699 to be used and is, therefore, acceptable.

The staff finds that the proposed modifications are acceptable and meet the requirements of GDC 26 and the acceptance criteria of NUREG-0800 Section 4.5.1. In addition, the NRC staff reviewed the proposed changes as they relate to Revision 16 of the AP1000 DCD. Revision 16 of the DCD incorporates the proposed changes identified in TR-106. Accordingly, these changes are generic and are expected to apply to all COL applications referencing the AP1000 certified design. At this time, the NRC has not issued a COL for any AP1000 plants. Thus, the proposed changes contribute to the increased standardization of the AP1000 certified design and, therefore, meet the requirements of 10 CFR 52.63(a)(1)(vii).

4.5.1.2.3 Conclusion

Based on the above evaluation, the staff finds that the revisions proposed by the applicant to DCD Section 4.5.1 meet the requirements of 10 CFR 50.55a, “Codes and standards,” and

ASME Code, Section III, and are, therefore, acceptable. The proposed changes have been incorporated into the AP1000 DCD. Furthermore, the staff finds that the TR-33, Revision 1, conclusions regarding the evaluation of the changes to the material specification are generic and are expected to apply to all COL applications referencing the AP1000 DC. Therefore, the proposed DCD changes are acceptable pursuant to 10 CFR 52.63(a)(1)(vii) on the basis that they contribute to the increased standardization of the certification information. In addition, based on the above evaluation, the staff finds that the revisions proposed by the applicant to AP1000 DCD, Section 4.5.1, meet the requirements of GDC 26 and, therefore, are acceptable. The AP1000 DCD incorporates the proposed changes, as identified in TR-106, Revision 1. Furthermore, the staff finds that the TR-106, Revision 0, conclusions regarding the evaluation of the changes to the material specification are generic and are expected to apply to all COL applications referencing the AP1000 DC. Therefore, the proposed DCD changes are acceptable pursuant to 10 CFR 52.63(a)(1)(vii) on the basis that they contribute to the increased standardization of the certification information.

4.5.2 Reactor Internal and Core Support Materials

In Revision 16 of the AP1000 DCD, the applicant proposed design changes related to the material specifications for AP1000 reactor internal components. This resulted in changes to Section 4.5.2.1. In a letter dated July 31, 2007, the applicant submitted TR-31, APP-GW-GLN-015, “Reactor Internals Material Changes for the AP1000 Plant,” Revision 1, which included WCAP-16624-P, Revision 1, “Reactor Internals Materials Changes for the AP1000 Plant,” to provide the technical justification for the proposed design changes related to the material specifications for reactor internal components.

In TR-31, the applicant proposed the following changes to the AP1000 reactor internal and core support material specifications: (1) the addition of American Iron and Steel Institute Types 304, 304H, and 304L SSs to the material specifications for reactor internal core structure components; (2) the use of nickel-based Alloys 718 and 750 for the clevis insert-to-vessel bolts in place of strain-hardened Type 316 SS; (3) the use of nickel-based Alloy 690 for the clevis inserts in place of 304-series SSs; (4) the addition of Stellite™ 6 to the hardfacing materials for the radial keys, clevis inserts, and alignment pins; and (5) the use of nickel-based Alloy 750 for the irradiation specimen springs in place of Type 302 SS.

Other related changes identified in TR-31 include: (1) an additional specification in DCD Section 4.5.2.1 for qualification of welding procedures in accordance with the staff guidance in RG 1.44; (2) revisions to the language in DCD Section 4.5.2.1 pertaining to the susceptibility of reactor internal components to irradiation-assisted stress-corrosion cracking (IASCC) and void swelling; and (3) an additional statement in DCD Section 4.5.2.1 indicating that Alloy 600 would not be used in the AP1000 reactor internal components.

Revision 16 to DCD Section 4.5.2.1 implements all of the above changes proposed in TR-31 as follows:

> The major core support structure material for the reactor internals is SA-182, SA-479, or SA-240 Types 304, 304L, 304LN, or 304H stainless steels. Fabricators performing welding of any of these materials are required to qualify the welding procedures for maximum carbon content and heat input for each welding process in accordance with RG 1.44. For threaded structural fasteners the material used is strain hardened Type 316 stainless steel and for the clevis insert-to-vessel bolts either Unified Numbering System for Metals and

Alloy UNS N07718 or N07750. Remaining internals parts not fabricated from Types 304, 304L, 304LN, or 304H stainless steels typically include wear surfaces such as hardfacing on the radial keys, clevis inserts, alignment pins (Stellite^{TM} 6 or 156 or low cobalt hardfaces); dowel pins (Type 316); hold down spring (Type 403 stainless steel (modified)); clevis inserts (UNS N06690); and irradiation specimen springs (UNS N07750). Core support structure and threaded structural fastener materials are specified in the ASME Code, Section III, Appendix I as supplemented by Code Cases N-60 and N-4. The qualification of cobalt free wear resistant alloys for use in reactor coolant is addressed in Subsection 4.5.1.3.

The use of cast austenitic stainless steel (CASS) is minimized in the AP1000 reactor internals. If used, CASS will be limited in carbon (low carbon grade: L grade) and ferrite contents and will be evaluated in terms of thermal aging effects.

The estimated peak neutron fluence for the AP1000 reactor internals has been considered in the design. Susceptibility to irradiation-assisted stress corrosion cracking or void swelling in reactor internals identified in the current pressurized water reactor fleet are being addressed in reactor internals material reliability programs. The selection of materials for the AP1000 reactor internals considers information developed by these programs. Ni-Cr-Fe Alloy 600 is not used in the AP1000 reactor internals.

4.5.2.1 Evaluation

GDC 1 and 10 CFR 50.55a require that SSCs important to safety be designed, fabricated, and tested to quality standards commensurate with the importance of the safety function to be performed. The staff's review of the AP1000 DCD changes related to this section covers material, components design, fabrication, and inspection to ensure structural integrity in compliance with 10 CFR 50.55a and GDC 1.

TR-31 proposes changes to the material specifications for the AP1000 reactor internal components. DCD Tier 2, Section 4.5.2.1, identifies the reactor internal material specifications. In Revision 15 of the DCD, the major materials of construction for the reactor internal core support structure components, excluding threaded structural fasteners, are Type 304LN SS. Revision 15 of the DCD specifies strain-hardened Type 316 SS for threaded structural fasteners. Other reactor internal materials specified in DCD Revision 15, Section 4.5.2.1, include Stellite^{TM} 156 or low cobalt hardfacing on the radial keys, clevis inserts, and alignment pins; Type 316 SS for the dowel pins; modified Type 403 SS for the holddown spring; and Type 302 SS for irradiation specimen springs.

The proposed material specification changes primarily involve the addition of Types 304, 304H, and 304L to the 304-series SSs specified for the reactor internal core support structure components. Other material changes include: (1) the use of nickel-based Alloys 718 and 750 for the clevis insert-to-vessel bolts in place of strain-hardened Type 316 SS; (2) the use of nickel-based Alloy 690 for the clevis inserts in place of 304-series SSs; (3) the addition of Stellite^{TM} 6 to the above hardfacing materials for the radial keys, clevis inserts, and alignment pins; and (4) the use of nickel-based Alloy 750 for the irradiation specimen springs in place of Type 302 SS. DCD Revision 16, Section 4.5.2.1, implements the changes to these material specifications.

Section 3 of TR-31 provides a technical description and justification for the proposed material specification changes. The addition of Types 304 and 304H SSs is significant because these SSs have higher carbon content than Type 304LN. Types 304 and 304H have a maximum carbon content of 0.08 percent (by weight) and 0.10 percent, respectively; whereas, Type 304LN is a low-carbon SS with a maximum carbon content of 0.03 percent. Type 304H, in particular, is notable as a high-carbon SS with a specified minimum carbon content of 0.04 percent. None of the other SS grades specified in DCD Revision 16, Section 4.5.2.1 (Types 304, 304L, 304LN), has a specified minimum carbon content. The 304H grade was developed to ensure better resistance to high-temperature creep by maintaining at least 0.04-percent carbon. The higher allowable carbon content in Types 304 and 304H austenitic materials can potentially result in a significant degree of sensitization to intergranular corrosion and IGSCC at elevated temperatures. In the temperature range of 426.7 °C to 815.6 °C (800 °F to 1,500 °F), chromium carbides, $(Fe,Cr)_{23}C_6$, are insoluble and precipitate at grain boundaries through the diffusion of carbon. Precipitation of chromium carbides at grain boundaries result in the depletion of chromium in the surrounding matrix alloy immediately adjacent to the grain boundaries. The chromium-depleted alloy at the grain boundaries is much less corrosion resistant than the rest of the bulk alloy (i.e., away from the grain boundaries). The galvanic coupling of chromium-depleted alloy at the grain boundaries with bulk alloy in the passive state (due to undepleted chromium) can result in significant intergranular corrosion. High-carbon SSs subjected to temperatures in the range of 426.7 °C to 815.6 °C (800 °F to 1,500 °F) for a sufficient time to allow for the formation of chromium carbides at the grain boundaries are sensitized to intergranular corrosion and IGSCC. When temperatures exceed 815.6 °C (1,500 °F), the chromium carbides are soluble, and below 426.7 °C (800 °F) the diffusion rate of carbon is not sufficient to permit the formation of chromium carbides. Therefore, it is specifically in the intermediate temperature range that sensitization is a significant concern for high-carbon SSs. Welding is known to produce sensitization in weld heat affected zones (HAZs), located on either side and, at times, somewhat removed from the actual weld bead. It is in these HAZs that the welding process can produce temperatures in this intermediate range for a sufficient time to allow for carbon diffusion and the formation of chromium carbides and chromium-depleted zones at the grain boundaries. The carbon content of low-carbon SS grades (i.e., SSs with a specified maximum carbon content of 0.03 percent) is not high enough for sensitization to be a significant concern because a sufficient quantity of carbon does not exist to cause significant chromium depletion at grain boundaries within a practical timeframe for the welding process.

High-carbon austenitic SSs in nuclear reactor structural components that have become locally sensitized are potentially susceptible to IGSCC at these sensitized locations. While significant intergranular corrosion is generally not an issue for unstressed parts, the presence of tensile stresses has been known to produce IGSCC in components where sensitization has occurred. For a given high-carbon SS component, the effects of sensitization can be minimized by controlling weld parameters, such as heat input and cooling rate. RG 1.44 describes acceptable methods for controlling the processing of SSs to avoid sensitization that could lead to IGSCC. The RG specifies that, for a given material composition, welding practices should be controlled to avoid excessive sensitization of base metal HAZs adjacent to welded joints. The RG also specifies an intergranular corrosion test for the qualification of welding procedures to be used for welding SSs having a carbon content of greater than 0.03 percent. DCD Revision 16, Section 4.5.2.1, includes language requiring that welding procedures be qualified in accordance with RG 1.44.

DCD Revision 16, Section 4.5.2.1, also added Type 304L, a low-carbon grade of SS (0.03-percent maximum) similar to Type 304LN, to the list of permissible SS grades for reactor internal core support structure components. Type 304L has a lower nitrogen content (0.10-percent maximum) than Type 304LN (0.10 percent to 0.16 percent). Because of its lower nitrogen content, Type 304L is not as strong as Type 304LN and high-carbon SS Types 304 and 304H. Relative to Type 304L, the higher nitrogen content in Type 304LN results in a strengthened material that is both resistant to sensitization (due to the low carbon content) and possesses the higher tensile and yield strength properties of Type 304 and 304H materials. Types 304LN, 304, and 304H all possess an ASME Code minimum tensile strength of 517.1 megapascals (MPa) (75 kilopounds per square inch (ksi)) and a minimum yield strength of 206.8 MPa (30 ksi). Type 304L possesses an ASME Code minimum tensile strength of 475.7 MPa (69 ksi) and a minimum yield strength of 172.4 MPa (25 ksi). Type 304L SS may be used for reactor internal core support structural applications where its lower strength properties are permitted, in accordance with ASME Code, Section III.

According to the applicant, the primary justification for adding Types 304, 304H, and 304L SSs to DCD Section 4.5.2.1 is the application of these materials in currently operating Westinghouse plants. The applicant indicated that SCC has not been experienced in reactor internal core support structure components fabricated with any of these three materials. The use of Type 304L, the lower strength grade, is unconditionally approved for currently operating Westinghouse reactors where its lower strength properties are permitted. The applicant stated that it previously implemented a change from Type 304 to Type 304H for certain reactor internal components in operating plants as the reactor design evolved over time; the applicant provided a list of plants to demonstrate the extensive application of Type 304H SS in reactor internal core support structure components for these later designs. The applicant noted that, for many of the later plants, carbon content in several Type 304 components was limited to a specified range of 0.04 percent to 0.08 percent. This was stated as being the equivalent of a Type 304H SS with a more restrictive 0.08-percent upper limit on carbon content. The applicant stated that, to be consistent with these later plants, the carbon content in Type 304H SSs should be limited to a maximum of 0.08 percent for reactor internal core support structure components in the AP1000 plant. The Westinghouse Utilities Requirements Document requires the use of RG 1.44. Accordingly, all fabricators will be required to establish maximum heat inputs for each welding process with respect to the maximum carbon content for each SS type.

Overall, the staff found that the applicant provided sound justification for the addition of Types 304, 304H, and 304L SSs to the material specifications in DCD Revision 16, Section 4.5.2.1. In particular, the staff noted that the currently operating Westinghouse plants have not experienced problems with IGSCC in reactor internal core support structure components fabricated from these materials. Furthermore, the staff noted that DCD Revision 16, Section 4.5.2.1, specifies that fabricators performing welding of any of these materials are required to qualify the welding procedures for maximum carbon content and heat input for each welding process in accordance with RG 1.44.

In an RAI dated March 11, 2007, the staff requested that the applicant clarify or elaborate on several issues. In RAI-TR31-001, Question 1, Part a, the staff noted an inconsistency in the language in Section 1.2, “Introduction and Brief Description of Change,” of TR-31. Specifically, the staff noted that Section 1.2 of TR-31 states that DCD Revision 15, Section 4.5.2.1, currently specifies Type 304LN SS for reactor internal core support structure components. However, Section 1.2 also states that reactor internal components were designed using Types 304, 304H, and 304L SSs. Therefore, the staff requested that the applicant clarify whether it changed the AP1000 design for the reactor internal components after the issuance of DCD Revision 15 to include these additional SS grades. In its response to RAI-TR31-001, Question 1, Part a, the applicant indicated that it did change the design of the AP1000 reactor internal components after the issuance of Revision 15 of the DCD to include Types 304, 304H, and 304L SSs in addition to Type 304LN SS as potential materials of construction for AP1000 reactor internal components. The staff concludes that this response resolved RAI-TR31-001, Question 1, Part a, because the applicant adequately clarified the statement made in Section 1.2 of TR-31 pertaining to reactor internal component design.

In RAI-TR31-001, Question 1, Part b, the staff requested that the applicant list the materials of construction for each reactor internal component based on the newly proposed reactor internal material specifications identified in TR-31. In its response to RAI-TR31-001, Question 1, Part b, the applicant provided a table depicting the materials of construction for each of the reactor internal components. The staff evaluated this table and determined that the predominate materials of construction for all major core support structures, excluding bolting, are essentially limited to Types 304, 304H, 304L, and 304LN SSs. Furthermore, the staff confirmed the exceptions to the use of the 304-series SSs identified previously, specifically the use of nickel-based Alloy 690 for the clevis inserts, nickel-based Alloys 718 and 750 for the clevis insert-to-vessel bolts, nickel-based Alloy 750 for the irradiation specimen springs, and the addition of Stellite™ 6 hardfacing for wear surfaces on the radial keys, clevis inserts, and alignment pins. These exceptions were verified to be applicable only to these specific components. The high yield and tensile strength properties and corrosion resistance of nickel-based alloys justify their use for these specific components. These alloys are all acceptable in accordance with ASME Code, Section III. Therefore, the staff identified no safety-related issue associated with their use in these instances. DCD Revision 15, Section 4.5.1.3, previously addressed the qualification of Stellite™ 6 hardfacing for use in RCSs. The staff concludes that the applicant adequately addressed RAI-TR31-001, Question 1, Part b, because it provided a comprehensive list of material specifications for each reactor internal component that is consistent with DCD Revision 16, Section 4.5.2.1.

In RAI-TR31-002, Question 2, the staff requested that the applicant elaborate further on how it addressed the susceptibility of Type 304 and 304H SSs to various forms of corrosion and SCC, where welding on components fabricated using these materials could result in sensitization due to chromium depletion at grain boundaries. In its response to RAI-TR31-002, Question 2, the applicant reiterated its assertion that these SS grades have been used extensively for reactor internal components for currently operating Westinghouse plants. The applicant further stated that the available technical data on environmental degradation applicable to the currently operating Westinghouse plants are also applicable to the design of AP1000 reactor internal components. In addition, these materials have been assessed for a reactor internal component design life of 60 years, with respect to known mechanisms of IASCC and void swelling. DCD Revision 16, Section 4.5.2.1, states that internal material reliability programs are addressing the susceptibility to IASCC and void swelling in reactor internal components identified in the currently operating Westinghouse fleet, and the selection of materials for AP1000 reactor internal components considers information developed by these programs. TR-12, which was provided in WCAP-16620-P, Revision 0, "Consistency of Reactor Vessel Internals Core Support Structure Materials Relative to Known Issues of Irradiation-Assisted Stress Corrosion Cracking (IASCC) and Void Swelling for the AP1000 Plant," dated July 31, 2006, addresses the evaluation of AP1000 reactor internal components for potential susceptibility to IASCC and void swelling over the 60-year design life and the application of the IASCC and void swelling criteria established by the above material reliability programs. The staff concludes that the applicant's response to RAI-TR31-002, Question 2 was acceptable because it demonstrated that the applicant had adequately addressed the susceptibility of reactor internal components fabricated from Types 304 and 304H SSs to known corrosion and SCC phenomena for reactor internal components.

Based on the above discussion, the staff concludes that the applicant provided an appropriate technical justification for the reactor internal material specification changes proposed in TR-31 because these proposed changes meet the requirements 10 CFR 50.55a and GDC 1 and will not adversely impact the safety of the AP1000 reactor design. Furthermore, the staff concludes that DCD, Section 4.5.2.1, fully represents these material changes. Therefore, the staff concludes that the DCD changes proposed by the applicant in TR-31 are acceptable.

The staff reviewed the proposed changes as they relate to Revision 16 of the AP1000 DCD. The AP1000 DCD incorporated the proposed changes identified in TR-31. Accordingly, these changes are generic and are expected for all COL applications referencing the AP1000 certified design. At this time, the NRC has not issued a COL for any AP1000 plant. Thus, the proposed changes contribute to the increased standardization of the certification information in the AP1000 DCD in accordance with 10 CFR 52.63(a)(1)(cii).

4.5.2.2 Conclusion

The staff finds that the changes to the material specifications for the reactor internal components proposed in TR-31 are technically acceptable because these changes meet the requirements of 10 CFR 50.55a and GDC 1 and will not adversely impact the safety of the AP1000 reactor design. Furthermore, the staff finds that the TR-31 conclusions regarding design changes related to the material specifications for AP1000 reactor internal components are generic and are expected to apply to all COL applications referencing the AP1000 DC. Therefore, the proposed DCD changes are acceptable pursuant to 10 CFR 52.63(a)(1)(vii) on the basis that they contribute to the increased standardization of the certification information.

4.5.3 Changes to In-Core Instrument Guide Tubes

In DCD Revision 17, the applicant proposed a change related to the replacement of in-core instrument guide tubes with QuickLoc assemblies, as well as several editorial modifications to DCD Tier 1, Section 2.1.3, “Reactor System.”

4.5.3.1 Evaluation

The technical change involved the replacement of in-core instrument guide tubes with QuickLoc assemblies, as supported by APP-GW-GLE-016, “Impact of In-core Instrumentation Grid, Quicklocs and Changes to Integrated Head Package (IHP).” Also, this change included specifying the incore instrumentation QuickLoc assemblies as ASME Code Section III Classification and Seismic Category I classification in Tier 1 Table 2.1.3-1, and the QuickLoc assemblies as the pressure boundary components in Table 2.1.3-2. The staff reviewed APP-GW-GLE-016 and issued RAI-SRP15.4.8-SRSB-01 related to the rod ejection analysis in DCD Section 15.4.8. The staff determined the QuickLoc-related changes, as described in DCD Revision 17, Tier 1, Section 2.1.3, to be acceptable.

The first editorial modification is found in Table 2.1.3-2, which includes Design Commitment 2.a, and stipulates inspections, tests, analyses, and acceptance criteria (ITAAC) for the reactor upper internals rod guide arrangement. The applicant made an editorial change to refer to the correct figure describing the reactor upper internals rod guide arrangement. Specifically, Revision 15 listed Figure 2.3.1-1 instead of the correct figure (Figure 2.1.3-1).

The applicant made additional editorial modifications throughout Section 2.1.3 to correct the owrd order of “rod cluster control assemblies” (from “rod control cluster assemblies”) and to clarify that the fuel assemblies are located in the containment location only after fuel loading (located in auxiliary building prior to fuel loading). The staff found these changes to be acceptable.

4.5.3.2 Conclusion

Based on the above evaluation, the staff concludes that the changes to DCD Tier 1, Section 2.1.3, are acceptable.

4.6 Functional Design of Reactivity Control Systems

The reactivity control systems for the AP1000 facility are the control rod drive system (CRDS), the reactor trip system, and the passive core cooling system, which can affect a safe shutdown, respond within acceptable limits during AOOs, and prevent or mitigate the consequences of postulated accidents.

4.6.2 Evaluation

In DCD Revision 17, Section 4.6, the applicant proposed the following revisions to Section 4.6.1, “Information for Control Rod Drive System”: (1) a clarification that DCD Figure 4.2-8 provides the configuration of the driveline, including the CRDM, not the layout of the CRDS; (2) the deletion of the statement that the CRDM outer shroud is an integral portion of the head lifting system; and (3) the deletion of the “conduits for the in-core instrumentation” from the components located among the CRDM and supported by the integral head package.

The staff reviewed these revisions and concluded that they are editorial in nature. The applicant made the latter two revisions for the purpose of accuracy and consistency with the DCD Section 3.9.4.1.1 modifications to the integrated head package and redesign of the in-core instrumentation. These changes do not alter the functional design of the reactivity control systems and are, therefore, acceptable.

4.6.3 Conclusion

The NRC staff concludes that revisions to AP1000 DCD Section 4.6 are acceptable because the changes are editorial and do not alter the functional design of the reactivity control systems.

5. REACTOR COOLANT SYSTEM AND CONNECTED SYSTEMS

5.1 Summary Description

5.1.1 Evaluation

The summary description of the “Reactor Coolant System and Connected Systems,” of the AP1000 reactor coolant system (RCS) and connected systems, as well as their design bases, were evaluated by the staff of the U.S. Nuclear Regulatory Commission (NRC) in NUREG-1793, “Final Safety Evaluation Report Related to Certification of the AP1000 Standard Design.” Conforming changes to this section have been included in the revisions to the design control document (DCD) to reflect the design and bases changes to the reactor coolant pump (RCP), steam generators (SG), pressurizer, and normal residual heat removal system (RNS) designs that are discussed in Sections 5.4.1, 5.4.2, 5.4.5, and 5.4.7, respectively, as well as other DCD changes addressed in this chapter.

In Section 5.1 of the DCD, the applicant modified Figure 5.1-5, “Reactor Coolant System Piping and Instrumentation Diagram” (Sheet 1 of 3). The applicant stated that Figure 5.1-5 was modified by relocating the Loop 1 narrow-range and diverse actuation system (DAS) resistance temperature detector (RTD) upstream of the pressurizer surge nozzle, and by relocating the wide-range RTD upstream of the passive residual heat removal (PRHR) nozzle.

The applicant explained that the present Loop 1 location of the narrow-range device is a problem because pressurizer outsurges will cause erroneously high signals for some of the T-hot channels. The faster the RCS temperature is decreasing, the larger the resulting outsurge will be, and the higher the indicated Loop 1 temperature. The applicant concluded the most appropriate of several solutions is to relocate the narrow-range device upstream of the pressurizer surge nozzle. The staff agrees that the relocation of these RTDs would alleviate the influence of pressurizer outsurge and finds this to be acceptable.

In addition, AP1000 post-accident monitoring requirements also require that both wide-range T-hot RTDs be located at the top of the hot legs in order to detect voids. DCD Table 7.5-1, “Post-Accident Monitoring System,” specifies two RCS wide-range T-hot measurements and one PRHR heat exchanger inlet temperature measurement. Therefore, the wide-range protection and safety monitoring system (PMS) hot leg RTD (TE-135A) needs to be relocated upstream of the PRHR nozzle to validate PRHR post-accident monitoring requirements. This location would also provide the desired direct post-accident reactor outlet temperature and PRHR inlet temperature. In conjunction with the Loop 2 hot leg wide-range RTD (TE-135B), the relocation of TE-135A satisfies the need for two wide-range T-hot and one PRHR inlet temperature for post-accident monitoring. In addition, the post-accident monitoring requirements also specify that both wide-range T-hot RTDs be located at the top of the hot leg in order to detect voids. Therefore, Note 24 is added to Figure 5.1-5 to specify that the thermal wells for the Loop 1 and Loop 2 wide-range RTDs (TE-135A and TE-135B) be located at the upper half of the hot leg. The staff finds this to be acceptable.

The information above was provided by the applicant in draft format but was not formally submitted to the staff. In a letter dated May 28, 2009, the applicant documented the details related to relocating the narrow-range and wide-range RTDs as discussed above which resolves this issue.

5.1.2 Conclusion

The staff has reviewed the proposed changes to Section 5.1, "Summary Description." Based on the evaluation described above, the staff concludes that the proposed changes to AP1000 DCD Figure 5.1-5 (Sheet 1 of 3) are acceptable pursuant to Title 10 of the *Code of Federal Regulations* (10 CFR) 52.63(a)(1)(vii), "Finality of standard design certifications," on the basis that they contribute to the increased standardization of the certification information.

5.2 Integrity of Reactor Coolant Pressure Boundary

5.2.1 Compliance with Codes and Code Cases

The staff approved Section 5.2.1.1, "Applicable Code Cases," of the AP1000 DCD, Revision 15, in the certified design. The applicant has proposed to make the following changes to Section 5.2.1 of the certified design:

5.2.1.1 Compliance With 10 CFR 50.55a

AP1000 DCD Tier 2, Section 5.2.1.1, "Code Compliance with 10 CFR 50.55a," uses the baseline code of the 1998 Edition throughout and including the 2000 Addenda for evaluations of the safety analysis and the AP1000 design certification (DC), except for 1989 Edition, 1989 Addenda for Articles NB-3200, NB-3600, NC-3600, and ND-3600 related to piping design. In a letter dated January 28, 2009, the applicant proposed changes to AP1000 DCD Tier 2, Section 5.2.1.1 to use 1989 Edition, 1989 Addenda for Articles NB-3210, NB-3620, NB-3650, NC-3620, NC-3650, ND-3620 and ND-3650. These proposed limitations represent only portions of Articles NB-3200, NB-3600, NC-3600, and ND-3600 disallowed by 10 CFR 50.55a(b)(1)(iii), "Codes and standards," for seismic design of piping. In request for additional information (RAI)-SRP5.2.1-EMB-03, the staff requested the applicant confirm whether the AP1000 piping design utilized the 1998 Edition, 2000 Addenda Article NB-3220 for the piping design. The staff also requested the applicant explain how the proposed changes would meet the requirements of 10 CFR 50.55a(b)(1)(iii), including the code requirements relevant to "Reversing Dynamic Loading in Piping," first introduced in the American Society of Mechanical Engineers (ASME) 1994 Addenda.

In the proposed changes to AP1000 Tier 2, DCD Section 5.2.1.1, the applicant indicated that it would use the 1989 Edition and the1989 Addenda sub-articles NB-3620, NC-3620, ND-3620, NB-3650, NC-3650 and ND-3650 for the seismic design of piping. The staff notes that these are the sub-articles describing the alternative provisions for seismic design of piping that were introduced in the 1994 Addenda Sections NB-3600, NC-3600, and ND-3600. The use of the above proposed sub-articles is consistent with the provisions of 10 CFR 50.55a(b)(1)(iii) and is, therefore, acceptable. Regarding the requirements in 10 CFR 50.55a(b)(1)(ii) relating to weld leg dimensions for socket welds, AP1000 piping design will comply with the requirements of 10 CFR 50.55a(b)(1)(ii) for socket weld dimensions, such that DCD Section 5.2.1.1 includes specific requirements including primary stress indices and stress intensification factor consistent with the requirements of 10 CFR 50.55a(b)(1)(ii). In its response dated April 1, 2009, to RAI-SRP5.2.1-EMB-03, the applicant stated that the AP1000 design does not utilize the alternative provisions introduced in NB-3200 from the 1994 Addenda for seismic design of piping. The applicant stated that AP1000 DCD Section 5.2.1.1 will be revised to include the use of the1989 Edition, 1989 Addenda for Subarticle NB-3220. The staff considers the applicant's response and the planned DCD changes to be acceptable. In a subsequent revision to the

AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

5.2.1.2 Applicable Code Cases

The staff approved Section 5.2.1.2, "Applicable Code Cases," of the AP1000 DCD, Revision 15, in the certified design. The applicant has proposed to make the following changes to Section 5.2.1.2 of the certified design:

1) DCD Tier 2 Section 5.2.1.2 was revised to reference Section 5.2.6.1, which includes a commitment that the combined license (COL) applicant will address consistency of the design with the construction practices (including inspection and examination methods) of the later ASME Code Edition and Addenda as well as Code cases approved subsequent to the DC.

5.2.1.2.1 Evaluation

The staff reviewed this change in accordance with Section 5.2.1.2, "Applicable Code Cases," of NUREG-0800, "Standard Review Plan [SRP] for the Review of Safety Analysis Reports for Nuclear Power Plants." The staff reviewed all changes identified by change marks in the AP1000 DCD. The staff did not re-review descriptions and evaluations in the AP1000 DCD, Revision 15, that were previously approved and that are not affected by the new changes.

The applicant revised DCD Tier 2, Section 5.2.1.2, to reference Section 5.2.6.1, which includes a commitment that the COL applicant will address consistency of the design with the construction practices (including inspection and examination methods) of the later ASME Code Edition and Addenda as well as Code cases approved subsequent to the DC. To ensure that appropriate Code cases are applied for inspection and examination, in RAI-SRP5.2.1-EMB01, the NRC asked the applicant to provide Code cases similar to those in DCD Table 5.2-3, which are applicable to regulatory guide (RG) 1.147, "Inservice Inspection Code Case Acceptability—ASME Section XI Division 1," and RG 1.192, "Operation and Maintenance Code Case Acceptability, ASME OM Code."

In a letter dated July 18, 2008, the applicant responded to RAI-SRP5.2.1-EMB-01 and indicated that the Code cases to be used for inservice inspection and testing should be included in the programs developed for these activities. The final safety analysis report (FSAR) in the COL application describes these programs. DCD Section 5.2.1.2 is not an appropriate place to identify the Code cases expected to be used for inservice inspection and inservice testing. However, the COL FSAR incorporates by reference the DCD statement that if Code cases other than those included in DCD Table 5.2-3 are used, a reconciliation review will be performed. It is important that the applicant provide the baseline Code cases similar to those in Table 5.2-3 that will be incorporated by reference in the COL application for use in inspection and testing. Without those baseline Code cases, the staff cannot determine whether the Code cases are the correct revision or if additional new Code cases are needed in the COL application to meet the requirements of 10 CFR 50.55a(a)(3), (b)(5), and (b)(6). The staff identified this as Open Item OI-SRP5.2.1-EMB-01.

In a letter dated July 15, 2009, the applicant stated that DCD Section 3.9.8.4 will be revised to require that the inservice test program identify the ASME Operation and Maintenance (OM) Code cases used. The applicant also indicated that DCD Section 5.2.1.2 would be revised to note that ASME Code, Section XI and the ASME OM Code and associated Code cases are not directly used in the design of the reactor coolant pressure boundary. The ASME Code cases used in the inservice inspection and inservice testing programs would be determined as the COL information based on regulatory guidance and regulations, since RG 1.192 is not applicable to the AP1000 DC. In considering the applicant's planned changes to have Code cases used for the preservice and inservice testing included in the COL information, the staff finds the supplemental information in the letter dated July 15, 2009, to be reasonable and acceptable, based on the requirements in 10 CFR 50.55a. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

In DCD Tier 2, Section 5.2.1.2, the applicant stated that the use of any Code case not approved in RG 1.84, "Design, Fabrication, and Materials Code Case Acceptability, ASME Section III," and RG 1.85, "Materials Code Case Acceptability—ASME Section III, Division 1," on Class 1 components is authorized as provided in 10 CFR 50.55a(a)(3) and the requirements of the DC. In RAI-SRP5.2.1-EMB-02, the staff asked the applicant to remove the reference to RG 1.85 from the DCD since the NRC withdrew it in 2003.

In a letter dated June 10, 2008, the applicant responded to RAI-SRP5.2.1-EMB-02 and noted that RG 1.85 is retained in the DCD for historical reasons. It also indicated that because the ASME Code used for the design of the AP1000 is the 1998 Edition, 2000 Addendum, RG 1.85 may include Code cases that are of interest. Since the last revision (Revision 31) of RG 1.85 includes Code cases with dates only up to 1994, the use of RG 1.85 is unrelated to meeting the requirements of the ASME Code, 1998 Edition through 2000 Addenda. Instead, the NRC withdrew RG 1.85 in 2003 but incorporated all Code cases from the original RG 1.85 into RG 1.84 and will continue to do so in its future updates. Therefore, the applicant should revise the DCD Tier 2 to RG 1.84 rather than RG 1.85 while updating the DCD Tier 2 to include the up-to-date information. The staff identified this as Open Item OI-SRP5.2.1-EMB-02.

In a letter dated June 17, 2009, the applicant indicated that DCD Section 5.2.1.2 would be revised to remove the references to RG 1.85. The applicant also indicated that the discussion of conformance to RG 1.84 in Appendix 1A would be revised from Revision 31 to Revision 32 to be consistent with the information in Table 1.9-1. The staff finds the applicant's response and the planned changes to the AP1000 DCD to be acceptable. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

Revision 17 of AP1000 DCD included three new Code cases used in the AP1000 design, which were added to Table 5.2-3. These Code cases are N-655, "Use of SA-738, Grade B, for Metal Containment Vessels, Class MC, Section III, Division 1"; N-757, "Alternative Rules for Acceptability for Class 2 and 3 Valves, NPS 1 (DN25) and Smaller with Welded and Non-welded End Connections other than Flanges, Section III, Division 1"; and N-759-1, "Alternative Rules for Determining Allowable External Pressure and Compressive Stresses for Cylinders, Cones, Spheres, and Formed Heads, Section III, Division 1." In RAI-SRP5.2.1-EMB-04, the staff requested the applicant confirm whether these Code cases were the most recent version and whether they were approved by the NRC in RG 1.84. If not, the staff requested that the applicant provide justification for using these Code cases in the AP1000 design in accordance with the requirements of ASME Code, Section III, NCA-1140.

In its response dated April 1, 2009, to RAI-SRP5.2.1-EMB-04, as supplemented by a letter dated June 8, 2009, the applicant stated that ASME Section III Code Cases N-757 and N-759-1 are not included in Revision 34 of RG 1.84. The staff notes that Code Case N-655 was conditionally approved by the NRC in Revision 33 of RG 1.84. The applicant also indicated that the AP1000 design would apply the latest Code Cases N-655-1, N-757-1 and N-759-2 as identified in its letter dated June 8, 2009. The applicant provided justification required by 10 CFR 50.55a for the use of these Code cases as discussed in the following paragraphs.

See Section 3.8.2.5 of this report for the evaluation of ASME Code Case N-655. Since Code Case N-655-1 revised Code Case N-655 by replacing Supplementary Requirement S-17 with Supplementary Requirement S-1, and is considered to be equivalent with respect to controlling the quality of the SA-738 material, the staff finds that Code Case N-655-1 provides an acceptable level of quality and safety and is authorized pursuant to 10 CFR 50.55a(a)(3)(i). The applicant indicated that DCD Table 5.2-3 would be revised to include Code Case N-655-1 in lieu of N-655. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

Code Case N-757 allows the use of alternate rules for the design of instrument, control and sampling line valves, Class 2 and 3 NPS 1 (DN25) and smaller, with welded and non-welded end connections other than flanges. The ASME Code requirements for the design of these valves are in Articles NC-3500 and ND-3500 for ASME Code Class 2 and 3 valves. The standard design rules in Paragraphs NC-3512 and ND-3512 require that the minimum wall thickness satisfy the thickness requirements specified in the valve standard ASME B16.34, “Valves- Flanged, Threaded, and Welding End.” Paragraphs NC-3513 and ND-3513 provide the alternate design rules that may be used in place of NC-3512 and ND-3512 when permitted by the design specification. However, these alternate rules only apply to valves with butt welding end connections and socket welding end connections. Code Case N-757-1 allows the use of the alternate design rules for welded and non-welded end connections other than flanges, in the design of small valves. Code Case N-757-1 states that these valves may meet the design requirements of Section III, Division 1, Class 2 and 3 rules in Paragraphs NC-3512 and ND-3512 provided specific additional requirements are met. Based on a discussion in a conference call with the staff on June 19, 2009, for the use of Code Case N-757-1, the applicant addressed, in a letter dated July 2, 2009, issues regarding the operating experience of non-welded valves identified in NRC Information Notice (IN) 84-55, “Seal Table Leaks at PWRs,” and IN 92-15, “Failure of Primary System Compression Fitting.” The applicant stated that information and cautions would be provided in design documents (e.g., design specifications and instruction manuals) including: (a) not mixing the parts from one manufacturer to another; (b) following manufacturer's recommended instructions for installing compression fittings; and (c) providing training and procedures for personnel performing the work. The staff concludes that the use of Code Case N-757-1 will provide an acceptable level of quality and safety for the design of instrument, control and sampling line valves, Class 2 and 3 NPS 1 (DN25) and smaller, with welded and non-welded end connections other than flanges, and is, therefore, authorized pursuant to 10 CFR 50.55a(a)(3)(i). The applicant indicated that DCD Table 5.2-3 would be revised to include Code Case N-757-1 in lieu of N-757. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

Code Case N-759-2, "Alternative Rules for Determining Allowable External Pressure and Compressive Stresses for Cylinders, Cones, Spheres, and Formed Heads, Section III, Division 1," is intended for use in the design of AP1000 to address an issue with the primary side depressurization transients. Code Case N-759-2 provides an alternative methodology for the SG tube collapse analysis based on theoretical buckling equations and buckling tests on fabricated cylindrical tubes.

In a letter dated July 2, 2009, the applicant provided supplemental information stating that the use of theoretical buckling equations and buckling tests provides assurance that Code Case N-759-2 would provide an acceptable level of quality and safety. The applicant also stated that compliance with the existing rules of the ASME Code without the use of Code Case N-759-2 would require a re-design of the AP1000 SG tube bundle. The staff finds that the use of Code Case N-759-2 provides an acceptable level of quality and safety and is, thus, authorized pursuant to 10CFR 50.55a(a)(3)(i). The applicant indicated that AP1000 DCD Tier 2, Table 5.2-3 would be revised to replace Code Case N-759-1 with N-759-2. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

Revision 17 to the AP1000 DCD, Introduction, Table 1-1, “Index of AP1000 Tier 2 Information Requiring NRC Approval for Change,” includes Tier 2* information requiring NRC approval for change. AP1000 DCD Tier 2, Table 5.2-3 also includes Tier 2* information as specified in the footnotes to the table. In RAI-SRP5.2.1-EMB-05, the staff requested the applicant revise Table 1-1 to be consistent with Table 5.2-3. In its response to RAI-SRP5.2.1-EMB-05, the applicant indicated that it had identified inconsistencies and an omission in Table 1-1 and planned to make several changes. For example, the reference to a specific Code case would be expanded to cover all ASME Code cases with a reference to Table 5.2-3. A note specifying that the 2001 Edition of the ASME Code, Section III, including 2002 Addenda, applies to containment design would be included in Table 1-1. The table would also be revised to remove incorrect references to Sections 3.8.2.5 and 5.2.1.1 for this item. An item would be added to Table 1-1 listing the baseline ASME Code Edition and Addenda with reference to Section 5.2.1.1. The staff considers the applicant’s planned changes to the DCD provide consistency in the applicable DCD sections and are, therefore, acceptable. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

By letters dated April 28 and June 8, 2009, the applicant requested the use of Code Case N-782, “Use of Code Editions, Addenda, and Cases Section III, Division 1,” for the AP1000 design. This code case is not included in RG 1.84, Revision 34. As required by 10 CFR 50.55a(a)(3), the applicant requested approval for the use of this ASME Code case as a proposed alternative to the rules of 10 CFR 50.55a.

Code Case N-782 provides that the Code Edition and Addenda endorsed in a design certified by the regulatory authority may be used for systems and components constructed to ASME Code, Section III requirements. This Code case updates Paragraph NCA-1140 of ASME Code, Section III to address the licensing process under 10 CFR Part 52, “License, certifications, and approvals for nuclear power plants.” The applicant indicated that the use and approval of Code Case N-782 was needed to align ASME Code requirements to the ASME Code Edition and Addenda cited in AP1000 DCD Tier 2, Section 5.2.1.1. A reference to Code Case N-782 would be included in component and system design specifications and design reports to permit certification of these specifications and reports to the Code Edition and Addenda cited in the DCD and approved by the NRC. The applicant indicated that the use of Code Case N-782 facilitates the use of the ASME Code Edition and Addenda included in the AP1000 DC. Therefore, it would provide the same level of quality and safety as was included in the information reviewed for the AP1000 DC. The information provided in the applicant’s letter is generic and applies to all COL applicants referencing the AP1000 DC. The staff concludes that the use of Code Case N-782 provides an acceptable level of quality and safety and is, therefore, authorized pursuant to 10 CFR 50.55a(a)(3)(i). AP1000 DCD Tier 2, Table 5.2-3 will be revised to reference Code Case N-782. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

5.2.1.2.2 Conclusions

Based on the information provided in the applicant's responses to the RAIs, the staff finds that the AP1000 DCD amendment conforms to the guidance provided in RG 1.206, "Combined License Applications for Nuclear Power Plants." This satisfies the requirements of 10 CFR 50.55a and General Design Criteria (GDC) 1, "Quality Standards and Records," in Appendix A, "General Design Criteria for Nuclear Power Plants," to 10 CFR Part 50, "Domestic licensing of production and utilization facilities," and, therefore, is acceptable.

5.2.3 Reactor Coolant Pressure Boundary Materials

5.2.3.1 Evaluation of Zinc Addition to the Reactor Coolant

5.2.3.1.1 Summary of Technical Information

In Revision 16 to the AP1000 DCD, the applicant proposed design changes to incorporate the ability to inject zinc into AP1000 reactor coolant. In a letter dated April 5, 2006, the applicant submitted TR-32, "Zinc Addition," APP-GW-GLN-002, to provide technical justification for the proposed zinc addition into the reactor coolant.

The request consists of a modification to the AP1000 design to incorporate the ability to inject a small quantity of zinc acetate into the RCS. Operation with chemical zinc in the cooling system has been shown to change the oxide film on primary components, reducing occupational radiation exposure and the potential for crud formation, crud deposition on the fuel rods, and subsequent power shifts. The applicant proposed to provide zinc addition as an optional mode of operation.

Implementation of the requested zinc injection capability in the AP1000 results in the following Tier 2 changes to the DCD:

1. Add note 7 in Table 5.2-2, "Reactor Coolant Water Chemistry Specifications," to specify the maximum zinc concentration.

2. In Table 6.2.3-1 revise the chemical and volume control system hydrogen injection to the RCS line isolation device to be normally open.

3. Revise the third paragraph of Section 9.3.6.2.1, "Purification," to the effect that the mixed bed demineralizers will also remove zinc.

4. Add Section 9.3.6.2.3.3, "Zinc Addition," to the effect that zinc may be added.

5. Revise Figure 9.3.6-1 to include: Valve V092 is changed to normally open, a reducer is added downstream of V065, the portion of the H2/ZINC ADD line from the reducer to the return line is renumbered as L064, and the specification of L064 is changed to .5" BBC.

5.2.3.1.2 Evaluation

GDC 4, "Environmental and Missile Dynamic Effects Design Bases," requires that structures, systems, and components (SSCs) important to safety shall be appropriately protected against environmental and dynamic effects. The staff reviewed changes related to this section to ensure the compatibility of components with the environmental conditions created by the addition of zinc.

In letters dated August 1, 2006, and September 28, 2006, the staff requested additional information regarding the effects of zinc injection. The applicant responded in letters dated September 8, 2006, and December 12, 2006. The staff reviewed the responses and included that information in the overall evaluation, which follows.

Zinc acetate will be added using the same piping and valving as the hydrogen addition. The proposed hardware change is to replace a portion of the 2.5 centimeter (cm) (1-inch (in)) pipe (downstream from the containment isolation valve) with a heavier wall 1.3 cm (½-in) pipe. This will reduce the piping volume and substantially reduce the transit time for the hydrogen and the zinc acetate injected material. The integrity of the pressure boundary is not affected. Both hydrogen and zinc acetate injections have low transit velocities; thus, flow stability is not a problem. The containment isolation function signal, the containment isolation, the valve designation as active (Table 3.9-12 in the DCD), the safety-related mission, the inservice testing type and frequency requirements (Table 3.9-16), and the valve functional requirements for containment isolation (Tier 1, Table 2.3.2-1) are not affected.

The staff concludes that zinc addition in the primary coolant reduces radiation fields and the formation of crud, which may result in increased personnel exposure and in axial power shifts, respectively. Regarding the effect of zinc in reducing primary water stress-corrosion cracking, the applicant clarified that it no longer takes credit for the mitigation of this type of cracking based on zinc addition. The applicant believes that there is sufficient margin in the selection of new materials and that credit from zinc addition is not needed. The staff finds that the presence of zinc in the primary water will not cause aging-related degradation; therefore, it is acceptable.

The staff questioned the effect of the thin oxide film that forms in the presence of zinc with respect to the potential increase of the heat transfer coefficient and the potential increase in fuel and cladding operating temperature. The applicant submitted additional information in the form of cladding oxidation results that demonstrated that existing plant operational data (using ZIRLO™ cladding) did not exhibit increased oxidation, suggesting that the cladding is operating at comparable temperatures. The staff finds that the presence of zinc meets the requirements of GDC 4 and does not decrease the cladding-to-coolant heat transfer coefficient; thus, the staff finds the presence of zinc in the primary water to be acceptable. These changes are generic and are expected for all COL applications referencing the AP1000 certified design. At this time, the NRC has not issued a COL for any AP1000 plant.

5.2.3.1.3 Conclusions

On the basis of its review of TR-32, the staff finds that the requested modification for zinc addition to the primary water meets the requirements of GDC 4 and is acceptable for ZIRLO™ fuel cladding. Furthermore, the staff finds that the TR-32 conclusions regarding the evaluation for zinc addition to the primary water are generic and are expected to apply to all COL applications referencing the AP1000 DC. Therefore, the proposed DCD changes are acceptable pursuant to 10 CFR 52.63(a)(1)(vii) on the basis that they contribute to the increased standardization of the certification information.

5.2.3.2 Evaluation of Reactor Coolant Pressure Boundary Materials

5.2.3.2.1 Summary of Technical Information

In Revision 16 to the AP1000 DCD, the applicant proposed design changes related to the AP1000 pressure boundary materials. In a letter dated May 24, 2007, the applicant submitted TR-33, “Pressure Boundary Material Change” APP-GW-GLN-009, Revision 1, which provides technical justification for the design changes related to the AP1000 pressure boundary materials. The pressure boundary materials selection appears in DCD Tier 2, Section 5.2, Table 5.2-1. The pressure boundary materials changes identified in TR-33 are: (1) the revision of some material designators to be consistent with the ASME Code of Record for the RCS pressure boundary components, which is the 1998 Code and 2000 Addenda; (2) the correction of discrepancies in the AP1000 DCD in the specification of materials for some components; (3) the addition of materials to DCD Table 5.2-1 to address previously identified issues, to provide fabrication flexibility, and to ensure adequate material supply; (4) the relaxation of the maximum copper limit allowed in the reactor vessel beltline forging and weld material to reduce schedule risk and cost while maintaining the required performance; and (5) the relaxation of the maximum delta ferrite limit in weld materials to reduce schedule risk and cost while maintaining the performance requirements.

Revision 17 revised Section 5.2.3.1 of the AP1000 DCD, Tier 2, to include ASME Code Filler Metal Specifications SFA 5.1 and 5.17 for carbon steel, ASME Code Filler Metal Specification SFA 5.22 for stainless steel which allows the use of fluxed-cored filler metal to be used for welding the root pass, and ASME Code Filler Metal Specification SFA 5.30 for consumable inserts. Revision 17 also revised AP1000 DCD, Table 5.2-1, to allow an option to use carbon steel (SA-508, Class 1A) instead of alloy steel (SA-508, Grade 3, Class 2) on the pressure forgings (including nozzles and tubesheets for the SG), and allows an option to use carbon steel (SA-508, Grade 1) instead of stainless steel (SA-336, Grades F304, F304L, F304LN, F316, F316L and F316LN) on the pressure forgings for the RCP. In addition, Table 5.2-1 of the DCD was changed in Revision 17 to add material specification SA-338 for the pressurizer nozzle safe-ends, and to replace material specifications SA-312 and SA-376 for seamless pipe with material specification SA-479 for hot-rolled or cold-rolled bar stock with a unified numbering system (UNS) designation S21800.

The staff reviewed information in the AP1000 TR-33 that supports Revision 16 to the AP1000 DCD, along with the associated changes made in Revision 17. The staff’s findings are summarized below.

5.2.3.2.2 Evaluation of Revision 16 Changes

This evaluation addresses the impact of the changes identified in TR-33 related to the Class 1 pressure boundary materials, in such areas as the reactor vessel and internals, pressurizer, and SGs.

a. ASME Code of Record Update

Reactor vessel components (head plates, shell courses, shell flange, and appurtenances to the control rod drive mechanism (CRDM) material designators) were revised to be consistent with the ASME Code of Record for the RCS pressure boundary components, which is the 1998 Code and 2000 Addenda. These changes have no impact on the safety evaluation performed by the staff because the materials identified continue to meet the requirements of the ASME Code, Section III. Hence, the changes are acceptable.

b. Material Addition

Reactor vessel components (appurtenances to the CRDM, instrumentation tube appurtenances, and monitor tubes) materials have been added. The added materials have been used in pressurized-water reactors (PWRs) in the past. In addition, reactor vessel components (nozzle safe ends, appurtenances to the CRDM, instrumentation tube appurtenances, upper head, monitor tubes, and vent pipe materials) currently identified in the DCD and TR-33 include corresponding class, grade, or type. The identified added materials and the additional information on grades, types, or classes meet the requirements of the ASME Code, Sections II and III in accordance with the guidance of NUREG-0800 Section 5.2.3. Therefore, the inclusion of the identified materials and the additional information on grades, types, or classes presented in TR-33 have no impact on the conclusions reached by the staff in its review of the AP1000 DCD, Revision 15. Hence, the additions are acceptable. Section 4.5.1 of this report discusses the evaluation of the material changes for the CRDM components.

c. Reactor Vessel Beltline Forging and Weld Chemical Composition

The current AP1000 DCD, Revision 15, specifies maximum 0.03 weight-percent (wt%) copper (Cu) for reactor vessel beltline forgings and welds. The copper limits were established to address irradiation embrittlement concerns. TR-33 proposed that the copper limit for the reactor vessel beltline forging and weld material be 0.06 wt%. Forgings with specified maximum copper limits of 0.03 wt% are outside the current practice for the potential forging suppliers since most specifications are commonly in the range of 0.05 to 0.1 wt%.

Changing the wt% of copper impacts the end-of-life (EOL) reference temperature-pressurized thermal shock (RT_{PTS}), which is calculated according to the methodology prescribed in 10 CFR 50.61(c)(1), “Fracture toughness requirements for protection against pressurized thermal shock events.” However, even though the RT_{PTS} value is increased, there is still substantial margin from exceeding the screening criteria limit set forth in 10 CFR 50.61(b)(2). Table 5-1 summarizes the impact of increased copper on the EOL RT_{PTS} (using the current RT_{PTS} criteria).

Table 5-1. Impact of Increased Copper on the EOL RT_{PTS}

	EOL RT_{PTS} CU =.03 wt% Current Limit	**EOL RT_{PTS} CU = 0.06 wt% Proposed Limit**	**EOL RT_{PTS} Screening Criteria**
Beltline Forging	18.9 °Celsius (C) (66 °Fahrenheit (F))	34.4 °C (94 °F)	<132.2 °C (270 °F)
Beltline weld	36.7 °C (98 °F)	64.4 °C (148 °F)	< 148.9 °C (300 °F)

Based on the data shown in Table 5-1, the impact of higher copper content on the beltline weld and beltline forging EOL RT_{PTS} is small and does not challenge the screening criteria of 10 CFR 50.61(b)(2).

Adjusted reference temperature (ART) will be slightly increased because of the higher copper content and that will decrease the allowable operating temperature. However, this will not result in any significant restrictions on plant operations. The pressure-temperature (P/T) curve changes will not significantly affect the low-temperature overpressure protection (LTOP) system evaluation and the resulting parameters for the normal RNS relief valve.

Thus, the impacts of the increase in copper content of the beltline weld and beltline forging are insignificant. Taking into consideration the increase in copper content, the staff's review finds that the requirements of GDC 1 and GDC 31, "Fracture Prevention of Reactor Coolant Pressure Boundary," and 10 CFR 50.55a regarding quality standards are met by compliance with the provisions of the ASME Code, Section III, for the beltline forgings and weld materials. The materials also meet the requirements of Appendix G, "Fracture Toughness Requirements," to 10 CFR Part 50 and 10 CFR 50.61. Therefore, the staff's review finds the changes to the reactor vessel beltline forging and weld chemical compositions acceptable.

d. Delta Ferrite Limits

AP1000 DCD Revision 15, specifies an upper delta ferrite limit of 13 ferrite number (FN). The proposed change is to increase the upper-shelf limit to 20 FN and to clarify the acceptable methods to verify the delta ferrite content. The proposed change to the maximum delta ferrite content is 20 FN for filler metal compositions with low molybdenum contents and 16 FN for weld filler materials with higher molybdenum content, such as Types 316/316L. The increase in maximum allowable delta ferrite levels will increase the availability of suppliers and flexibility in fabrication, resulting in a decrease in cost and fabrication time without compromising material performance.

The upper-shelf limit of 20 FN is still within the guidelines established by the staff under RG 1.31, "Control of Ferrite Content in Stainless Steel Weld Metal," which states that weld pad test results showing an average FN from 5 to 20 indicate that the filler metal is acceptable for production welding of Class 1 and 2 austenitic stainless steel components and core support structures. In addition, the upper- and lower-shelf limit FN content is within the acceptance standards under ASME Code, Section III, NB-2000. Based on the discussion above, the change is within the limits prescribed by the staff and the ASME Code and is acceptable.

e. Primary and Auxiliary Piping

Section 3B.2, "Potential Failure Mechanisms for AP1000 Piping," of Appendix 3B, "Leak-Before-Break Evaluation of the AP1000 Piping," to the AP1000 DCD, Revision 15, states that SA312TP316LN- and SA304TP304L-grade steels selected for primary and auxiliary piping are both resistant to intergranular stress-corrosion cracking and wall thinning due to erosion-corrosion effects. The proposed change replaces the references from specific materials to a more generic statement, which calls for Series 300 stainless steel materials. The proposed change also states that these materials were chosen because of their proven operating experience in low- or no-oxygen environments with no incidents for a number of years. The proposed change also states that RG 1.44, "Control of the Use of Sensitized Stainless Steel," "will be used to maintain experiences of the PWR applications for the use of Series 300 stainless steel materials." The applicant also revised Table 5.2-1 of DCD Section 5.2 to include the specific material Types 304, 304L, 316, and 316L, in addition to the current Types 304LN and 316LN used for the reactor coolant pressure boundary components, including piping.

In proposing this change, higher carbon stainless steel materials (Types 304 and 316) could be used in the reactor coolant pressure boundary, including piping, and may be more susceptible to sensitization due to heat treatments or welding. However, for the applications proposed, the reactor coolant environment to which these materials will be exposed is either a low- or no-oxygen environment in part because of the use of oxygen scavenger chemicals such as gaseous hydrogen and hydrazine. Past operating experience with the use of Series 300 stainless steels in such low- or no-oxygen environments has not shown any significant challenges to piping integrity for a number of years. Therefore, the staff concurs that the use of Series 300 stainless steels is the most proven application in the fleet, taking into consideration operational experience. In addition, the DCD mentions RG 1.44 as the guideline followed in the selection and use of the material and the control methods to avoid sensitization. Therefore, the staff finds that the use of these stainless steel materials exposed to PWR reactor coolant water is acceptable. However, the staff notes that the use of these materials on any piping that implements leak-before-break will be verified as part of inspections, tests, analyses, and acceptance criteria (ITAAC) during the COL phase using the actual material properties and final, as-built piping analysis to ensure that the piping using these materials still meets the leak-before-break bounding analysis curves (which were originally evaluated for Types 304LN and 316LN piping material).

f. Steam Generators

TR-33 revises the material designations for pressure boundary components to be consistent with the ASME Code of Record (1998 Code with 2000 Addenda).

Table 5.1-2 of the DCD updates material class and grade designators. For example, the SG tubing material designator was revised from SB-163 TP 690TT to SB-163 N06690. ASME Specification SB-163 identifies the chemical and physical properties of the material and notes that the material is annealed. Section 5.2.3.1.1 of this report states that the SG tubes are made of thermally treated Alloy 690 material. Section 5.2.3.1, “Material Specifications,” of the DCD Revision 15 also states that the SG tubes use Alloy 690 in the thermally treated form.

The material designators for the SG manway closure studs and nuts were also updated to reflect the more correct way to identify bolting material. The studs are SA-193 Gr. B-7 and the nuts are SA-194 Gr. 2H.

The staff finds that the revisions and updates to the DCD related to the SG components do not alter the staff’s conclusions in NUREG-1793 and are consistent with NUREG-0800 Section 5.2.3. Furthermore, the requirements of GDC 1, GDC 30, “Quality of Reactor Coolant Pressure Boundary,” and 10 CFR 50.55a regarding quality standards are met for material specifications by compliance with the applicable provisions of ASME Code, Section III. Therefore, the staff finds these changes to the DCD related to SG components acceptable.

5.2.3.2.3 Evaluation of Revision 17 Changes

a. Use of Carbon Steel

Revision 17 to the AP1000 DCD proposed the use of carbon steel as an option for reactor coolant pressure boundary components, which include the SG and the RCP. Therefore, the staff requested the applicant provide justification and operating experience on the use carbon steel or remove the use of carbon steel in reactor coolant pressure boundary components.

In its December 31, 2009 response to RAI-SRP5.2.3-CIB1-01, Revision 1, the applicant stated that carbon steel is used only for those pressure boundary components which are not normally exposed to the reactor coolant (i.e., RCP components - stator main flange, stator shell and external heat exchanger supports). These components use carbon steel in lieu of 304 stainless steel due to the stresses induced by the studs and the main flange. Specifically, a 304 stainless steel main flange may experience an increase in the main flange stud load at operating conditions due to the thermal expansion between the steel studs and the 304 stainless steel main flange. Therefore, the carbon steel will provide a higher margin against stud/nut to main flange bearing stresses. In addition, Note 4 is proposed to be added to Table 5.2.3-1 of the AP1000 DCD to state the use of carbon steel base material and weld material are limited to only these components of the RCP. In addition, in its April 7, 2010 response to RAI-SRP5.2.3-CIB1-01, Revision 2, the applicant stated that carbon steel will not be used for the SG reactor coolant pressure boundary forgings, and proposed to remove the carbon steel material from Table 5.2-1. The staff notes that carbon steel is only used in 3 components for the RCP that is not in contact with the reactor coolant. Therefore, the staff finds the use of carbon steel for only non-wetted components of the RCP acceptable, and that there is no other use of carbon steel for the reactor coolant pressure boundary. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

b. Use of Flux-cored Welding in Root Pass

Revision 17 to the AP1000 DCD included the use of ASME Code Filler Metal Specification SFA 5.22, which allows the use of fluxed-cored filler metals to be used for welding the root pass in all stainless steel reactor coolant pressure boundary components. The staff has concerns that the use of flux-cored filler metal in the root pass may introduce slag inclusions in the root weld layer in contact with the reactor coolant, thereby providing a crack initiation site. In its August 12, 2009 response to RAI-SRP5.2.3-CIB1-01, Revision 0, the applicant stated that the use of flux bearing weld processes for root welds in which the root layer is exposed to the reactor coolant are prohibited unless the backside is first back-gouged to remove the root layer and re-welded from the backside. In addition, in its April 7, 2010 response to RAI-SRP5.2.3-CIB1-01, Revision 2, the applicant proposed Notes 3 and 8 to Table 5.2-1 of the AP1000 DCD, which specifies this prohibition of using flux-bearing filler metal for weld root passes. The NRC staff finds the use of fluxed-cored filler metals with the addition of Notes 3 and 8 to Table 5.2-1 of the AP1000 DCD acceptable since it prohibits the use of flux containing weld processes on the root layer, which would be in contact with the reactor coolant, thereby ensuring the weld integrity by minimizing the occurrence of a crack initiation site in the root layer. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

c. Use of Consumable Inserts

Section 5.2.3.1 of the AP1000 DCD, Revision 17 proposed the use of ASME Code Filler Metal Specification SFA 5.30 for consumable inserts for stainless steel. In addition, Table 5.2-1 of the AP1000 DCD, Revision 17 included Alloy 690 safe ends for the SG nozzle. However, Revision 17 did not include ASME Code Filler Metal Specification SFA 5.30 for consumable inserts joining the SG Alloy 690 safe ends to the RCP casing to ensure full penetration of the weld joint. In its response to RAI-SRP5.2.3-CIB1-01, Revision 3, dated July 9, 2010, the applicant stated that welding of the SG Alloy 690 safe end to the RCP casing is performed from both sides to achieve full penetration. The weld design features a double-sided weld since there is access to the second side for back-gouging and re-welding. Therefore, the staff finds the addition of SFA 5.30 acceptable for providing a weld joint to achieve full penetration, particularly for installation closure welds, and the use of a double-sided weld for the SG to the reactor coolant weld to ensure full penetration, which is in accordance with Section III of the ASME Code.

d. RCP – Use of Carbon Steel and the RCP Flywheel Analysis

Since carbon steel will be utilized in the RCP, the staff reviewed how this would affect the flywheel analysis described in Section 5.4.1.4 of this report. In its August 12, 2009 response to RAI-SRP5.2.3-CIB1-01, Revision 0, and its December 31, 2009 response to RAI-SRP5.2.3-CIB1-01, Revision 1, the applicant stated that carbon steel is only used for the stator main flange, stator shell and the external heat exchanger supports. The staff determined that since the flywheel analysis described in Section 5.4.1.4 only credits the RCP casing, thermal barrier, stator closure ring and the stator lower flange for containing the flywheel, the use of carbon steel has no impact on the flywheel analysis.

However, to clarify the use of the carbon steel base material and welding filler metal for the RCP, the applicant stated in response to RAI-SRP5.2.3-CIB1-01, Revision 1, that full penetration weld joints are used for welding the stator shell (carbon steel) to the stator main flange (carbon steel) and the stator lower flange (stainless steel). The stator shell (carbon steel) to the stator lower flange (stainless steel) is a dissimilar metal weld. The stator shell is buttered with ASME Code Filler Metal Specification 5.9, Classification ER309, and then the weld joining the lower flange to the ER309 buttering uses ASME Code Filler Metal Specification 5.9, Classification 308. Both welds have radiographic inspection requirements pursuant to Section III of the ASME Code, and are surface examined on both the inside and outside diameter surfaces. The staff finds the welding and inspections for the carbon steel components for the RCP will be performed in accordance with the criteria of Section III of the ASME Code for full penetration to ensure the integrity of the welded components.

However, the NRC staff noted that since Filler Metal Specification SFA 5.9, Classification ER309 is used for the weld buttering on the RCP stator shell, which is subsequently post-weld heat treated, the ER309 buttering may become sensitized when exposed to the post-weld heat treatment. In its response to RAI-SRP5.2.3-CIB1-01, Revision 2, dated April 7, 2010, the applicant proposed to add Note 5 to Table 5.2-1 of the AP1000 DCD to clarify the maximum carbon content for stainless steel welds, which would be exposed to post-weld heat treatment that may cause sensitization. In its response to RAI-SRP5.2.3-CIB1-01, Revision 3, dated July 9, 2010, the applicant further clarified the carbon content of stainless steels, which meets the guidance in RG 1.44. Therefore, since the maximum carbon content is specified to prevent sensitization and the guidance of RG 1.44 is used when post-weld heat treating stainless steel, the staff finds Note 5 acceptable. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

e. Use of EC and EQ

In addition, the applicant's letter dated April 7, 2010, proposed new changes to Table 5.2-1 of the AP1000 DCD to add strip electrodes (EQ) for SFA 5.9 filler materials, and composite cored/stranded electrodes (EC) for SFA 5.9 and SFA 5.14 filler materials from ASME Code, Section II. EQ filler materials currently listed in SFA 5.9 and SFA 5.14 of ASME Code, Section II are used for cladding purposes, and have been used in current operating plants. The use of this filler material allows increase weld surface area deposition, which is particularly beneficial when performing weld cladding of vessels. In its response to RAI-SRP5.2.3-CIB1-01, Revision 3, the applicant provided additional information on the use of EC filler material and clarified the use of EQ and EC in Table 5.2-1 of the AP1000 DCD. The applicant stated that EC filler material can be in the form of stranded wire and metal cored wire. The stranded wire is used primarily for automatic gas-tungsten arc welding since it is more flexible, which aids in smooth and consistent wire feeding into the weld puddle. The staff notes that EC filler material provides a more consistent and repeatable weld, which aids in minimizing welding defects, thereby improving the integrity of the weld. Therefore, the staff considers the use of EC filler materials specified in the Section II of the ASME Code acceptable.

The applicant also stated in its response to RAI-SRP5.2.3-CIB1-01, Revision 3, that the metal cored composite filler metal, EC, is used with the gas metal arc welding (GMAW) process, and due to the higher current density of these filler materials, results in higher weld deposition, and can be better controlled by the welder, thereby enabling acceptable welds to be produced consistently. The EC filler material contains no flux, and the mechanical and chemical properties of the resulting weld are identical to other filler materials used for the GMAW process. Therefore, the staff finds the use of EC filler material specified in SFA 5.9 of the ASME Code, Section II, acceptable since these filler materials produce welds that have the same chemical and mechanical properties as other SFA 5.9 filler materials allowed by the ASME Code. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

f. Use of 52M

In a letter dated April 7, 2010, the applicant proposed new changes to Section 5.2.3.1 and Table 5.2-1, Note 7, to include the use of ASME Code Filler Metal Specification 5.14, Type ENiCrFe-7A (UNS N06054) SFA 5.14. In its response to RAI-SRP5.2.3-CIB1-01, Revision 3, the applicant clarified that the use of the nickel alloy weld material in SFA 5.14, which includes UNS N06054 (Alloy 52M) would improve weldability. The NRC staff notes that N06054 filler material is more resistant to ductility dip cracking than UNS N06052 and W86152 filler materials, thereby ensuring the integrity of the weld. In addition, other filler material in this classification have been, and are currently being developed to further improve the weldability by minimizing the potential for both hot cracking and ductility dip cracking (microfissuring). Therefore, the staff agrees that the use of these filler material alloys developed for improved weldability for SFA 5.14, which are included in ASME Code, Section II, can be used since these filler materials provide an acceptable level of quality to ensure the integrity of the weld. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

g. Pressurizer Safe-ends

Material Specification SA-338, Grades F316, F316L and F316LN was added in Revision 17 of AP1000 DCD, Table 5.2-1 for the pressurizer safe-ends. However, the NRC notes that this material specification does not exist in ASME Code, Section II. In its response to RAI-SRP5.2.3-CIB1-02, dated December 11, 2009, the applicant changed the material specification to SA-336 to correct the editorial error. The staff finds the addition of Material Specification SA-336 for stainless steel acceptable for use on the pressurizer safe-ends since it is in Section II of the ASME Code and has acceptable operating experience in current plants. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

h. Use of Quickloc and SA-479

Table 5.2-1 of the AP1000 DCD was changed in Revision 17 to replace Material Specifications SA-312 and SA-376 (seamless pipe) with Material Specification SA-479 for hot-rolled or cold-rolled bar stock with no supporting justification or operating experience. In addition, the UNS designation S21800 for Material Specification SA-479 has higher carbon content than Types 304 and 316, along with lower chromium content with no molybdenum additions, thereby making the material susceptible to sensitization if welded. Therefore, the staff requested a discussion on the compatibility of this material with the reactor coolant, along with operating experience. In its response to RAI-SRP5.2.3-CIB1-01, Revision 1, the applicant stated that Material Specification SA-479 replaced SA-312 and SA-376 because the AP1000 design incorporated a Quickloc mechanism to replace the previous incore instrument thimble assemblies (IITAs). The new design includes eight Quickloc penetrations in lieu of the 42 individual IITA penetrations on the reactor vessel head. The applicant also provided operating experience for this material, which includes:

- Used for Quicklocs on several operating plants (Waterford 3, St. Lucie 1 and 2, and Calvert Cliffs 1 and 2) starting from the mid 1990’s.
- Used for core exit nozzle assembly pressure boundary parts since 1988 in approximately 50 plants worldwide.
- Used for various reactor vessel internal parts.

The Material Specification SA 479, UNS 21800 (also known as Nitronic 60) is procured in the solution annealed condition, and is used primarily for areas to minimize wear, galling and fretting due to the additions of silicon and manganese. The staff notes that although Nitronic 60 has a maximum carbon content of 0.10 percent versus 0.08 percent for Types 304 and 316 stainless steels, sensitization of the Nitronic 60 is not a concern for the Quickloc since it is provided in the solution annealed condition and is not subject to welding. In addition, intergranular corrosion tests are performed in accordance with the American Society for Testing and Materials (ASTM) A262-02a, Practice E, as outlined in RG 1.44, to ensure the material is not sensitized. The staff finds that the Nitronic 60 material has satisfactory operating experience in contact with the reactor coolant since the mid 1980’s and, therefore, finds the use of SA 479, UNS 21800 (Nitronic 60) to be acceptable for use in the Quickloc design, and is fabricated to ensure it is not sensitized. However, since the applicant stated that this material is not welded, the staff requested how the Quickloc mechanism is attached to the reactor vessel head.

In its response to RAI-SRP5.2.3-CIB1-03, Revision 0, dated January 15, 2010, and in response to RAI-SRP5.2.3-CIB1-03, Revision 1, dated March 21, 2010, the applicant stated that the Nitronic 60 material is used for the Quickloc plug and Quickloc nut, which are not welded, since these are mechanical parts. The Quickloc plug is inserted into the Quickloc instrument nozzle. The Quickloc instrument nozzles are welded to a weld-buildup of alloy steel on the reactor vessel head. The staff notes that this weld buildup (Material Specifications SFA 5.5, 5.23 or 5.28 of Section II to the ASME Code) is deposited on the top of the reactor vessel head and then machined to form a nozzle that penetrates the reactor vessel head. This weld build up nozzle has corrosion-resistant cladding applied to the inside diameter similar to the rest of the reactor vessel head. The applicant also stated that the buttering (Alloy 52/152) is applied to the top of the weld buildup to facilitate the welding of the Quickloc instrument nozzle to this buttering using Alloy 52/152. Therefore, there is a dissimilar metal weld using Alloy 52/152 attaching the

SA-182, Type 304 stainless steel Quickloc instrument nozzle to the Alloy 52 buttering on the alloy steel weld buildup nozzle. The applicant also provided information from the design drawing that the Quickloc instrument nozzle is welded to the Alloy 52/152 buttering after final post-weld heat treatment of the reactor vessel head. The staff finds that welding the Type 304 stainless steel Quickloc instrument nozzle after the final post-weld heat treatment of the reactor vessel closure head and Quickloc nozzle weld buildup minimizes the sensitization of the stainless steel Quickloc instrument nozzle. Therefore, the staff finds that the fabrication sequence of the Quickloc parts to the reactor vessel head using ASME Code, Section III ensures the integrity of the weld, including the final post-weld heat treatment of the reactor vessel head with the Quickloc nozzle weld buildup to ensure the material properties of the low alloy steel are retained.

In addition, the applicant stated that the Quickloc mechanism contains both pressure boundary and non-pressure boundary (internal structure) parts. The pressure boundary parts meet the requirements of ASME Code, Section III, Subsection NB, while the non-pressure boundary parts meet the requirements of ASME Code, Section III, Subsection NG. The staff finds the design and fabrication of the pressure boundary to be acceptable since it is evaluated in accordance with Class 1 requirements of ASME Code, Section III. The NRC staff also finds it appropriate for the design and fabrication of the non-pressure boundary parts to be designed and fabricated to the requirements of ASME Code, Section III, Subsection NG, which applies to reactor vessel internals and core support structures.

In regard to inspection during fabrication, the applicant provided the specific inspections to be performed for the pressure boundary parts in its response to RAI-SRP5.2.3-CIB1-03, Revision 0, dated January 15, 2010, and in response to RAI-SRP5.2.3-CIB1-03, Revision 1 dated April 21, 2010. These inspections included radiography and ultrasonic testing of the weld buttering and dissimilar metal weld. The weld buildup would also receive a magnetic particle inspection and an ultrasonic inspection, while the cladding and dissimilar metal weld would receive a liquid penetrant inspection. The inspections for the buttering and cladding would be performed in accordance with ASME Code, Section V, while the remainder of the inspections would be performed in accordance with Section III of the ASME Code, Subsection NB-5000. Since the fabrication inspections include volumetric examination of all the welds, and the inspections are in accordance with the ASME Code, the staff finds these inspections acceptable to ensure the integrity of the welds and base material.

However, to ensure the integrity of the welds is maintained, the NRC staff asked what type of inservice inspection is performed for these welds. In a letter dated January 15, 2010, the applicant stated that the dissimilar metal weld joining the stainless steel Quickloc instrument nozzle to the Alloy 52 buttering on the alloy steel Quickloc weld buildup requires an inservice inspection in accordance with Section XI of the ASME Code, Table IWB-2500-1, Item Number B5.10 (Category B-F). The NRC staff finds that Category B-F, Item Number B5.10 for dissimilar metal welds in pipe sizes larger than 10.2 cm (4 in) is the appropriate category for this weld to verify that the structural integrity is maintained as required by 10 CFR Part 50, Appendix A, GDC 30 and GDC 32, “Inspection of Reactor Coolant Pressure Boundary.”

In its response to RAI-SRP5.2.3-CIB1-03, Revision 1, the applicant stated that the Quickloc nozzle weld buildup is a base metal weld buildup, and is considered an extension of the reactor vessel head forging and, therefore, would require no inservice inspections. The NRC staff does not agree that inservice inspections are not required, since even a non-structural attachment weld to the reactor vessel, Examination Category B-K in the ASME Code, Section XI, requires a surface examination for inservice inspections. The staff also notes that the Quickloc nozzle weld buildup (maximum height of 37.03 cm (14.58 in) with a 19.1 cm (7.5 in) outside diameter and approximately 2.5 cm (1 in) thick) is designed as a nozzle penetration in the reactor vessel head, which forms the reactor coolant pressure boundary. Therefore, the overall dimensions of the weld buildup and the fact that this weld buildup serves as both a pressure boundary for the reactor coolant and a structural member to attach the Quickloc mechanism would necessitate that an inservice inspection be performed in order to verify that the structural integrity of the weld buildup is maintained as required by 10 CFR Part 50, Appendix A, GDC 30 and GDC 32.

In its response to RAI-SRP5.2.3-CIB1-03, Revision 3, dated August 3, 2010, the applicant stated that the inservice inspection of the Quickloc nozzle weld buildup is not a design issue and, therefore, should be addressed in the inservice inspection program to be developed by the COL applicant. Therefore, the applicant proposed a COL item in Section 5.3.6.6 of the AP1000 DCD, which states:

> The Combined License holder will establish an in-service inspection program prior to fuel load. The in-service inspection program will include the performance of a 100 percent volumetric examination of the weld build-up on the reactor vessel head for the instrumentation penetrations (Quickloc) conducted once during each 120-month inspection interval in accordance with the ASME Code, Section XI. The weld buildup shall meet the acceptance standards of ASME Code, Section XI, IWB-3514. Personnel performing examinations and the ultrasonic examination systems shall be qualified in accordance with ASME Code, Section XI, Appendix VIII. Alternatively, the Combined License holder may develop an alternative inspection in conjunction with the voluntary consensus standards bodies (i.e., ASME) and submit to the NRC for approval.

The staff agrees that the COL applicant should include the appropriate inservice inspection for the Quickloc nozzle weld buildup, since Section XI of the ASME Code does not specifically address this type of weld buildup on the reactor vessel head. The NRC also agrees that a volumetric examination (ultrasonic) of all eight Quickloc nozzle weld buildups performed with procedures and personnel with similar qualifications (ASME Code, Section XI, Appendix VIII) for other Class 1 ASME Code welds in the reactor coolant pressure boundary provides assurance of the integrity of this reactor coolant pressure boundary weld. The staff also finds the acceptance criteria of IWB-3514 for Category B-F welds in Section XI of the ASME Code is the appropriate acceptance standard for detecting the type of flaws that could affect the integrity of the Quickloc nozzle weld buildup and the reactor coolant pressure boundary. The staff notes that the inspection of the Quickloc nozzle weld buildup can be performed in conjunction with the adjacent dissimilar metal weld using the same inspection procedures. As experience is gained on this weld, technical basis for alternative examinations can be developed through the voluntary consensus standards body process, such as ASME, and submitted for NRC approval. Therefore, the staff finds that this COL item adequately addresses the concern for inservice inspection of the Quickloc nozzle weld buildup, because it ensures that the COL applicant's inservice inspection program will include the appropriate inservice inspection for this weld, thereby assuring its integrity as required by 10 CFR Part 50, Appendix A, GDC 30 and GDC 32. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

5.2.3.2.4 Conclusions

In summary, the staff finds that the requested modification for the materials is acceptable because it satisfies the requirements in Section VIII B.5.b or Section VIII B.5.c of

10 CFR Part 52, Appendix D, "Design Certification Rule for the AP1000 Design." The staff concludes that the changes to the pressure boundary materials in Revision 1 to TR-33 are technically acceptable. Section 4.5.1 of this report discusses the evaluation of the material changes for the CRDM components. The staff concludes that the TR-33, Revision 1, changes have been included in the AP1000 DCD are acceptable pursuant to 10 CFR 52.63(a)(1)(vii) on the basis that they contribute to the increased standardization of the certification information.

5.3 Reactor Vessel

5.3.2 Reactor Vessel Materials

5.3.2.1 Summary of Technical Information

In Revision 17 to the AP1000 DCD, the applicant proposed to resolve COL Information Item 5.3-3 (COL Action Item 5.3.2.2-1) by addressing the surveillance capsule lead factors and azimuthal locations in TR-23, "Surveillance Capsule Lead Factor and Azimuthal Location Confirmation," APP-GW-GLR-023, Revision 0, of September 2006. The applicant submitted TR-23 for staff review to demonstrate that it has met the requirements of COL Information Item 5.3-3. The submittal proposes a design change to locate the surveillance capsules in the minimum flux azimuthal locations to achieve lead factors in the range of 1.8 to 2.3, and as such satisfies the requirements in 10 CFR Part 50, Appendix H, "Reactor Vessel Surveillance Material Requirements," regarding surveillance capsule lead factors. The proposed change will eliminate the need for COL applicants to address the surveillance capsule lead factors and azimuthal locations requirement of COL Action Item 5.3.2.2-1.

In Section 5.3.6.3 of the AP1000 DCD, Revision 15, the COL action item states the following:

> The Combined License applicant will address confirmation of the surveillance capsule lead factors and azimuthal locations through an analysis which includes modeling of the capsule/holder.

In Revision 17 to the AP1000 DCD, the applicant proposed to resolve COL Information Item 5.3-3 by addressing the surveillance capsule lead factors and azimuthal locations in TR-23. The proposed revision to Section 5.3.6.3 of the DCD states the following:

> The Combined License information requested in this subsection has been completely addressed in APP-GW-GLR-023 (Reference 7), and the applicable changes are incorporated into the DCD. No additional work is required by the Combined License applicant to address the Combined License information requested in this subsection.
>
> The following words represent the original Combined License Information item commitment, which has been addressed as discussed above:
>
>> The Combined License applicant will address confirmation of the surveillance capsule lead factors and azimuthal locations through an analysis which includes modeling of the capsule/holder.

5.3.2.2 Evaluation

The surveillance capsule location in Figure 5.3-4 in Revision 15 of the DCD is at 29.70 degrees on either side of the 0- to 180-degree axis. The total number of surveillance capsules is eight. In this location, the estimated lead factor is outside (higher than) the range recommended in ASTM Standard E 185-82, “Standard Practice for Conducting Surveillance Test for Light-Water Cooled Nuclear Power Reactor Vessels,” incorporated by reference into Appendix H to 10 CFR Part 50. To resolve this issue, the applicant proposed to use the locations (at the azimuthal minimums of the neutron flux, E > 1.0 million electron volts) at 45, 135, 225, and 315 degrees. However, the 45-degree location cannot be used because of mechanical interference with reactor internals; therefore, it is proposed to have three capsules per location at the 135- and 315-degree locations and two capsules at 225 degrees.

The applicant performed an analysis for the anticipated range of lead factors at the proposed locations, and the results indicate that the values are in the range 1.8 to 2.3 (i.e., within the required values in Appendix H). The calculations were carried out for an equilibrium core power distribution and adhere to the guidance in RG 1.190, “Calculational and Dosimetry Methods for Determining Pressure Vessel Neutron Fluence.” As stated in the guide, the cross-sections used (BUGLE-96) are based on the ENDF/B-VI file, the scattering cross-section approximation is the P_3 Legendre polynomial expansion, the angular quadrature approximation is S_8, and a 1/8 core symmetry was used. Because the 225-degree location contains only two capsules, two 1/8 core symmetry models were developed, one each for the two- and the three-capsule arrangements. Both models are based on the synthesis method; that is, the three-dimensional power distribution is derived from the synthesis of the (r, θ) and (r, z) distributions. The flux and fluence distributions derived in this manner are acceptable because the applicant followed the guidance in RG 1.190. This satisfies the requirements in GDC 14, “Reactor Coolant Pressure Boundary,” GDC 30, and GDC 31.

Section 5.3.6.3 of the DCD, Revision 17, references TR-23 in its entirety. Although the entire report can be referenced for additional information, the staff finds that for clarity and completeness of the DCD as a stand-alone document, the DCD should include portions of the TR describing important design details. The staff issued RAI-SRP5.3.1-CIB1-01 on February 19, 2008, asking the applicant to include the following information in the AP1000 DCD: (1) the azimuthal locations of the capsules (in degrees) and the basis for these locations; (2) the calculated lead factors; and (3) Figure 1, “Surveillance Capsule Azimuthal Location.” The applicant’s RAI response, dated March 28, 2008, appropriately described the changes to the DCD to incorporate information from the TR. These design details were incorporated into Section 5.3.2.6 and Figure 5.3-4 of Revision 17 and subsequent DCD revisions.

In addition, the submittal states that the applicant examined the presence of the surveillance capsules in the proposed locations and concluded that there is no interference with required potential actions to mitigate severe accidents.

The staff found that the DCD, Revision 16 changes discussed by the applicant in TR-23 meet the requirements of Appendix H to 10 CFR Part 50 and are acceptable. Therefore, AP1000 COL Information Item 5.3-3 is resolved. These DCD changes are generic and are expected for all COL applications referencing the AP1000 certified design. At this time, the NRC has not issued a COL for any AP1000 plant. Thus, the changes incorporated into Revision 17 contribute to the increased standardization of the certification information in the AP1000 DCD.

5.3.2.3 Conclusions

On the basis of its review of TR-23 and the associated changes to the DCD, the staff concludes that the proposed change meets the requirements of Appendix H to 10 CFR Part 50, and that the applicant has provided sufficient design information to close out COL Information Item 5.3-3. Furthermore, the staff finds that the TR-23 conclusions regarding the surveillance capsule lead factors and azimuthal locations are generic and are expected to apply to all COL applications referencing the AP1000 DC. Therefore, the proposed DCD changes are acceptable pursuant to 10 CFR 52.63(a)(1)(vii) on the basis that they contribute to the increased standardization of the certification information.

5.3.3 Pressure-Temperature Limits

5.3.3.1 Introduction

In Revision 16 of the AP1000 DCD, the applicant included generic bounding P/T limits. In a letter dated May 30, 2008, the applicant submitted APP-RXS-Z0R-001, "AP1000 Generic Pressure Temperature Limits Report," Revision 1, which describes the generic pressure-temperature limits report (PTLR) for the AP1000. The generic bounding P/T limits in Revision 17 to the DCD are the same P/T limits used in the generic PTLR. The applicant plans to have AP1000 COL applicants use the generic PTLR described in APP-RXS-Z0R-001, Revision 1, when developing their plant-specific P/T limits.

The applicant submitted TR-33 and supporting information in a letter dated June 7, 2007, to provide technical justification for the proposed changes. The staff's evaluation of the proposed changes is provided below.

5.3.3.2 Evaluation

The NRC has established requirements in 10 CFR Part 50 to protect the integrity of the reactor coolant pressure boundary in nuclear power plants. The staff evaluates P/T limit curves based on the following NRC regulations and guidance: 10 CFR Part 50, Appendix G; RG 1.99, Revision 2, "Radiation Embrittlement of Reactor Vessel Materials," issued May 1988; and NUREG-0800 Section 5.3.2. RG 1.99 describes the methodologies for determining the increase in transition temperature and the decrease in upper-shelf energy resulting from neutron irradiation. Appendix G to 10 CFR Part 50 requires that P/T limit curves for the reactor pressure vessel (RPV) be at least as conservative as those obtained by applying the methodology of Appendix G to ASME Code, Section XI.

a. Background

NUREG-0800 Section 5.3.2 provides an acceptable method of determining the P/T limit curves for ferritic materials in the beltline of the RPV based on the linear elastic fracture mechanics methodology of Appendix G to ASME Code, Section XI. The basic parameter of this methodology is the stress intensity factor, K_I, which is a function of the stress state and flaw configuration. Appendix G to ASME Code, Section XI, requires a safety factor of 2.0 on stress intensities resulting from reactor pressure during normal and transient operating conditions, and a safety factor of 1.5 on stress intensities resulting from hydrostatic testing. Appendix G to ASME Code, Section XI, also requires a safety factor of 1.0 on stress intensities resulting from thermal loads for normal and transient operating conditions as well as for hydrostatic testing. The methods of Appendix G postulate the existence of a sharp surface flaw in the RPV that is normal to the direction of the maximum stress (i.e., of axial orientation). This flaw is postulated to have a depth that is equal to 1/4 of the RPV beltline thickness and a length equal to six times its depth. The critical locations in the RPV beltline region for calculating heatup and cooldown P/T limit curves are the 1/4 thickness (1/4T) and 3/4T locations, which correspond to the maximum depth of the postulated inside surface and outside surface defects, respectively. The methodology found in Appendix G to ASME Code, Section XI, requires that licensees determine the ART (or adjusted RT_{NDT}) at the 1/4T and 3/4T locations. The ART is defined as the sum, the initial (unirradiated) reference temperature (initial RT_{NDT}), the mean value of the adjustment in reference temperature caused by irradiation (ΔRT_{NDT}), and a margin term.

RG 1.99 provides guidance on the determination of ΔRT_{NDT} and the margin term. ΔRT_{NDT} is a product of a chemistry factor and a fluence factor. The chemistry factor is dependent upon the amount of copper and nickel in the material and may be determined from tables in RG 1.99, or from surveillance data. The fluence factor is dependent upon the neutron fluence at the maximum postulated flaw depth. The margin term is dependent upon whether the initial RT_{NDT} is a plant-specific or a generic value and whether the chemistry factor was determined using the tables in RG 1.99, or surveillance data. The margin term is used to account for uncertainties in the values of the initial RT_{NDT}, the copper and nickel contents, the fluence, and the calculation procedures.

b. The Applicant's Evaluation

In RAI-TR33-001, dated April 23, 2007, the staff asked the applicant to provide the following information:

1. Detailed methodology used in the development of the P-T limit curves.
2. Beltline material properties (Cu, Ni) assumed, including initial RT_{NDT} of materials.
3. Fluence assumed in the calculation of adjusted of RT_{NDT}.
4. P/T data points.

The applicant provided this information in a letter dated June 7, 2007, since it plans for the curves to be used by the COL holders as bounding curves.

The methodologies provided by the applicant are consistent with those in Westinghouse Commercial Automatic Power (WCAP)-14040-A, "Methodology Used to Develop Cold Overpressure Mitigating System Setpoints and RCS Heatup and Cooldown Limit Curves," Revision 4 of May 2004. The P/T limits, which are valid for up to 54 effective full-power years (EFPYs) of operation, were calculated with chemistry factors obtained from the tables in RG 1.99. As discussed in Section 5.2.3.2.2 of this report, the applicant proposed (and the staff agrees with) changing the maximum wt% of copper to 0.06 percent. This is the value the applicant used for the calculations of AP1000 bounding P/T limit curves. The initial RT_{NDT} values are generic values for the design. Table 5-2 shows the values the applicant has provided for limiting ART calculations of the beltline girth welds at two locations.

Table 5-2. Values for Limiting ART Calculations of the Beltline Girth Welds

	1/4T Location	3/4T Location
Fluence at 54 EFPYs	1.510×10^{19}	5.51×10^{18}
Chemistry Factor	82	82
ΔRT_{NDT}	32.9 °C (91.3 °F)	20.2 °C (68.3 °F)

Table 5-2. Values for Limiting ART Calculations of the Beltline Girth Welds

	1/4T Location	3/4T Location
Initial RT_{NDT}	-28.9 °C (-20 °F)	-28.9 °C (-20 °F)
Margin	18.6 °C (65.5 °F)	18.6 °C (65.5 °F)
ART	58.3 °C (137 °F)	45.6 °C (114 °F)

In addition, the applicant provided P/T data points without margins for instrumentation errors. The staff used this information to evaluate the acceptability of the proposed bounding P/T limit curves.

c. Evaluation

As discussed previously, the applicant requested approval for bounding P/T limit curves to be used by COL holders with the AP1000 design. The staff performed independent calculations of the ART values using the methodology in RG 1.99. Based on these calculations, the staff verified the limiting ART values at the beltline girth welds.

Given the acceptability of the applicant's calculated ART values for the limiting beltline material to 54 EFPYs, the staff evaluated the P/T limit curves for acceptability by performing a finite set of check calculations based on information submitted by the applicant and by using the methodologies referenced in the ASME Code (as indicated in NUREG-0800 Section 5.3.2). The staff verified that the proposed P/T limit curves satisfy the requirements in Section IV.A.2 of Appendix G to 10 CFR Part 50.

In addition, Appendix G to 10 CFR Part 50 also imposes a minimum temperature at the closure flange region based on the reference temperature for the flange material. Section IV.A.2 of Appendix G to 10 CFR Part 50 states that when the pressure exceeds 20 percent of the preservice system hydrostatic test pressure, the temperature at the closure flange region, which is highly stressed by the bolt preload, must exceed the reference temperature of the material in that region by at least 71.1 °C (160 °F) for core critical operation, 48.9 °C (120 °F) for normal, noncritical core operation, and by 32.2 °C (90 °F) for hydrostatic pressure tests and leak tests. Based on this limiting flange reference temperature, the staff has determined that the proposed P/T limits have satisfied the above requirements for the closure flange region during all modes of normal operation and for hydrostatic pressure and leak testing.

Based on this independent assessment, the staff concludes that the applicant's proposed P/T limit curves meet the requirements of Appendix G to 10 CFR Part 50 and are acceptable for operation of an AP1000 design through 54 EFPYs of facility operation. This determination; however, is only valid for the material properties and the projected fluence identified in this SER. Any changes to these values will require additional review. Revision 17 to the AP1000 DCD includes these revised P/T limit curves.

These revised P/T limits are generic and may be used by COL holders referencing the AP1000 certified design, contingent upon verification by the COL holder of the material properties and fluence projection. At this time, the NRC has not issued a COL for any AP1000 plant. Therefore, the proposed P/T limits contribute to the increased standardization of the certification information in the AP1000 DCD.

In AP1000 DCD, Revision 15, COL Information Item 5.3.6.1, the applicant stated that COL applicants will address the use of plant-specific P/T limits. In TR-6, "AP1000 As-Built COL Information Items," APP-GW-GLR-021, Revision 0 of June 2006, the applicant proposed to change the responsibility from the COL applicant to the COL holder. However, in subsequent discussions between the NRC staff and the applicant, the applicant decided to provide a generic PTLR in conjunction with a future AP1000 DCD amendment for use by AP1000 COL applicants. Upon review and approval of the PTLR, COL applicants will be able to use it for their respective plants as long as the PTLR methodology remains the same. In conjunction with the Bellefonte reference COL application review, the staff is requesting the COL applicant provide license conditions in which the COL holder will be required to: (1) update its P/T limits using the PTLR methodologies approved in the AP1000 DCD and using plant-specific material properties; and (2) to inform the NRC of its plans to use updated P/T limits. The applicant provided its generic PTLR for NRC review and approval in a letter dated May 30, 2008. The NRC discussed its evaluation of the PTLR in a letter to the applicant dated December 30, 2008. However, the staff finds that the applicant needs to provide the PTLR reference in its DCD. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

In reviewing the AP1000 PTLR, the staff noted one inconsistency between the AP1000 PTLR and Revision 17 to the DCD concerning the listed nickel content of the circumferential reactor vessel beltline weld. Table 3 of the AP1000 PTLR listed the maximum allowable nickel content as 0.95 percent by weight. However, Table 5.3-1 in Revision 17 of the DCD listed the maximum allowable nickel content as 0.85 percent. In RAI-SRP5.3.2-CIB1-01 dated July 31, 2008, the NRC asked the applicant to resolve this discrepancy by amending either the DCD or the AP1000 PTLR to specify the same maximum nickel content of 0.85 percent or 0.95 percent. In its response dated September 5, 2008, the applicant indicated that the actual limiting value of the nickel content of the reactor vessel beltline weld is 0.85 percent by weight. Furthermore, the applicant indicated that this limiting nickel content value would be changed in Table 3 of the AP1000 PTLR to be 0.85 percent, consistent with the value established in Section 5.3 of the AP1000 DCD, Revision 17. In a letter dated April 2, 2009, the applicant provided Revision 2 of the AP1000 PTLR, which includes the proposed changes. The staff finds that the applicant has appropriately addressed the RAI and has verified that Revision 2 of the AP1000 PTLR incorporates the proposed revision to the maximum nickel content. As a result, RAI-SRP5.3.2-CIB1-01 is closed.

Criterion 3 of PTLR (Reference generic letter (GL) 96-03, "Relocation of the Pressure Temperature Limit Curves and Low Temperature Overpressure Protection System Limits") requires the evaluation of the LTOP system. AP1000 Technical Specification Limited Condition for Operation (LCO) 3.4.14 does not specify the normal RNS suction relief valve lift pressure setpoint. The applicant should revise LCO 3.4.14 to state that the RNS suction relief valve lift setpoint be within the specified limit in the PTLR. In a letter dated May 20, 2009, the applicant provided a supplemental response to RAI-SRP5.3.2-CIB1-02, which includes a revision to the PTLR with the following addition:

> 2.1 Low Temperature Overpressure Protection (LTOP) System
>
> > The Normal Residual Heat Removal System (RNS) pump suction line relief valve will have a lift setpoint of 500 psig with a full open pressure of 550 psig. The lift setpoint has been developed using the NRC approved methodology specified in Reference 2.

From the review of the applicant's response, the staff concludes that the provisions in the response are acceptable because they adequately address PTLR Criterion 3 of GL 96-03. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

5.3.3.3 Conclusions

The staff finds that the proposed bounding P/T limit curves meet the requirements of Appendix G to 10 CFR Part 50 and are acceptable for the stated material properties and projected fluence for 54 EFPYs. Furthermore, the staff finds that the TR-33 conclusions regarding the bounding P/T limit curves are generic and are expected to apply to all COL applications referencing the AP1000 DC. The staff reviewed and approved the applicant's PTLR methodology for the AP1000. Therefore, the proposed DCD changes are acceptable pursuant to 10 CFR 52.63(a)(1)(vii) on the basis that they contribute to the increased standardization of the certification information.

5.3.6 Reactor Vessel Insulation

The applicant has completed the design of the reactor vessel insulation system (RVIS). In TR-24, "Reactor Vessel Insulation System - Verification of In-Vessel Retention Design Bases," APP-GW-GLR-060, the applicant provided information to demonstrate that the RVIS is designed to provide adequate cooling to ensure in-vessel retention of a damaged and relocated core. On this basis, the applicant proposed to close COL Information Item 5.3-5 (COL Action Item 19.2.3.3.1.3.2-1). The staff's evaluation of the RVIS design is in Section 19.2.3.3.1.3.2 of this report.

5.4 Reactor Coolant System Component and Subsystem Design

5.4.1 Reactor Coolant Pump Assembly

5.4.1.1 Summary of Technical Information

In Section 5.4.1 of Revision 17 of the DCD, the applicant proposed to make changes related to the certified RCP design. These changes include: (1) change of the canned motor RCP design description to a more generic sealless pump; (2) use of an externally mounted heat exchanger; (3) change of the RCP flywheel design from depleted uranium to bimetallic construction; and (4) other miscellaneous changes.

5.4.1.2 Pump and Motor Design

The certified AP1000 RCP design, as described in Section 5.4.1.2.1, "Design Description," of Revision 15 to the DCD, is a single-stage, hermetically sealed, high-inertia, centrifugal canned motor pump. In TR-34, "AP1000 Licensing Design Change Document for Generic Reactor Coolant Pump," submitted by letter dated November 17, 2006, the applicant proposed to replace the specific term "canned motor pump" with a generic sealless pump design to provide flexibility in the selection of a specific pump design and pump vendors. In DCD Revision 17, the applicant revised Section 5.4.1.2.1 to replace the term "canned-motor pump" with the phrase "sealless pump of either canned motor or wet winding design." In addition, in many DCD Tier 2 sections (e.g., Sections 1.9.3, 1.9.4.2.3, 1.9.5.1.6, 3.5.1.2.1.4, 3.9.2.3, 4.4.4.6, 5.1.2, and 5.1.3.3 and Table 5.1-2) associated with the RCPs, the applicant replaced the term "canned-motor pump" with "sealless pump," or "sealless pump of canned motor design." In

DCD Tier 1, Section 2.1.2, “Reactor Coolant System,” the applicant replaced the term “canned motor reactor coolant pumps” in the design description with the phrase “sealless reactor coolant pumps.”

The canned motor pump design contains the motor and all rotating components inside a pressure vessel designed for full RCS pressure. Since the shaft for the impeller and rotor is contained within the pressure boundary, seals are not required to restrict leakage out of the pump into containment. Thus, the concern regarding RCP seal failure is eliminated. The staff agrees that the use of the generic term “sealless pump” achieves the same objective as specifying a “canned motor pump” with regard to the seal failure concern. However, the NRC had based its review and acceptance of the AP1000 DCD on the canned motor pump design. In DCD Revision 16, the applicant did not provide materials related to the wet winding pump design.

Revised DCD Figure 5.4-1, “Reactor Coolant Pump,” and Reference 10 in DCD Section 5.4.16 are based on a canned motor pump. In the June 7, 2007, response to RAI-TR34-1, the applicant stated that the RCP design and licensing basis for the standard AP1000 plant is the canned motor RCP. In the October 5, 2007, response to RAI-TR34-SRSB-01, the applicant stated that for an applicant to use the wet winding sealless RCP, Reference 10 in Section 5.4.16 and Figure 5.4-1 of the DCD would need to be changed in the COL FSAR to incorporate the wet winding sealless design. This change would be a departure from the DCD and would open licensing review of the design change. Detailed design information on a wet winding sealless RCP design would be needed for NRC review and approval. In the April 11, 2008, response to RAI-SRP5.4.1-CIB-01, the applicant proposed changes to DCD Revision 16 to identify the canned motor design as the RCP design for the standard design, eliminating the mention of the wet winding motor design from the DCD. In DCD Revision 17, the applicant revised Section 5.4.1.2.1 to state that the RCP is a “single-stage, hermetically sealed, high-inertia, centrifugal sealless pump of canned motor design.” This sentence is re-classified as Tier 2* information in that staff approval is required before implementing a change in this information. Therefore, the AP1000 design basis for the RCP is a sealless pump of canned motor design. Use of a sealless pump design of another type, such as a wet winding motor design, would be a departure from the DCD and would require detailed design information in the COL FSAR for NRC review and approval. The staff finds this acceptable.

In DCD Tier 1, Section 2.1.2, “Reactor Coolant System,” the applicant also replaced the term “canned motor reactor coolant pumps” in the design description with the phrase “sealless reactor coolant pumps.”

5.4.1.3 Heat Exchanger Design

In DCD Revision 17, the applicant proposed to change the heat removal design of the RCP by using an externally mounted, conventional shell and tube heat exchanger and a stator cooling jacket to replace the existing thermal barrier internal cooling coils and wraparound heat exchanger configuration. The applicant revised DCD Sections 5.4.1.2.1 and 5.4.1.2.2 to describe the revised motor cooling arrangement. An auxiliary impeller at the lower part of the rotor shaft circulates a controlled volume of the reactor coolant through the motor cavity, where the rotor, bearing and stator are cooled, and through an external heat exchanger where the coolant is cooled to about 65 °C by the component cooling water (CCW) circulating on the shell side. The CCW also circulates through a cooling jacket on the outside on the motor housing to cool the stator. The applicant revised DCD Figure 5.4-1 to show the external heat exchanger configuration. In addition, it revised DCD Section 5.4.1.3.3, “Pressure Boundary Integrity,” to include the external piping and tube side of the external heat exchangers as a part of the pressure boundary components that meet the requirements of ASME Code, Section III.

In TR-34, the applicant explained that it changed to an external heat exchanger for the RCP because as the detailed design of the pump progressed, the increased heat transfer requirements on the heat exchanger resulting from increased motor power requirements and the effects of design transients on motor operation have resulted in significant manufacturing challenges associated with the wraparound heat exchanger design. Therefore, a conventional shell and tube heat exchanger mounted on the pump flange is implemented to replace the current wraparound heat exchanger.

In its June 7, 2007, response to RAI-TR34-2, the applicant summarized the RCP cooling design. This includes the heat source from motor electrical loss, fluid and friction losses, hot primary coolant crossing the thermal barrier into the motor, and the heat removal capacity of heat exchanger and water jacket. The external heat exchanger is specified to remove 2.4 megawatts with 540 gallons per minute (gpm) of CCW at 35 °C and 600 gpm of primary flow at 69 °C. In the October 5, 2007, supplemental response to RAI-TR34-SRSB-02, the applicant indicated that the RCP design specification defining the external heat exchanger design requirements is passed to the external heat exchanger supplier.

Establishment of the design requirements allows for the finalization of the design. The external heat exchanger generic design report will provide detailed design information for the external heat exchanger. In its July 3, 2008, response to RAI-SRP5.4.1-SRSB-01, the applicant indicated that this design report would be available for NRC review on October 31, 2008. In addition, each pump would be performance tested with the heat exchanger intended for field use before shipment. The applicant also indicated that the auxiliary impeller has been designed for an Euler head rise of 240 feet (ft) at 1782 revolutions per minute. Prototype RCP testing in the future will verify that the actual bearing water flow rate is sufficient to satisfy design requirements. If an unpredicted difference occurs between the calculated bearing water flow rate and the measured test value, an easily implemented design change of adding an annular ring to the motor shaft may be executed to increase auxiliary impeller flow capacity.

The staff identified review and acceptance of the external heat exchanger design report as Open Item OI-SRP5.4.1-SRSB-01.

In a letter dated March 26, 2010, the applicant submitted a response to Open Item OI-SRP5.4.1-SRSB-01 that included the external heat exchanger design specifications regarding its functions and design requirements. The design specifications specify the objective of the external heat exchanger to cool primary side water used in a RCP motor, and specify that the primary-side and secondary-side components of the heat exchanger shall meet Section III, Division 1, Class 1 and Class 3, respectively, of the ASME Code. In addition, the external heat exchanger shell will serve as supports for Section III, Class 1 heat exchanger tubes that form part of the primary pressure boundary, and as such cannot be allowed to fail in such a way as to prevent the Class 1 pressure boundary from performing its function. The heat exchanger design requirements specify the heat exchanger configuration and nozzle size, the design basis life of 60 years, normal operating conditions, allowable pressure drop of the primary and secondary sides, design pressure and temperature, and thermal transient operating conditions, material, and vibration analysis. Regarding the vibration analysis, it specifies that the heat exchanger shall be designed to avoid flow-induced tube vibration under maximum expected flows and design temperature conditions. The adequacy with respect to flow-induced vibration shall be demonstrated by either: (a) an identical heat exchanger having operated satisfactorily under flow and temperature conditions at least as severe as those expected for the heat exchanger; or (b) the maximum expected secondary side flow velocities will be below the critical velocities for fluid-elastic excitation, and the lowest tube natural frequency exceeds by a factor of 1.5 the vortex shedding frequency calculated for the maximum expected secondary side flow velocity. Based on this review, the staff concludes that the applicant has successfully addressed the open item; therefore, Open Item OI-SRP5.4.1-SRSB-01 is closed.

5.4.1.4 Reactor Coolant Pump Flywheel Integrity

5.4.1.4.1 Summary of Technical Information

In Revision 16 to the AP1000 DCD, the applicant proposed to change the RCP design from a canned motor RCP with a depleted uranium flywheel to a generic sealless RCP with a bimetallic flywheel assembly. TR-34 identified changes to the design of the RCP and the technical justification for the proposed changes.

The AP1000 DCD, Revision 15, had specified a canned motor RCP with a depleted uranium flywheel. The Revision 16 changes to the AP1000 DCD specify a generic sealless RCP with a bimetallic flywheel assembly. Changing to a generic sealless RCP will provide flexibility in selecting a specific pump design and thus increase the number of possible pump vendors. Revision 16 to the AP1000 DCD includes a revised flywheel assembly design of bimetallic construction.

Concerning the material specifications for the flywheel, TR-34 stated that the preliminary flywheel design (in Revision 15 of the AP1000 DCD) employed an upper and lower flywheel assembly constructed of forged depleted uranium disks fitted to an inner stainless steel hub, which was fitted to the motor shaft. Structural integrity of the flywheel assemblies relied upon the strength of the depleted uranium forged disks. The depleted uranium flywheel was designed to meet the minimum rotating inertia value, 695.3 kilograms - square meter (kg-m^2) (16,500 pounds - square foot (lb-ft^2)), given in DCD Tier 2, Table 5.4-1. As the design progressed, it was determined that this inertia value needed to be increased to meet the pump coastdown used in the safety analyses as given in DCD Figure 15.3.2-1. To achieve the required inertia, the depleted uranium flywheel design required increases in length and/or diameter. However, increases in diameter resulted in stress levels beyond the design criteria limits and increases in length resulted in violation of the RCP space envelope as well as unacceptable rotor dynamics. Therefore, a revised flywheel assembly design of bi-metallic design with heavy tungsten alloy inserts was developed.

In a letter dated September 28, 2007, the applicant provided additional information concerning the materials and design of the flywheel assembly. The design features heavy tungsten alloy annular or cylindrical segments, which are machined and fitted around a central Type 403 stainless steel hub. The segments are held in place by an interference fit of an 18-Ni maraging steel retainer cylinder placed over the outside of the assembly. Alloy 690 endplates and an outer thin shell hermetically seal the assembly from primary coolant. Structural integrity of the flywheel assembly relies upon the stainless steel hub and the retainer cylinder. Both the upper and lower flywheels are of the same design.

In a letter dated June 12, 2007, the applicant submitted TR-106, “AP1000 Licensing Design Changes for Mechanical Systems and Component Design Updates,” which revised the flywheel enclosure (endplates and outer thin shell) materials. Design change 245 in TR-106 stated that the applicant would revise Section 5.4.1.3.6.3 of the AP1000 DCD by replacing references to

“Alloy 690” with the phrase “corrosion resistant material” for the flywheel enclosure (endplates and outer thin shell) to meet the intent of creating a generic RCP design description that would facilitate other future RCP suppliers. In addition, the applicant stated that the RCP supplier had proposed the material change from Alloy 690 to Alloy 625 because of the low coefficient of thermal expansion and better weldability of Alloy 625. In a letter dated October 5, 2007, the applicant provided supporting information concerning the test results and experience of using Alloy 625 in contact with the reactor coolant. The applicant also concluded that the AP1000 DCD should not include such detailed design information as referencing the specific material (i.e., Alloy 625); therefore, the AP1000 DCD would only specify “corrosion-resistant material.”

5.4.1.4.2 Evaluation

GDC 4 requires that SSCs important to safety shall be appropriately protected against environmental and dynamic effects, including the effects of missiles that may result from equipment failure. GDC 1 requires that SSCs important to safety shall be designed, fabricated, erected, and tested to quality standards to ensure a quality product in keeping with the required safety function. The staff’s view of the Revision 16 changes related to Section 5.4.1.3.6.3 of the DCD is that they minimalize the potential for RCP flywheel failures and that the materials are adequate to ensure a quality product commensurate with the importance to safety.

Section 5.4.1.2.1 of the AP1000 DCD, Revision 16, changes the pump design from standard (canned motor) to a more generic “sealless” pump design (canned motor, wet-winding, etc.). The applicant revised Section 5.4.1.3.6.3 of the AP1000 DCD, Revision 16, to state that the analysis to determine the capacity of the housing to contain the fragments of the bi-metallic flywheel appears in Curtiss-Wright Electro-Mechanical Corporation Report AP1000 RCP-06-009-P, “Structural Analysis Summary for the AP1000 Reactor Coolant Pump High Inertia Flywheel,” dated October 2006. This Curtiss-Wright report is only applicable for the canned-motor design. In RAI-SRP5.4.1-CIB1-01, the staff asked the applicant to change the DCD to provide the following:

- A specific RCP/flywheel design (i.e., a single-stage, high-inertia, centrifugal, sealless RCP of canned-motor design). Currently, this is the only RCP design that has a supporting analysis for the flywheel integrity and missile generation.

- The material specifications for the flywheel and the specific inspections to be performed on the flywheel.

- The material type for the end plates and outer shell since TR-106 replaced the material type “Alloy 690” with “corrosion resistant” from AP1000 DCD, Revision 16, Section 5.4.1.3.6.3.

In a letter dated April 11, 2008, the applicant responded to RAI-SRP5.4.1-CIB1-01 and provided the following:

- RCP design and flywheel structural analysis: AP1000 DCD, Revision 16 will be changed to incorporate the standard design RCP (a single-stage, hermetically sealed, high-inertia, centrifugal, sealless pump of canned-motor design).

- Flywheel material and inspections: information identifying the materials used in the flywheel, and the inspections that will be performed on the flywheel.

- Flywheel enclosure material: information identifying the materials used in the flywheel enclosure.

The staff reviewed this information and provides the following summary and evaluation of each issue.

Flywheel Material and Inspections

The Curtiss-Wright Electro-Mechanical Corporation Report AP1000 RCP-06-009-P, dated October 2006, used the material properties from the material specifications for the flywheel (Type 403 stainless steel inner hub—ASTM A336, Grade F6, 18-Ni maraging steel outer hub—AMS 6519, Vascomax T250 (UNS 6075) and heavy tungsten inserts—ASTM B777, Class 4) to evaluate the flywheel integrity and ability to minimize missile generations. AP1000 DCD Section 5.4.1.3.6.3 also relies on the material specifications and preservice nondestructive testing to demonstrate the integrity of the flywheel and justify the removal of the flywheel from an inservice inspection program. Therefore, to ensure structural integrity of the flywheel, as evaluated in the Curtiss-Wright report, the applicant should change the AP1000 DCD to include these material specifications or reference the Curtiss-Wright report for the material specifications to be used. The staff previously addressed this in RAI-SRP5.4.1-CIB1-01. The staff identified this as Open Item OI-SRP5.4.1-CIB1-01.

In a letter dated May 26, 2009, in response to RAI-SRP5.4.1-CIB1-01, Revision 1, the applicant stated that the flywheel outer hub material was changed from 18-Ni maraging steel to 18Mn-18Cr alloy steel (ASTM A289, Grade 8) as a result of lessons learned during a flywheel mockup assembly, and that the 18Mn-18Cr alloy steel is not susceptible to stress corrosion cracking and hydrogen embrittlement. A proposed change to Section 5.4.1.3.6.3 of the AP1000 DCD to include the new material specification was also provided in this letter. The staff confirmed that this material is more resistant to stress corrosion cracking than 18-Ni maraging steel based on the current operating experience of 18Mn-18Cr alloy steel retaining rings on generators used since the mid 1980's. The generator environment is more aggressive due to the hydrogen cooling and the wet oxygenated environment compared to the PWR reactor coolant water, which controls the oxygen content. Also, the staff notes that this alloy steel has a high chromium content, which is similar to stainless steels currently used in the reactor coolant. The 18Mn-18Cr material is similar to a high strength stainless steel with yield strength of 195 kips per square inch (ksi) compared to 250 ksi for the 18-Ni maraging steel. Since this alloy steel is not a nickel based alloy, such as Alloy 600, primary water stress corrosion cracking is not a concern. The NRC also notes that the 18Mn-18Cr alloy steel outer hub will be enclosed in an Alloy 625 flywheel enclosure to prevent the outer hub from contacting the reactor coolant. Therefore, the staff finds the use of the 18Mn-18Cr alloy steel acceptable based on the current operating experience of this material in an aggressive stress corrosion environment, and even if the flywheel ruptures, the flywheel would be contained in the RCP as discussed below, thereby preventing a missile that could impact safety-related equipment or structures, which meets the requirements of GDC 4.

In a letter dated August 4, 2009, in response to RAI-SRP5.4.1-CIB1-01, Revision 2, the applicant provided the material specifications for the inner hub (ASTM A336, Grade F6) and the tungsten inserts (ASTM B777, Class 4) in a proposed change to Section 5.4.1.3.6.3 of the AP1000 DCD as requested by the staff, which partially resolves Open

Item OI-SRP5.4.1-CIB1-01. In a subsequent revision to the AP1000 DCD the material specifications as stated in letters dated May 26, 2009 and August 4, 2009 were included, which resolves this issue.

However, since the outer hub material was changed to 18MNn-18Cr, the evaluation of the flywheel in Curtiss-Wright Electro-Mechanical Corporation Report AP1000 RCP-06-009-P, dated October 2006, is no longer valid since it does not bound the new material (18Mn-18Cr). In a letter dated August 4, 2009, the applicant submitted a revised flywheel analysis, Curtiss-Wright Electro-Mechanical Corporation Report AP1000 RCP-06-009-P, Revision 2, dated July 2009, which included the new material (18Mn-18Cr), and is, therefore, part of Open Item OI-SRP5.4.1-CIB1-01, which is discussed in the "RCP design and flywheel structural analysis" section below.

In regard to the preservice inspection of the flywheel, the applicant provided changes to AP1000 DCD, Revision 17, Section 5.4.1.3.6.3, to include surface examinations and volumetric inspections of the inner hub and retainer cylinder ring, and an overspeed spin test followed by a visual inspection and leak test of the final assembly in accordance with ASME Code, Section III. In addition, impact/fracture toughness testing will also be conducted on the inner hub and retainer cylinder ring. The staff finds that these inspections provide reasonable assurance of the integrity of the flywheel during fabrication and ensure that the basis for safe operation of the RCP will be maintained.

Flywheel Enclosure Material

Design change 245 in TR-106 stated that the applicant would revise Section 5.4.1.3.6.3 of the AP1000 DCD by replacing references to "Alloy 690" with the phrase "corrosion resistant material" for the flywheel enclosure (endplates and outer thin shell) to meet the intent of creating a generic RCP design description. The NRC staff notes that Section 5.4.1.3.6.3 of the AP1000 DCD credits the use of the flywheel enclosure to prevent contact with the reactor coolant and to minimize the potential for corrosion of the flywheel and contamination of the reactor coolant. A leak in the flywheel enclosure during operation could result in an out-of-balance flywheel assembly. In addition, the applicant stated that the use of the required material specifications and nondestructive testing during fabrication of each flywheel demonstrates the quality of the flywheel, thereby permitting the removal of the requirement for periodic inservice inspections of the flywheel to ensure that the basis for safe operation of the RCP is maintained. Based on the above, the NRC staff notes that, although the flywheel enclosure is not credited for retaining potential flywheel missiles, the flywheel enclosure is an integral part of ensuring the integrity of the flywheel so that it will not generate a missile. In the course of its review, the staff identified that Section 5.4.1.3.6.3 of the AP1000 DCD should be revised to state the material type (i.e., Alloy 690 and/or Alloy 625) for the flywheel enclosure.

In a letter dated April 11, 2008, the applicant included Alloy 625 in Section 5.4.1.3.6.3 of the AP1000 DCD as the material used for the flywheel enclosure. Therefore, the NRC staff considers Alloy 625, as referenced in ASTM B-443, "Standard Specification for Nickel-Chromium-Molybdenum-Columbium Alloy (UNS N06625) and Nickel-Chromium-Molybdenum-Silicon Alloy (UNS N06219) Plate, Sheet, and Strip," and ASTM B-564, "Standard Specification for Nickel Alloy Forging," to be an acceptable material for the flywheel enclosure, based on current operating experience in fuel assemblies and testing performed by Bettis Atomic Power Laboratory, which was discussed in the applicant's letter dated October 5, 2007. With the inclusion of the material specification for the flywheel enclosure, the staff finds the change to Section 5.4.1.3.6.3 acceptable.

RCP Design and Flywheel Structural Analysis

Concerning the RCP design, see Section 5.4.1.2 of this report for the staff's evaluation. The staff concludes this standard design type (a single-stage, hermetically sealed, high-inertia, centrifugal, sealless pump of canned-motor design) is supported by an applicable flywheel integrity analysis, and it standardizes the certification information for all COL applicants.

The structural analysis of the bimetallic flywheel with heavy tungsten alloy inserts for the sealless RCP with canned motor and including a missile containment evaluation of a fractured flywheel was initially documented in Curtiss-Wright Electro-Mechanical Corporation Report AP1000 RCP-06-009-P, issued October 2006.

However, due to a change in material (18Mn-18Cr) for the outer hub of the flywheel, the applicant submitted a revised flywheel analysis, Curtiss-Wright Electro-Mechanical Corporation Report AP1000 RCP-06-009-P, Revision 2, dated July 2009, in a letter dated August 4, 2009. The August 4, 2009, letter also provided a proposed change to Section 5.4.16 of the AP1000 DCD, which references this new Curtiss-Wright analysis. This analysis used the material properties of 18Mn-18Cr, using a similar methodology as the previous analysis. However, the NRC staff noted that there were other changes to the RCP including material changes to the pump, dimensional changes to the flywheel, and an additional pump part (stator closure ring) adjacent to the upper flywheel that would contain the upper flywheel if it were to rupture. In addition, a missile generated from a fractured portion of the upper flywheel would now have to penetrate three parts (stator closure, stator closure ring, and thermal barrier) which are bolted together. Therefore, the staff identified this as part of Open Item OI-SRP5.4.1-CIB1-01, Revision 1, in that the analysis should also account for shearing of the bolts connecting these three parts.

In response to Open Item OI-SRP5.4.1-CIB1-01, Revision 1, in a letter dated June 6, 2011, the applicant stated that the new analysis assumes that the flywheel is contained by the three parts (stator closure, stator closure ring, and thermal barrier) which are bolted together, and act as one unit. These three parts act as one unit due to the combination of large compressive stresses from the main flange bolts and the recessed fits between the three parts, which transfer the shear load from one part to another. The NRC staff notes that the analysis is conservative since only a portion of the entire volume of the three parts (stator closure, stator closure ring, and thermal barrier) was credited in the analysis with respect to containing a fractured flywheel. Therefore, the NRC staff finds that the shear mechanism was analyzed and bounded by the analysis. In addition, Revision 2 of the analysis accounted for the dimensional changes in the flywheel, and the outer hub material properties of 18Mn-18Cr.

In response to RAI-SRP5.2.3-01, Revisions 1 and 2, dated December 31, 2009, and April 7, 2010, respectively, the applicant provided information on material changes to carbon steel for specific parts of the pump, which are the stator main flange, stator shell, and external heat exchanger supports. These parts are not exposed to reactor coolant and are not credited for containing a fractured flywheel. Therefore, the NRC staff agrees that these material changes to the stator main flange, stator shell, and external heat exchanger supports have no effect on the flywheel analysis. In addition, the staff finds the use of carbon steel for these parts acceptable, since they are not exposed to the reactor coolant. Therefore, the staff finds Open Item OI-SRP5.4.1-CIB1-01 completely resolved. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

The flywheel analysis, Curtiss-Wright Electro-Mechanical Corporation Report AP1000 RCP-06-009-P, Revision 2, issued July 2009, demonstrates that the calculated stresses during both normal operating conditions and design conditions are less than the applicable stress limits. In addition, missile penetration calculations show that in the unlikely event of a flywheel fracture, the flywheel assembly components will not have sufficient energy to penetrate the pump pressure boundary structures. Therefore, the NRC staff finds the structural analysis for the bi-metallic flywheel with heavy tungsten alloy inserts acceptable because the missile penetration calculations show that if the flywheel fractures, the flywheel assembly components will not have sufficient energy to penetrate the pump pressure boundary structures; therefore, the design meets the requirements of GDC 4. The NRC staff had approved the previous AP1000 canned motor design with a depleted uranium flywheel assembly, which also relies on the pump casing to confine the flywheel if the flywheel fractures. The missile penetration calculations for both material designs used similar methodologies.

5.4.1.4.3 Conclusion

Based on the above evaluation, the staff finds that the material specifications used and the preservice inspections provide reasonable assurance of the flywheel integrity, and that the Curtiss-Wright Electro-Mechanical Corporation Report AP1000 RCP-06-009 demonstrates that if the flywheel assembly fails, the flywheel components will not penetrate the pump pressure boundary structures. Therefore, the staff finds the RCP flywheels acceptable since they meet the requirements of GDC 1, GDC 4, and ASME Code, Section III.

The NRC staff reviewed the changes in Section 5.4.1.3.6.3 of the AP1000 DCD and finds that the AP1000 DCD adequately incorporates the proposed changes, as identified in TR-34 and the RAI responses. Furthermore, the staff finds that these changes are generic and are expected to apply to all COL applications referencing the AP1000 DC. Therefore, the proposed DCD changes are acceptable pursuant to 10 CFR 52.63(a)(1)(vii) on the basis that they contribute to the increased standardization of the certification information.

5.4.1.5 Other Changes

In Revision 17 to the DCD, the applicant also proposed to change the following RCP design parameters in Table 5.4-1: (1) maximum continuous CCW inlet temperature; (2) motor/pump rotor minimum required moment of inertia; and (3) RCP estimated unit overall height and weight.

The applicant revised DCD Table 5.4-1 by adding Note 1, associated with the maximum continuous CCW inlet temperature of 95 °F, stating that an elevated CCW supply temperature of up to 110 °F may occur for up to 6 hours. In its response to RAI-SRP5.4.1-SRSB-02, the applicant explained that it intended Note 1 to clarify that although the design temperature of the CCW system cooling water to the RCP is 95 °F, transient conditions during normal plant cooldown or extreme climate events may occur during which the CCW system temperature may exceed 95 °F (but no more than 110 °F) for a short time. The staff concludes that the addition of Note 1 is acceptable.

In DCD Table 5.4-1, the applicant changed the motor/pump rotor minimum required moment of inertia from 16,500 lb-ft^2 to the phrase “Sufficient to provide flow coastdown as given in Figure 15.3.2-1.” The applicant had previously proposed a similar change to the acceptance criterion of the RCP rotating inertia in DCD Tier 1, Table 2.1.2-4, “Inspections, Tests, Analyses, and Acceptance Criteria,” to a specific pump coastdown curve specified in DCD Tier 1,

Figure 2.1.2-2, “Flow Transient for Four Cold Legs in Operation, Four Pumps Coasting Down,” which is consistent with DCD Tier 2, Figure 15.3.2-1. The applicant proposed this change because the specified pump rotating inertia does not guarantee that the flows produced during pump coastdown will satisfy the analyses in the absence of information on pump resistance. The staff had found this change to be acceptable, as described in Supplement 1 to NUREG-1793. Therefore, the proposed change to Table 5.4-1 regarding pump rotor minimum required moment of inertia is made to be consistent with the four-pump coastdown curve in DCD Figure 15.3.2-1, which is used in the safety analysis of the design-basis transient of a complete loss of reactor coolant flow described in DCD Section 15.3.2; therefore, it is acceptable.

In Table 5.4-1, the applicant changed the RCP estimated unit overall height from 6.693 m (21 ft 11.5 in) to 6.706 m (22 ft), and it changed the total estimated weight of the motor and casing from 83688 kg (184,500 pounds mass (lbm)) to 90718 kg (200,000 lbm). These changes reflect the changes in the pump casing discharge nozzle and the use of the bi-metallic flywheel design.

In DCD Section 5.4.1.2.1, the applicant changed the RCP vibration monitoring system instrumentation from three-axis monitoring to five vibration monitors. In TR-34, the applicant stated that the instrumentation of the RCP is modified from the preliminary design to provide a more robust monitoring and diagnostic capability of the RCP. These changes include the addition of key phasors to aid in diagnostics in the event of high-vibration indications, and the addition of more vibration monitors to supply measurements in two planes at two different axial locations for diagnostic purposes. The staff concludes that these RCP instrumentation changes provide a more robust monitoring and diagnostic capability of the RCP without affecting RCP performance; therefore, they are acceptable.

In Revision 17 of DCD, the applicant updated Section 5.4.1.3.6.1 to specify the minimum damped natural frequency of the RCP rotating assembly as greater than 120 percent of the normal operating speed. The staff reviewed the various factors that were considered in determining the damped natural frequency of the RCPs. There is considerable energy dissipation from the effects of bearing films, can or winding annular fluid interaction, motor magnetic phenomena, and pump structure. The determination of the damped natural frequency of the RCP rotor bearing system model considered these effects on the damped natural frequency. The high degree of damping as a result of energy dissipation ensures a stable and smooth operation of the pump over a sufficiently wide range of pump operating speeds. The pumps have been analyzed for the response of the rotor and stator to external forcing functions. The analysis considered the support and connection of the pump to the SG and piping. The applicant evaluated the responses using criteria that included critical loads, stress deformation, and wear and displacement limits to establish the actual system critical speeds. The staff finds the evaluation criteria for determining the RCP damped natural frequency and critical speeds to be reasonable and acceptable. The staff also finds that there is high energy dissipation because of the various damping factors, which would ensure stable and smooth pump operation.

5.4.1.6 Conclusions

The staff has reviewed the proposed changes to the RCP design. Based on the evaluation described, the staff concludes that the AP1000 RCP design meets the requirement in GDC 10, “Reactor Design”; therefore, it is acceptable. The staff finds that the material specifications used and the preservice inspections provide reasonable assurance of the flywheel integrity, and that the Curtiss-Wright report demonstrates that, if the flywheel assembly fails, the flywheel components will not penetrate the pump pressure boundary structures. Therefore, the revisions proposed by the applicant to AP1000 DCD, Section 5.4.1, meet the requirements of GDC 1 and 4 and ASME Code, Section III and are acceptable.

5.4.2 Steam Generators

5.4.2.1 Steam Generator Design

5.4.2.1.1 Summary of Technical Information

In Revision 17 to the AP1000 DCD, the applicant proposed changes to its SG design. In a letter dated November 29, 2006, the applicant submitted for staff review TR-35, Revision 0, "AP1000 Steam Generator Description Changes" (APP-GW-GLN-010), which provides the technical justification for the proposed SG design changes. Additional information regarding TR-35 appears in letters dated June 7, 2007, and September 7, 2007. The proposed design changes are described below.

Antivibration Bar

The original design of the antivibration bar is described in DCD Section 5.4.2.4.2 and detailed in DCD Figure 5.4-2. In Revision 17, the applicant revised the description by removing the words "wide strips of" from Section 5.4.2.4.2 and reconfiguring Figure 5.4-2 to show a general antivibration bar design.

Tube Expansion

DCD Sections 5.4.2.2, 5.4.2.4.1, and 5.4.2.4.2 describe the tube expansion process as a hydraulic expansion through the full depth of the tubesheet. The intent remains to achieve full depth expansion; however, the requirement to hydraulically expand through the full depth limits the manufacturing processes available for this expansion. In Revision 16, the applicant removed the reference to hydraulic expansion from DCD Sections 5.4.2.2, 5.4.2.4.1, and 5.4.2.4.2.

Primary Separator Design

The original design of the moisture separators is described as a 19.1cm (7.5-in) separator arrangement. The applicant determined that this design could not achieve the industry standard upper bound limit for moisture carryover (0.1 percent) and, therefore, changed the design to a 50.8-cm (20-in) separator arrangement. In Revision 17, the applicant revised Figure 5.4-2 to illustrate its typical 50.8-cm (20-in) separator arrangement.

Primary Separator Material

DCD Section 5.4.2.4.1 states, "Nickel-chromium-iron alloy in various forms is used for parts where high velocities could otherwise lead to erosion/corrosion. These include the nozzles on the feedwater ring, startup feedwater sparger, and some primary separator parts." In Revision 16 to the DCD, the applicant removed the phrase "and some primary separator parts."

Startup Feedwater Elevation

DCD Section 5.4.2.2 describes the startup feedwater nozzle elevation as being “just below” the main feedwater nozzle. In Revision 17 to the DCD, the applicant revised this to state that the startup feedwater nozzle elevation is the same as the main feedwater nozzle elevation.

Table 5.2-1 Correction

DCD Section 5.4.2.4.1 includes the table for the list of materials and is called “Table 5.2.3-1.” In Revision 16 to the DCD, the applicant revised the table number to “Table 5.2-1.”

Tube Location Identification

DCD Section 5.4.2.5 describes the number of tubes being scribed as “large.” However, the space between the tubes and welds is not sufficient to allow for scribing a large fraction of the tubes. In Revision 17 to the DCD, the applicant removed the word “large” from Section 5.4.2.5.

5.4.2.1.2 Evaluation

GDC 32 requires, in part, that the designs of all components that are part of the reactor coolant pressure boundary permit periodic inspection and testing of critical areas and features to assess their structural and leak-tight integrity. The staff reviewed changes to this section as related to the proposed SG design changes.

In TR-35, the applicant proposed design changes to its SGs. Specifically, the applicant made minor description changes to the following: antivibration bars, tube expansion process, primary separator design, primary separator material, startup feedwater elevation, and tube location identification. The staff finds that these proposed changes meet the requirements of GDC 32 and are acceptable because they are consistent with current industry designs and practices and do not present a challenge to the integrity of the SG. Some of the changes were necessary to correct erroneous statements and inaccurate descriptions.

The NRC staff reviewed the proposed changes to the AP1000 DCD. The proposed changes establish the proposed design as the single, standard design for all AP1000 plants. These DCD changes are generic and are expected for all COL applications referencing the AP1000 certified design. At this time, the NRC has not issued a COL for any AP1000 plant. Thus, the proposed changes contribute to the increased standardization of the certification information in the AP1000 DCD.

5.4.2.1.3 Conclusions

Based on the above evaluation, the staff concludes that the SG design changes meet GDC 32 and are acceptable because they are consistent with current industry designs and practices and do not present a challenge to the integrity of the SG. Furthermore, the staff finds that the conclusions regarding the proposed SG design changes are expected to apply to all COL applications referencing the AP1000 DC. Therefore, the proposed DCD changes are acceptable pursuant to 10 CFR 52.63(a)(1)(vii) on the basis that they contribute to the increased standardization of the certification information.

5.4.2.2 Steam Generator Inservice Inspection

5.4.2.2.1 Summary of Technical Information

In Revision 17 to the AP1000 DCD, proposed changes to the AP1000 generic Technical Specification (TS) related to adopting Technical Specification Task Force Traveler (TSTF)-449, “Steam Generator Tube Integrity,” Revision 4 of May 6, 2005. The current Westinghouse Owners Group Standard Technical Specifications (STS), NUREG-1431, “Standard Technical Specifications Westinghouse Plants,” Revision 3.1, dated December 1, 2005, incorporates TSTF-449. These changes also relate to COL Information Item 5.4-1 identified in DCD Section 5.4.15. Implementation of TSTF-449 includes the following TS changes:

- clarification to the definition of identified leakage
- changes to TS 3.4.7, “Reactor Coolant System Operational Leakage,” which modifies two condition statements and the two associated surveillance requirements
- addition of new TS 3.4.18, “Steam Generator (SG) Tube Integrity”
- modification of TS 5.5.4, which is renamed, “Steam Generator (SG) Program”
- modification of TS 5.6.8, “Steam Generator Tube Inspection Report”
- associated changes to the TS bases

5.4.2.2.2 Evaluation

GDC 32 requires, in part, that components that are part of the reactor coolant pressure boundary shall be designed to permit periodic inspection and testing of important areas and features to assess their structural and leaktight integrity. The staff evaluated the applicant’s proposed changes to the AP1000 generic TS as they relate to adopting TSTF-449 to ensure consistency with the latest revision of the STS using the acceptance criteria in NUREG-0800 Section 5.4.2.2, “Steam Generator (SG) Program.” In addition, 10 CFR 50.55a(b)(2)(iii) states that if the TS include SG surveillance requirements that are different than those in Article IWB-2000 of ASME Code, Section XI, then the SG tube inspection requirements are governed by the TS.

Accordingly, the staff compared the proposed changes to the corresponding language in the STS (NUREG-1431, Revision 3.1). The staff determined that the changes are consistent with the approved STS and are appropriate to leakage and SG tube integrity requirements as they apply to the AP1000 standard plant design. Therefore, they are acceptable. With respect to tube integrity considerations, the Model Delta-125 SG planned for the AP1000 closely resembles the Model Delta-75 SGs installed as replacements at some operating plants. The staff also confirmed that Revision 17 to the DCD retains Section 5.4.15, which requires COL applicants to address SG tube integrity with a SG tube surveillance program and periodic monitoring of degradation of SG internals. .

5.4.2.2.3 Conclusions

Based on the evaluation above, the staff concludes that the changes proposed to the AP1000 TS for SG tube integrity are acceptable and meet the requirements of GDC 32. This conclusion is based on the consistency of the SG tube integrity program with the STS for the applicant's domestic PWRs. Furthermore, the staff finds that the conclusions regarding the changes to the TS for SG tube integrity will apply to all COL applications referencing the AP1000 DC. Therefore, the proposed DCD changes are acceptable pursuant to 10 CFR 52.63(a)(1)(vii) on the basis that they contribute to the increased standardization of the certification information.

5.4.4 Main Steam Line Flow Restriction

5.4.4.1 Summary of Technical Information

In Revision 17 of DCD Section 5.4.4, two changes are made regarding the main steam line flow restrictor.

- In Section 5.4.4.2, the material for the steam generator flow restrictor venturi inserts is changed from nickel-chromium-iron Alloy 600 (ASME 163) to nickel-chromium-iron Alloy 690.
- In Section 5.4.4.3, the pressure drop of the flow restrictor at 100 percent steam flow is changed from approximately 8.0 pounds per square inch (psi) to 15 psi.

5.4.4.2 Evaluation

For Section 5.4.4.2, since Alloy 690 is used in the AP1000 SG design, the change of the flow restrictor venturi insert material from Alloy 600 to Alloy 690 is consistent with the SG design and is acceptable.

For Section 5.4.4.3, the pressure drop change is based on the design analysis and is acceptable.

5.4.4.3 Conclusion

The staff has reviewed the proposed changes to DCD Section 5.4.4. Based on the above evaluation, the staff concludes that the proposed changes are acceptable.

5.4.5 Pressurizer

Section 5.4.5 of DCD Revision 17 refers to TR-36, "AP1000 Pressurizer Design" APP-GW-GLR-016 of May 2006. In TR-36, the applicant summarizes the design changes for the AP1000 pressurizer to accommodate the available space as a result of piping analysis. The pressurizer design changes preserve the same total internal volume of 59.5 cubic meter (m^3) (2100 cubic feet (ft^3)), while reducing the vessel height from 1541.8 cm (607 in) to 1277.6 cm (503 in) and increasing the vessel diameter from 228.6 cm (90 in) to 254.0 cm (100 in). Though DCD Revision 17, Table 5.1-2 reflects the dimensional change, Section 5.4.5 does not, because the total pressurizer volume did not change. However, DCD Revision 17, Section 15.0 did change, because the changes to the pressurizer vessel cross-section area and vessel height affect the pressurizer water level and setpoints of several functions of the reactor protection system and engineered safety feature actuation systems. Chapter 15 of this SER addresses the effects on the transient and accident analyses.

5.4.7 Normal Residual Heat Removal System

5.4.7.1 Summary of Technical Information

The AP1000 RNS is a nonsafety-related system and is not required to operate to mitigate design-basis events. The primary functions of the RNS include the following: (1) remove decay heat and sensible heat from the core and the RCS; (2) provide LTOP; (3) provide a flow path for long-term, post accident makeup to the containment inventory; and (4) provide RCS and refueling cavity flow to the chemical and volume control system (CVS) for purification.

In Revision 17 to the DCD, the applicant proposed the following changes related to the RNS design:

- Revise the method of flow control through the RNS heat exchangers (HX) to improve the cooldown rate control.
- Provide auto close to V029, RNS motor-operated flow control valve to CVS, on high temperature to prevent potential damage to CVS demineralizer resin.
- Resize the RNS suction line relief valve to reduce valve instability.
- Increase ambient wet bulb temperature to 86.1 °F with zero percent exceedance to facilitate consideration of other potential nuclear plant sites.
- Relocate the RCS hot leg RTDs to provide required post accident monitoring data to upstream of the HX to indicate the RCS hot-leg temperature when in reduced inventory conditions.
- Revise the RNS long term makeup flow path to provide a simplified flow path for containment makeup through the manual containment isolation test connection valve in the discharge of the RNS.
- Revise Figure 5.4-7 to reflect containment penetration valve and piping changes.

5.4.7.2 Evaluation

The staff reviewed the changes to DCD Section 5.4.7 in accordance with NUREG-0800 Section 5.4.7, “Residual Heat Removal (RHR) System.” The changes are acceptable if the system continues to satisfy the relevant requirements in NUREG-0800 Section 5.4.7.

In Section 5.4.7.4.2, “Plant Cooldown,” an editorial change provides a description of the method used to control the cooldown rate as stated: “The cooldown rate is controlled by throttling the flow through the heat exchanger based on reactor coolant temperature.” Flow through the RNS heat exchangers will be controlled with the HX discharge valves, V006A(B). This is accomplished by switching the control signals on valves V008A(B) with those on valves V006A(B). The NRC staff agrees that this method of control will reduce the probability of an operator error during a plant cooldown condition because this is the standard method of controlling cooldown rate. Also, this revision is pictorially reflected on Figure 5.4-7 of the control signals to the valves. The NRC staff finds this change acceptable because it has the potential to improve operator performance by reducing the potential for operator error.

An additional revision to Figure 5.4-7 included a modification to V029, RNS motor-operated control valve downstream of the RNS HX connecting to the CVS. This change will allow the valve to auto close on high temperature. The reason for this change is to prevent high temperature fluid from passing through the demineralizers with the potential of damaging the resin. The resin in the CVS demineralizers can be damaged if the temperature through the demineralizers exceeds 60 °C (140 °F) for extended periods of time. The NRC staff finds this change acceptable because the change improves the reliability of the CVS system by reducing the potential damage to the resin.

In another revision to Figure 5.4-7, the RNS suction line relief valve is resized from a 10.2 cm (4 in) inlet and a 15.2 cm (6 in) outlet to a 7.6 cm (3 in) inlet and a 10.2 cm (4 in) outlet. RNS suction line relief valve resizing is implemented to reduce valve instability caused by the valve being fluid starved, which has the potential to cause valve chattering. The RNS relief valve is sized to mitigate primary overpressure events at low temperature conditions due to a heat injection and/or mass injection transient where the mismatch flow rate is no higher than 177 gpm. The staff finds this change acceptable because it improves the reliability of the valve by reducing potential damage to the valve due to unnecessary valve chatter.

The applicant modified DCD Section 5.4.7.1.2.1 to state that the CCW system supply temperature to the RNS HX is based on the maximum normal ambient wet bulb temperature as defined in Chapter 2, Table 2-1. The maximum normal ambient temperature is assumed for shutdown cooling. DCD Section 5.4.7.1.2.3 revises the maximum ambient design wet bulb temperature from 27.2 °C (81 °F) to 30.1 °C (86.1 °F) to facilitate consideration of other potential nuclear plant sites. The applicant has stated that the evaluation indicates there is sufficient margin in the systems design for the RNS, CCW system, and service water system (SWS) to maintain the same criteria and design basis with the increased ambient wet bulb temperature. In RAI-SRP5.4.7-SRSB-01, the staff requested that the applicant provide the results of the evaluation that demonstrate the RNS maintains sufficient margin. In its July 17, 2008, response, the applicant stated that "cooling the [in-containment refueling water storage tank] IRWST with the RNS, CCS, and SWS is not required to ensure that the plant can be maintained in a long-term safe condition." Therefore, under these circumstances, the staff agrees that the RNS, CCW system, and SWS designs would maintain sufficient margin with the revised higher ambient wet bulb temperature. The staff concludes that the proposed changes are acceptable because the analysis demonstrates that the RNS system can perform its intended function for normal operating conditions and is not required during transients since the RNS is not considered a safety-related system, i.e., no operational credit is assigned in Chapter 15, "Accident Analysis."

Section 5.4.7.2.1 was revised to clarify the temperature instrumentation employed to monitor the RCS hot leg for RNS operation during different RCS level conditions. For normal RCS inventory conditions, the RCS hot-leg wide-range temperature instruments are monitored; whereas, during reduced RCS inventory conditions, the RNS temperature instruments located upstream of the HX are monitored for the RCS hot-leg temperature. The staff finds that the revision is an editorial clarification with no impact on the RNS functionality. Therefore, the staff concludes the revision is acceptable.

Safety-related makeup water can be provided through the RNS for long-term post accident containment makeup. DCD Revision 17 changed Section 5.4.7.5 to state that this makeup is provided through the manual containment isolation test connection valve in the discharge of the RNS. This change simplifies the long-term makeup flow path setup by eliminating a component in the flow path, improves the RNS long-term makeup flow method, and has no impact on the functionality of the RNS. Therefore, the staff concludes that the change is acceptable.

In Tier 1, Table 2.3.6-1, the applicant deleted RNS HX A and B channel head drain valves RNS-PL-V046A and B and added RNS discharge containment isolation test connection RNS-PL-V012 to reflect the new RNS long-term makeup flow path to provide containment makeup. It also revised Figure 2.3.6-1 to reflect this change to the long-term makeup flow path configuration.

5.4.7.3 Conclusions

The staff reviewed the proposed changes to DCD Section 5.4.7 and concludes that the proposed changes improve overall system performance with the potential for improved operator performance without having a significant effect on the RNS design basis or RNS interfacing systems and meet the relevant acceptance criteria of NUREG-0800 Section 5.4.7.

6. ENGINEERED SAFETY FEATURES

Westinghouse has submitted information in support of its design certification (DC) amendment application that Westinghouse (the applicant) considers "proprietary" within the meaning of the definition provided in Title 10 of the *Code of Federal Regulations* (10 CFR) 2.390(b)(5), "Public inspections, exemptions, requests for withholding." The applicant has requested that this information be withheld from public disclosure and the Nuclear Regulatory Commission (NRC) staff agrees that the submitted information sought to be withheld includes proprietary commercial information and should be withheld from public disclosure. This chapter of the NRC staff's evaluation includes proprietary information that has been redacted in order to make the evaluation available to the public. The redacted information appears within "square brackets" as follows:

[ ]

The complete text of this chapter, including proprietary information can be found at Agencywide Documents Access and Management System (ADAMS) Accession Number ML112091879 and can be accessed by those who have specific authorization to access Westinghouse proprietary information.

6.1.1 Metallic Materials

6.1.1.1 Summary of Technical Information

The applicant revised Section 6.1.1.2 of the AP1000 design control document (DCD) Tier 2 to reflect a proposed modification to DCD Tier 2, Table 5.2-2, "Reactor Coolant Water Chemistry Specifications," to allow the injection of zinc into reactor coolant water. The basis for this change appeared in Westinghouse Electric Company, LLC, technical report (TR)-32, APP-GW-GLN-002, "AP1000 Licensing Design Change Document Zinc Addition," dated April 5, 2006. The proposed change to Section 6.1.1.2 deletes the reference to zinc as a material that is not allowed to come into contact with engineered safety feature (ESF) components made of stainless steel. In Revision 17 of the DCD, the applicant changed Section 6.1.1.2 to make it consistent with Table 5.2-2.

The applicant revised DCD Tier 2, Section 6.1.1.3, to replace American Society for Testing and Materials (ASTM) A240 Type XM-29 with ASTM/American Society of Mechanical Engineers (ASME) A240/SA-240 UNS S32101 (LDX 2101) for the fabrication of the in-containment refueling water storage tank (IRWST). Westinghouse's TR-106, APP-GW-GLN-106, "AP1000 Standard Combined License Technical Report, AP1000, Licensing Design Changes for Mechanical System and Component Design Updates," Revision 1, dated September 28, 2007, identified and justified this change. Westinghouse's TR-134, "AP1000 DCD Impacts to Support COLA Standardization," Revision 5, dated June 27, 2008, details the modifications pertaining to DCD Section 6.1.1.3. DCD Tier 2, Revision 17, incorporates the proposed modifications.

In addition, the applicant revised DCD Tier 2, Section 6.1.1.4, to add a design requirement that aluminum excore detectors be enclosed in stainless steel or titanium to address, in part, Generic Safety Issue (GSI)-191, "Assessment of Debris Accumulation on PWR Sump Performance." The applicant also modified DCD Tier 1, Table 2.2.3-4, "Inspections, Tests, Analyses, and Acceptance Criteria," to require verification that the excore detector surfaces are made of stainless steel or titanium. TR-134 details the modifications to the DCD. The justification for these modifications appears in Westinghouse's TR-26, APP-GW-GLR-079, "AP1000 Verification of Water Sources for Long-Term Recirculation Cooling Following a LOCA," Revision 7, dated February 26, 2010, and APP-GW-GLE-002, "Impacts to the AP1000 DCD to Address Generic Safety Issue (GSI)-191," Revision 7, dated July 13. DCD Tier 1 and 2, Revision 17, incorporates the proposed modifications.

6.1.1.2 Evaluation

DCD Tier 2, Section 6.1.1.2, states that lead, antimony, cadmium, indium, mercury, zinc, and tin metals and their alloys are not allowed to come into contact with ESF component parts made of stainless steel or high-alloy metals during fabrication or operation. The applicant proposed to modify DCD Tier 2, Section 6.1.1.2, to delete zinc as a material that is not allowed to come into contact with ESF components made of stainless steel. This proposed modification results from a proposed change in the reactor coolant water chemistry specifications, detailed in Table 5.2-2, to allow the injection of zinc into reactor coolant water. The basis for this proposed change relates to the benefits resulting from the addition of zinc to primary coolant which reduces radiation fields and the formation of crud. Section 5.2.3 of this safety evaluation report (SER) includes a detailed staff evaluation of the applicant's proposed change related to the addition of zinc to reactor coolant, which the staff finds acceptable. This proposed modification is generic and is expected to apply to all combined license (COL) applications referencing the AP1000 DC. Therefore, the proposed DCD change is acceptable pursuant to 10 CFR 52.63(a)(1)(vii), "Finality of standard design certifications," on the basis that it contributes to the increased standardization of the certification information.

DCD Tier 2, Section 6.1.1.3, describes the materials for nonpressure-retaining portions of ESFs in contact with borated water or other fluids. The IRWST liner and the passive containment cooling system (PCS) storage tank liner are primary examples of these items.

General Design Criterion (GDC) 4, "Environmental and Dynamic Effects Design Basis," of Appendix A, "Design Criteria for Nuclear Power Plants," to 10 CFR Part 50, "Domestic licensing of production and utilization facilities," requires that structures, systems, and components (SSCs) important to safety be designed to accommodate the effects of, and to be compatible with, the environmental conditions associated with normal operations, maintenance, testing, and postulated accidents, including loss-of-coolant accidents (LOCAs). In order for the IRWST to meet the requirements of GDC 4, the materials used must be compatible with ESF fluids.

Currently, AP1000 DCD, Section 6.1.1.3, states that ASTM A240 Type XM 29 (Nitronic 33) may be used to fabricate the IRWST. Table 6.1-1 specifies that XM-29 or TP304 will be used to fabricate the IRWST. The applicant proposed to modify the stainless steel surfaces of the containment internal structural modules as part of design change 049, which is described in TR-106. This design change will affect the IRWST, which is part of the ESFs. The proposed change to Section 6.1.1.3 specifies ASTM/ASME A240/SA240 UNS S32101, commonly known as LDX 2101, for fabrication of the IRWST.

The applicant provided its basis for the selection of LDX 2101 in TR-106, which stated that the proposed change to use LDX 2101 is because of the limited availability of Nitronic 33 in the required plate sizes. The applicant also stated that LDX 2101 has similar corrosion resistance and is easily welded.

LDX 2101 is an austenitic-ferritic (duplex) stainless steel. LDX 2101 provides adequate resistance to uniform corrosion, pitting, crevice corrosion, and stress-corrosion cracking in most media. It has higher mechanical strength than traditional stainless steels such as 304, 316L, and XM-29. LDX 2101 can be readily welded with commonly used welding processes. LDX 2101 is a relatively new material that was adopted in ASTM SA-240 in 2007. Its current commercial uses range widely from chemical storage tanks, waste water treatment facilities, and over-the-road chemical transportation tanks. This material is now widely used in several industries as a replacement for grade 304 and 316 stainless steels. The information provided by the applicant and the manufacturer's literature suggest that this material will perform adequately when exposed to borated water environments. Duplex stainless steels are considered to have more than adequate resistance to general corrosion and stress-corrosion cracking in aqueous solutions containing boric acid and chlorides.

A material's resistance to pitting can be compared to other materials using its pitting resistance equivalent (PRE) number. The PRE number is a theoretical method to compare the resistance to pitting and crevice corrosion of different types of stainless steels based on their chemical composition. In response to request for additional information (RAI)-TR106-CIB1-04, dated January 29, 2008, the applicant provided PRE numbers for stainless steel materials 304, 316L, and XM-29. The applicant also provided PRE numbers for LDX 2101, 2304 duplex stainless steel, and 2205 duplex stainless steel. The information provided by the applicant suggests that LDX 2101 has improved resistance to pitting and crevice corrosion when compared to 304, 316L, and XM-29 stainless steels. The applicant provided data in its January 29, 2008, letter that indicates that duplex stainless steels perform better than or equal to austenitic stainless steels, such as Types 304 and 316L, when exposed to borated water and chlorides. In addition, the applicant stated that it was just beginning its corrosion testing program for LDX 2101 base material and LDX 2101 welds. The staff notes that the information supplied by the applicant included data for duplex stainless steels 2304 and 2205 but did not include data for LDX 2101. While the staff agreed that LDX 2101 was likely to perform in a manner similar to 2304 and 2205 duplex stainless steels in borated water, confirmatory testing must be completed before the staff can approve the use of this material.

In supplemental RAI-TR106-CIB1-05, the staff asked the applicant to discuss its corrosion test plan and acceptance criteria for LDX 2101 base material and LDX 2101 weld filler materials. In addition, the staff requested that the applicant provide a technical justification for its testing plan and acceptance criteria that describe its adequacy to ensure that the materials will not be subject to general corrosion, stress-corrosion cracking, or other form of degradation from corrosion for the life of the plant.

The applicant responded to RAI-TR106-CIB-05 in a letter dated May 14, 2008. The applicant stated that it would conduct a confirmatory corrosion testing program to demonstrate the adequacy of LDX 2101. The applicant's confirmatory corrosion testing program includes LDX 2101 base material and weld filler materials that bound those filler materials that will be used during fabrication. Tests that will be conducted include uniform corrosion, stress-corrosion cracking, and crevice corrosion tests. The applicant stated that its test program was designed to establish test data on LDX 2101 material and its welds in terms of their susceptibility to degradation under exposure to oxygenated boric acid with halogen (chloride) contamination and in crevice corrosion conditions under accelerated service conditions to demonstrate a service life of 60 years. All tests will use Type 304 austenitic stainless steel as a reference sample. The staff notes that it approved Type 304 stainless steel, in addition to XM-29, for use in the fabrication of the IRWST liner in NUREG-1793, "Final Safety Evaluation Report Related to Certification of the AP1000 Standard Design," issued September 2004.

The staff found that the information that the applicant provided suggests that LDX 2101 duplex stainless steel material is likely to perform adequately in the IRWST environment. However, given the lack of specific corrosion data for LDX 2101, the staff asked, in RAI-SRP6.1.1-CIB1-02, that the applicant provide the results from its LDX 2101 corrosion testing program and describe the extent to which the results confirm that LDX 2101 will not be subject to general corrosion, stress corrosion, or other forms of degradation for the design life of the plant. The applicant responded in a letter dated June 30, 2010, and stated that it has completed a confirmatory testing program that included LDX 2101 and its associated welds under service conditions in the AP1000 IRWST. The test program included testing for three different types of corrosion: uniform corrosion, crevice corrosion, and stress-corrosion cracking. The testing also included Type 304 L stainless steel samples as reference samples for benchmarking. The staff notes that it approved Type 304 austenitic stainless steel for use in the IRWST, as documented in NUREG-1793. The applicant stated that the overall results of its confirmatory tests demonstrate that S32101 (LDX 2101) duplex stainless steel and its welds exhibited superior performance under accelerated service conditions in comparison with 304L stainless steel for use in the AP1000 structural modules [ ]. The staff notes that Types 304 and 304L are commonly used materials for applications such as the IRWST in operating plants. Westinghouse Commercial Atomic Power (WCAP)-17280-P, “Confirmatory Corrosion Testing of S32101/LDX2101 Duplex Stainless Steel Base and Weld Materials for the AP1000 Structural Module Applications,” issued June 2010, documents the test program and the results. The staff conducted an audit of WCAP-17280-P at Westinghouse’s Rockville, Maryland, office on June 28, 2010. As a result of the audit, the staff concluded that the test data in WCAP-17280-P provide reasonable assurance that LDX 2101 will not be subject to general corrosion, stress corrosion, or other forms of degradation for the design life of the plant and is, therefore, acceptable.

The staff finds that the proposed modifications to Section 6.1.1.3 are acceptable and meet the requirements of GDC 4 and the acceptance criteria of NUREG-0800, “Standard Review Plan [SRP] for the Review of Safety Analysis Reports for Nuclear Power Plants,” Section 6.1.1, “Engineered Safety Features Materials,” Revision 2, issued March 2007. Revision 17 of the DCD and TR-134, Revision 5, incorporate the proposed changes as identified in TR-106. Accordingly, these changes are generic and are expected to apply to all COL applications referencing the AP1000 certified design. At this time, the NRC has not issued a COL for any AP1000 plants. Thus, the proposed changes contribute to the increased standardization of the AP1000 certified design and, therefore, meet the requirements of 10 CFR 52.63(a)(1)(vii).

DCD Tier 2, Section 6.1.1.4, describes the materials’ compatibility with reactor coolant and ESF fluids. Section 6.1.1.4 currently states that in the postaccident environment, both aluminum and zinc surfaces in the containment are subject to chemical attack, resulting in the production of hydrogen. The applicant proposed to modify Section 6.1.1.4 to state that in the postaccident environment, both aluminum and zinc surfaces in the containment are subject to chemical attack, resulting in the production of hydrogen or chemical precipitants or both that can affect long-term core cooling. Primary sources of aluminum in the AP1000 containment are the excore detectors. To avoid sump water contact with the excore detectors, the applicant proposed to modify the DCD to state they will be enclosed in stainless steel or titanium housings. In addition, the applicant has proposed to modify DCD Tier 1, Table 2.2.3-4, to include inspections, tests, analyses, and acceptance criteria (ITAAC) to verify that exposed surfaces of the excore detectors are made of stainless steel or titanium. The applicant’s basis for the proposed change appears in Westinghouse DCD Impact Document and TR-26. These proposed modifications are intended to address, in part, GSI-191. Section 6.2.1.8 of this report provides a detailed staff evaluation of the applicant's design related to GSI-191. The staff finds the applicant's proposal to enclose the excore detectors in stainless steel or titanium acceptable because these materials will prevent the degradation of the aluminum excore detectors, which could result in chemical precipitants that can affect long-term core cooling. Revision 17 of the DCD incorporates the proposed changes, as identified above. Accordingly, these changes are generic and are expected to apply to all COL applications referencing the AP1000 certified design. At this time, the NRC has not issued a COL for any AP1000 plants. Thus, the proposed changes contribute to the increased standardization of the AP1000 certified design and, therefore, meet the requirements of 10 CFR 52.63(a)(1)(vii).

6.1.1.3 Conclusion

Based on the above evaluation, the staff finds that the revisions proposed by the applicant to the AP1000 DCD, Section 6.1.1, are acceptable. Revision 17 to the AP1000 DCD incorporates the proposed changes, as identified in TR-134, TR-32, TR-26, TR-106 and the AP1000 DCD Impact Document. Furthermore, the staff finds that the conclusions in the above supporting documentation on the evaluation of these proposed DCD modifications are generic and are expected to apply to all COL applications referencing the AP1000 DC. Therefore, the proposed DCD changes are acceptable pursuant to 10 CFR 52.63(a)(1)(vii) on the basis that they contribute to the increased standardization of the certification information.

6.1.2 Organic Materials

6.1.2.1 Summary of Technical Information

The DCD changes described below are based on DCD Revision 17 and Westinghouse document APP-GW-GLE-002, Revision 7 (DCD Impact Document). The applicant modified DCD Tier 2, Section 6.1.2.1, in several places to change or clarify the types of coatings, the locations where they are used, and the associated quality assurance requirements.

The staff evaluated coatings for the certified AP1000 design based on NUREG-0800 Section 6.1.2. The staff concluded that the design met the quality assurance requirements of Appendix B to 10 CFR Part 50, as they relate to protective coatings. This conclusion was based on the design's conforming to the guidance in regulatory guide (RG) 1.54, "Service Level I, II, and III Protective Coatings Applied to Nuclear Power Plants," Revision 1, including the provisions for design basis accident testing. RG 1.54, Revision 1, also provides guidance for coatings application and assessment.

The changes in DCD Revision 17 and the DCD Impact Document were proposed in order to meet the relevant requirements of GDC 35, "Emergency Core Cooling," GDC 38, "Containment Heat Removal," and 10 CFR 50.46(b)(5), "Acceptance criteria for emergency core cooling systems for light-water nuclear power reactors," for cooling water following a LOCA. Coatings are discussed in that context in Section 6.3 of the AP1000 DCD and 6.2 of the staff's corresponding safety evaluation. The proposed changes include the COL information required in Section 6.1.3.2 for consistency with Section 6.1.2. Additional information was provided in TR-26.

6.1.2.2 Evaluation

Inside containment, as described in the revised Section 6.1.2.1.5, inorganic zinc (IOZ) will be applied only to surfaces that exceed the temperature limit for epoxy during normal operation. All

IOZ inside containment will be classified as Service Level I. The staff finds these changes acceptable, since appropriately qualified epoxy coatings are suitable replacements for corrosion protection at lower temperatures, and because the Service Level I designation conforms to RG 1.54, Revision 1. Section 6.1.2.1.2 also introduces self-priming high-solids epoxy (SPHSE) without a zinc primer for structural modules, and the zinc/epoxy combination is eliminated except for the inside of the containment vessel up to seven feet above the operating floor. SPHSE is also added as a possible coating on concrete floors and walls. The staff finds this acceptable because the technical and quality requirements relating to the epoxy selection, and conformance to RG 1.54, Revision 1, are not changed. SPHSE is a standard type of coating, and SPHSE products have been design basis accident (DBA) qualified for steel and concrete. Eliminating the zinc/epoxy combination (except on the containment shell near the operating floor) is acceptable because there is no change in the quality requirements for the SPHSE.

Another significant change for inside containment is that coatings on manufactured components below the LOCA flood zone or in locations susceptible to debris transport must have a density of at least 1602 kilograms per cubic meter (kg/m^3) (100 pounds per cubic foot (lb/ft^3)) or a report, approved by the NRC, demonstrating the debris from that coating will not transport. This is discussed in DCD Sections 6.1.2.1.5 and 6.1.2.1.6. The staff finds this acceptable because the high density requirement limits transport of potential debris, while other coating requirements are not changed. SPHSE was also introduced as a coating for outside containment. According to the modifications in Section 6.1.2.1.4, carbon steel outside containment will be coated with either SPHSE or IOZ with epoxy top coat. Concrete floors and walls will be coated with epoxy or SPHSE. Section 6.1.2.1.6 was changed to clarify that procurement of Service Level II coatings outside containment, unlike inside containment, is not a safety-related, 10 CFR Part 50, Appendix B activity.

DCD Section 6.1.3.2, the COL information item called “Coating Program,” was modified to state that the COL applicant must include Service Level II coatings in the coatings program, and the coatings program includes inspection along with procurement, application, and monitoring. (This is also identified in the DCD as COL Information Item 6.1-2.) As indicated in Tier 2 Appendix 1A of the DCD, there is an exception to RG 1.54, Revision 1 due to the use of coatings inside containment that are designated Service Level II. The quality assurance requirements for these coatings are discussed in DCD Section 6.1.2.1.6. The change to Section 6.1.3.2 was proposed in a March 31, 2010, response to RAI-SRP6.1.2-CIB1-01. The staff found it acceptable because it makes the COL information required by Section 6.1.3.2 consistent with the information in Section 6.1.2.1.6. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

Tier 1, Table 2.2.3-4, Item “x,” was modified to add two requirements to the existing requirement for nonsafety-related coatings used inside containment on walls, floors, ceilings, and structural steel (except for inside a chemical and volume control system (CVS) room that drains to the waste liquid processing system). The existing requirement (acceptance criterion) is a report concluding that these coatings have a dry film density of at least 1602 kg/m^3 (100 lb/ft^3). The two additional acceptance criteria are for a report showing that these coatings will not transport if the density is less than 1602 kg/m^3 (100 lb/ft^3) and for a report concluding that inorganic zinc coating used on these surfaces is safety Service Level I. (This ITAAC includes components in the LOCA flood zone, or above the flood zone and not in an enclosure.) The staff finds these changes acceptable because they supplement the existing ITAAC intended to ensure coatings chips generated by a LOCA will not transport.

6.1.2.3 Conclusion

Based on the above evaluation, the staff finds that the revisions proposed by the applicant to the AP1000 DCD, Section 6.1.2 are acceptable. The proposed changes are incorporated in Revision 17 of the DCD and in the AP1000 DCD impact document, APP-GW-GLE-002, Revision 7. Furthermore, the staff finds that conclusions about these DCD modifications in the documents cited above are generic and are expected to apply to all COL applications referencing the AP1000 DC. Therefore, the proposed DCD changes are acceptable pursuant to 10 CFR 52.63(a)(1)(vii) on the basis that they contribute to the increased standardization of the certification information.

6.2.1 Primary Containment Functional Design

6.2.1.1 Containment Pressure and Temperature Response to High-Energy Line Breaks

6.2.1.1.1 Wet Bulb Temperature

6.2.1.1.1.1 Summary of Technical Information

As described in APP-GW-GLE-036, “Impact of a Revision to the Current Wet Bulb Temperature Identified in Table 5.0-1 (Tier 1) and Table 2-1 (Sheet 1 of 3) of the DCD (Revision 16),” Revision 0, issued June 27, 2008, the site parameters for external wet bulb temperatures are increased from 26.7 °Celsius (C) to 30 °C (80 °Fahrenheit (F) to 86.1 °F) coincident and 29.7 °C to 30 °C (85.5 °F to 86.1 °F) noncoincident to encompass more sites in the eastern United States. The change to the coincident wet bulb temperature corresponds to an increase in relative humidity from 22 percent to 31 percent at the maximum dry bulb temperature of 46.1 °C (115 °F) and atmospheric conditions. The change to the noncoincident wet bulb temperature increases the temperature at which 100 percent relative humidity can occur. The external temperature and relative humidity are initial conditions in the containment analysis.

6.2.1.1.1.2 Evaluation

In response to RAI-SRP6.2.1.1-SPCV-05, dated October 1, 2008, the applicant stated that the containment analysis results are not sensitive to the external relative humidity. The staff audited one of the supporting analyses, Appendix A.3 to APP-GW-GSC-040, “AP1000 WGOTHIC Containment Models for Integrated Safety Analysis Evaluation: Disposition of Design Change Proposals and Modification of the Containment Model,” and observed that when the relative humidity of the NRC-approved AP1000 WGOTHIC model for a double-ended cold-leg guillotine (DECLG) LOCA was increased from 22 percent to 31 percent at an external temperature of 46.1 °C (115 °F), the resulting peak pressure increase was negligible. This study also demonstrated that the increase to noncoincident wet bulb temperature is less limiting than the increase to coincident wet bulb temperature with respect to peak pressures. Additional sensitivity studies documented in Section 5.6 of WCAP-15846, “WGOTHIC Application to AP600 and AP1000,” Revision 1, issued March 2004, showed that the AP600 WGOTHIC LOCA and main steamline break models are insensitive to external humidity for select initial conditions. The staff ran confirmatory analyses using the CONTAIN model of the AP1000 containment developed by the staff during the DCD review. When the outside relative humidity in this model was increased to 31 percent, there was negligible impact on the peak pressures resulting from a main steamline break and DECLG. There was also a negligible increase in the pressure 24 hours after the DECLG LOCA.

While the staff found the increase to external wet bulb temperatures acceptable, it was not clear how the containment analyses referenced in the DCD would incorporate this change. In its July 12, 2009, Revision 2 response to RAI-SRP6.2.1.1-SPCV-06, the applicant stated that DCD changes to reference a more recent WGOTHIC model, which includes the increase to external wet bulb temperature, will be included in its submittal of APP-GW-GLR-096, “Evaluation of the Effect of AP1000 Enhanced Shield Building Design on the Containment Response and Safety Analysis.” Revision 1 of APP-GW-GLR-096 was issued August 2010, and it does propose adding APP-GW-GLR-096 as a reference to the DCD. The staff confirmed that the model used in this study includes the increased wet bulb temperature, and is satisfied with the response. The evaluation of APP-GW-GLR-096 is documented in Chapter 23.

6.2.1.1.1.3 Conclusion

Based on the evaluations by the applicant and the confirmatory analysis by the staff, the staff concludes that that the containment functional design capability is essentially unchanged by the proposed increase in maximum site wet bulb temperatures. The conclusions reached in NUREG-1793, Sections 6.2.1 and 6.2.1.1, remain applicable, including that the design is compliant with regulatory requirements.

6.2.1.1.2 External Pressure Analysis

6.2.1.1.2.1 Summary of Technical Information

In DCD Revision 15, the maximum external pressure event is alleviated by the operator action of opening either set of purge valves. On August 16, 2010, the applicant submitted Change Number 74 to add a vacuum relief system that replaces the operator action. The “NRC Review Package” attached to this letter includes the revised analysis and proposed DCD changes for Section 6.2.1.1.4.

6.2.1.1.2.2 Evaluation

The staff evaluation of the adequacy of the vacuum relief system to mitigate the maximum expected external pressure scenario as described in Change Number 74 will be included in Chapter 23.

6.2.1.1.2.3 Conclusion

The staff’s conclusion regarding the external pressure analysis is provided in Chapter 23.

6.2.1.2 Subcompartment Analysis

6.2.1.2.1 Summary of Technical Information

APP-GW-GLR-016, “AP1000 Pressurizer Design,” issued May 2006, describes changes made to the diameter and height of the pressurizer and to the wall heights of the pressurizer compartment in order to obtain satisfactory piping analysis results. As a result of the shorter pressurizer walls, the applicant decreased the upper elevation of the assumed pressurizer spray break in DCD Tier 2, Section 6.2.1.2.3.2, from 52.1 to 49.7 meters (m) (171 to 163 feet (ft)).

6.2.1.2.2 Evaluation

The subcompartment analysis previously approved by the staff used the TMD computer code with models described in WCAP-15965, "AP1000 Subcompartment Models," issued November 2002. As reported in the July 18, 2008, response to RAI-SRP6.2.1.2-SPCV-01, the applicant performed a conservative calculation to evaluate the impact of the pressurizer changes. The results showed that the differential pressure (dP) in the pressurizer cubicle remained below the 34.5 kilopascal (kPa) (5 pounds per square inch differential (psid)) structural threshold. The staff ran a confirmatory analysis using COMPARE with input compiled from the pressurizer compartment model described in WCAP-15965 and the changes to the pressurizer described in APP-GW-GLR-016. The staff analysis predicted that the pressurizer changes would increase the maximum dP from [ ], which is consistent with the applicant's results.

The revised height of the pressurizer wall is 48.8 m (160 ft). Based on the July 18, 2009, response to RAI-SRP6.2.1.2-SPCV-02, the pressurizer spray line extends 0.9 m (3 ft) above the top of the wall; therefore, changing the upper elevation for the assumed pressurizer spray break to 49.7 m (163 ft) is appropriate.

While the staff found the changes to the pressurizer and pressurizer compartment acceptable with respect to subcompartment analyses, it was not clear how the revised analysis would be incorporated into the DCD. In a letter dated August 31, 2009, in response to RAI-SRP6.2.1.2-SPCV-01 Revision 2, the applicant revised the DCD to state that the impact of the dimensional changes to the pressurizer and pressurizer compartment on the subcompartment analysis was evaluated in APP-GW-GLR-138, "Evaluation of the Pressurizer Changes on the AP1000 TMD Analyses," issued August 2009, and the existing conclusions remain valid. The staff is satisfied with this response. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

6.2.1.2.3 Conclusion

Based on the results of the applicant's analysis and the staff's confirmatory calculations, the staff agrees that the changes made in the DCD related to the pressurizer compartment have a negligible impact on the AP1000 subcompartment analysis. The conclusions reached in NUREG-1793, Section 6.2.1.2, remain applicable, including that the containment subcompartment pressurization analysis is acceptable.

6.2.1.3 Mass and Energy Release Analyses for Postulated Loss-of-Coolant Accidents

6.2.1.3.1 Summary of Technical Information

While the applicant did not change DCD Section 6.2.1.3.2.1 regarding the 1 percent full-power allowance for calorimetric error in the energy release calculations, the applicant's response to RAI-SRP15.0-SRSB-02 proposes a change to this section as discussed below.

6.2.1.3.2 Evaluation

For analyses of heat sources during a postulated LOCA, paragraph I.A of Appendix K, "ECCS Evaluation Models," to 10 CFR Part 50 permits an assumed power level allowance of less than 2 percent full power if it has been demonstrated to account for uncertainties related to power level instrumentation error. The power level used to determine the maximum containment pressure in Chapter 6 of the DCD was based on a calorimetric error of less than 2 percent full power, but there was no associated justification. In a May 6, 2009, response to RAI-SRP15.0-SRSB-02, the applicant stated that the AP1000 will use the proven technology of high-accuracy instrumentation to demonstrate a 1 percent design uncertainty and added COL Information Item 15.0-1, described in DCD Section 15.0.15, to track this commitment. The applicant also added a note to the DCD Section 6.2.1.3.2.1 assumptions on energy release to reference this COL item. This is appropriate as it provides justification for the uncertainty value, as required by the stated criteria.

6.2.1.3.3 Conclusion

The change is acceptable, and the conclusions reached in NUREG-1793, Sections 6.2.1.3 and 6.2.1.4, remain applicable, including that the methods and assumptions are acceptable for the licensing analyses.

6.2.1.8 Adequacy of In-Containment Refueling Water Storage Tank and Containment Recirculation Screen Performance

DCD Tier 2, Section 6.3.2.2.7, describes the evaluation of the water sources for long-term recirculation cooling following a LOCA, including the design and operation of the AP1000 passive core cooling system (PXS) debris screens. DCD Section 6.3.8 describes the associated COL information items, and DCD Tier 1, Section 2.2.3, includes the associated design descriptions and ITAAC. DCD Revision 17 incorporated many changes to these sections, as did APP-GW-GLE-002, which identified changes beyond those included in DCD Revision 17. Because the revisions are so extensive, the staff will not address each change independently but will perform a complete evaluation of the final configuration. As such, this section of the SER amendment replaces the analysis documented in NUREG-1793, Revision 0, in its entirety. In a subsequent revision to the AP1000 DCD, the applicant incorporated the DCD text proposed in APP-GW-GLE-002, Revision 7, dated July 13, 2010.

One of the changes made is the closure of COL Information Item 6.3-2 from DCD Tier 2, Table 1.8-2. DCD Tier 2, Section 6.3.8.2, “Verification of Water Sources for Long-Term Recirculation Cooling Following a LOCA,” originally made the following commitment:

> The Combined License applicants referencing the AP1000 will perform an evaluation consistent with RG 1.82, Revision 3, and subsequently approved NRC guidance, to demonstrate that adequate long-term core cooling is available considering debris resulting from a LOCA together with debris that exists before a LOCA. As discussed in DCD Subsection 6.3.2.2.7.1, a LOCA in the AP1000 does not generate fibrous debris due to damage to insulation or other materials included in the AP1000 design. The evaluation will consider resident fibers and particles that could be present considering the plant design, location, and containment cleanliness program. The determination of the characteristics of such resident debris will be based on sample measurements from operating plants. The evaluation will also consider the potential for the generation of chemical debris (precipitants). The potential to generate such debris will be determined considering the materials used inside the AP1000 containment, the post-accident water chemistry of the AP1000, and the applicable research/testing.

In DCD Revision 17, the applicant stated the following:

> The Combined License information item requested in this subsection has been fully addressed in APP-GW-GLR-079 (Reference 3), and the applicable changes are incorporated into the DCD. The design of the recirculation screens is complete. Testing to assess the screen performance and downstream effects is complete. A study of the effects of screen design and performance on long-term cooling is complete. No additional work is required by the Combined License applicant to address the aspects of the Combined License information requested in this subsection.

The following Commission regulations are related to the evaluation of the water sources for long-term recirculation cooling following a LOCA:

- GDC 35, as it relates to providing abundant emergency core cooling to transfer heat from the reactor core following a LOCA

- GDC 38, as it relates to the ability of the containment heat removal system to rapidly reduce the containment pressure and temperature following a LOCA and to maintain these indicators at acceptably low levels

- 10 CFR 50.46(b)(5), as it relates to requirements for long-term cooling in the presence of LOCA-generated and latent debris

As directed by NUREG-0800 Section 6.2.2, "Containment Heat Removal Systems," Revision 5, the staff performed the review in accordance with RG 1.82, "Water Sources for Long-Term Recirculation Cooling Following a Loss-of-Coolant Accident," Revision 3, issued November 2003, as supplemented by the Nuclear Energy Institute (NEI) Guidance Report NEI 04-07, "Pressurized Water Reactor Sump Performance Evaluation Methodology," Revision 0, Volume 1, issued December 2004, and the associated NRC safety evaluation, "Safety Evaluation by the Office of Nuclear Reactor Regulation Related to NRC Generic Letter 2004-02," issued December 2004. The review was also informed by WCAP-16406-P, "Evaluation of Downstream Sump Debris Effects in Support of GSI-191," Revision 1, dated August 2007, as supplemented by "Final Safety Evaluation for Pressurized Water Reactor Owners Group Topical Report WCAP-16406-P," "Evaluation of Downstream Sump Debris Effects in Support of GSI-191, Revision 1," Revision 0, dated December 20, 2007; the NRC letter dated March 28, 2008, "Revised Guidance for Review of Final Licensee Responses to Generic Letter 2004-02," with enclosures addressing the areas of chemical effects, coatings, and head loss testing; the final safety evaluation by the Office of Nuclear Reactor Regulation on TR WCAP-16530-NP, "Evaluation of Post-Accident Chemical Effects in Containment Sump Fluids to Support GSI-191," dated December 21, 2007; and the NRC letter dated April 6, 2010, "Revised Guidance Regarding Coatings Zone of Influence for Review of Final Licensee Responses to Generic Letter 2004-02."

In addition to the DCD, as modified by APP-GW-GLE-002, the staff reviewed APP-GW-GLR-079-P and APP-GW-GLR-086-NP (TR-26), "AP1000 Verification of Water Sources for Long-Term Recirculation Cooling Following a LOCA," Revision 8, dated July 20, 2010, and APP-GW-GLN-147-P and -NP (TR-147), "AP1000 Containment Recirculation and IRWST Screen Design," Revision 3, issued November 2009, which are identified as DCD references. The following submittals from the applicant provided additional information: WCAP-16914-P and -NP, "Evaluation of Debris Loading Head Loss Tests for AP1000 Recirculation Screens and In-Containment Refueling Water Storage Tank Screens," Revision 5, issued June 2010; WCAP-17028-P and -NP, “Evaluation of Debris Loading Head Loss Experiments Across AP1000 Fuel Assemblies During Post-Accident Recirculation,” Revision 6, issued June 2010; APP-PXS-GLR-001, “Impact on AP1000 Post-LOCA Long-Term Cooling of Postulated Containment Sump Debris,” Revision 4, dated February 26, 2010; APP-GW-GLR-092-P and APP-GW-GLR-093-NP, ”Statistical Evaluation of AP1000 Fuel Assembly Debris-Loading Head loss Tests,” Revision 0, issued February 2010; and APP-GW-GLR-110-P and APP-GW-GLR-111-NP, “Boric Acid Precipitation Tests During Post-LOCA Conditions,” Revision 0, issued February 2010.

The applicant responded to staff RAIs in letters dated November 6 and 11, 2008; April 22, May 12, May 13, May 14, May 15, May 20, May 27, June 4, July 7, July 22, July 31, September 17, September 22, and November 2, 2009; and January 29, February 26, March 12, March 26, April 1, April 16, April 26, April 29, May 11, May 13, May 28, June 14, June 28, June 30 and July 30, 2010.

6.2.1.8.1 Summary of Technical Information

The AP1000 has two containment recirculation screens and three IRWST screens to capture debris following a LOCA. All screens are designed to be vertically oriented and have solid top covers so that debris that settles out of the water does not fall on the screening surfaces. The screens are constructed of stainless steel to be corrosion resistant and comprise individual pockets to provide greater filtering areas for a given volume. All AP1000 screens use the same pocket geometry, with each pocket having a frontal face area greater than or equal to 40 square centimeters (cm^2) (6.2 square inches (in^2)), a screen surface area greater than or equal to 903 cm^2 (140 in^2), and a hole size less than or equal to 1.59 millimeters (mm) (0.0625 inch (in)). This pocket design also provides the trash rack function because it prevents a single object from blocking a large portion of the screen.

Three separate screens are located inside the IRWST at the bottom of the tank. Two of the screens are located at opposite ends of the tank, each with a frontal area greater than 1.9 square meters (m^2) (20 square feet (ft^2)) and a surface area greater than 46.5 m^2 (500 ft^2). The third screen, with a frontal area greater than 3.7 m^2 (40 ft^2) and a surface area greater than 92.9 m^2 (1,000 ft^2), is located in the center of the tank. Each of the smaller screens supplies one of the two recirculation lines and is joined to the center screen through cross-connect piping, which distributes the flow. The lowest screening surfaces are located 0.2 m (6 in) above the IRWST floor to prevent debris from being swept along the floor into the screen. During recirculation, the only flow entering the IRWST is the steam condensate that forms inside of the containment shell and collects in the IRWST gutter. The gutter feeds the IRWST through two drainpipes that terminate within 1.5 m (5 ft) of the IRWST floor and at least 3.7 m (12 ft) away from any screen face, which prevents debris from entering the tank close to the screens. For minimum floodup conditions during recirculation, the water level is a few inches above the top of the screen assembly.

The containment recirculation sump for the AP1000 is the loop compartment. Two containment recirculation screens, each with a frontal area greater than 9.8 m^2 (105 ft^2) and a surface area greater than 232 m^2 (2,500 ft^2), are located next to one another along walls on the loop compartment floor. The loop compartment floor is 3.5 m (11.5 ft) above the reactor vessel cavity floor, which is the lowest level in containment. Each screen supplies one of the two recirculation lines. The screens are cross-connected with flow channels so that even if only one recirculation line is operating, both containment recirculation screens will be available to filter the flow. A 0.6 m (2 ft) high curb is located in front of the screens to prevent debris from being swept along the floor into the screen. Protective plates, which cover the screen and extend outward at least 3 m (10 ft) in front of the screen face and 2.13 m (7 ft) beyond the sides of the screen, are located no more than 0.3 m (1 ft) above the top of the containment recirculation screens. These plates are designed to prevent debris from settling into the water close to the screens. During recirculation, even at minimum floodup conditions, the water level remains about 3 m (10 ft) above the top of the screens.

The AP1000 is equipped with an active nonsafety-related injection and recirculation system (the residual heat removal system or RNS). This system is an investment protection system and will be used following a LOCA if there is power and the system is available. The RNS initially injects water from the cask loading pit and then switches to recirculate the sump water. The system is not credited in the safety analysis; however, the applicant has evaluated the screens and core assuming the higher RNS flow rates to demonstrate that the RNS system will function following a LOCA.

During the AP1000 recirculation phase, some portions of the reactor coolant system (RCS) piping are submerged. LOCAs resulting from pipe breaks in these locations will then be flooded, allowing sump fluid to bypass the screens and flow directly to the core. Because of this, the core is evaluated as a separate debris filtering location.

6.2.1.8.2 Evaluation

6.2.1.8.2.1 Break Selection

A primary objective of break selection is to identify the break location that results in debris generation that produces the largest head loss across the screens. Section 3.3 of NEI 04-07 describes a process; whereby, different break locations are systematically evaluated to determine which is limiting. In the AP1000 design, there are only three sources of debris that transport with the recirculating water: latent or resident containment debris, debris from postaccident chemical effects, and debris from coatings located in the zone of influence (ZOI) of a LOCA jet. The limiting break for each filtering location (screens or core) is determined by examining the debris generation and transport assumptions for each of these debris types.

6.2.1.8.2.1.1 Containment Recirculation Screens and In-Containment Refueling Water Storage Tank Screens Break Selection

In the AP1000, the amounts of latent and chemical debris generated and transported to the containment recirculation and IRWST screens are independent of break location; therefore, the only consideration for break selection is coatings debris. Because all coatings in the ZOI are assumed to generate fine transportable particulates, the limiting break location is the one whose ZOI contains the largest amount of coatings. The applicant described its break selection process for cold leg (CL) and hot leg (HL) LOCAs in the June 30, 2010, Revision 2 response to RAI-SRP6.2.2-SPCV-25. The applicant determined that the limiting breaks would occur in the largest diameter lines: the main loop CL, which has a 55.9 centimeter (cm) (22 in) inner diameter (ID) and the main loop HL, which has a 78.7 cm (31 in) ID. These breaks encompass potential breaks on smaller lines because the main loop pipes are located in the same general area and have significantly larger ZOIs than the smaller lines.

The applicant then selected the terminal ends of the main loop lines as potential break locations and quantified the amount of both epoxy and inorganic zinc coatings at each site by multiplying the surface area of coated beams, pipes and flat surfaces located in the ZOI by the coating thickness and density. The limiting CL location was the terminal end at reactor coolant pump (RCP) #2, in the west loop compartment. The limiting HL break was the terminal end at either steam generator, due to similarity between the compartments. The applicant then assessed potential break locations at 5 ft intervals along each CL and HL line, as recommended by the safety evaluation on NEI 04-07, to demonstrate that these sites, with potentially different coating inventories were bounded by the limiting breaks. This analysis employed plant layouts to identify the location of coated surfaces such as walls, plates, pipes and beams with respect to each postulated ZOI. When necessary, the applicant estimated the increase or decrease to each type of coated surface to show that the net amount of coatings was bounded by the limiting break.

The staff finds that the spectrum of breaks evaluated is acceptable because, while the unique characteristics of the AP1000 greatly simplify the break selection process, the applicant's procedure meets the intent of the NEI 04-07 and the related safety evaluation, and Regulatory Position C.1.3.2.3 of RG 1.82, Revision 3.

6.2.1.8.2.1.2 Core Break Selection

Because of the relatively high containment floodup level during long-term recirculation operation in the AP1000 design, some LOCA break locations will be flooded, resulting in a portion of recirculation flow with unfiltered containment debris entering the reactor core through the submerged break. The DECL break at the reactor vessel, DEHL break at the reactor vessel, and double-ended direct vessel injection (DEDVI) line break in the loop compartment are breaks that could be submerged in the flooded containment sump and allow unfiltered debris into the reactor vessel during the post-LOCA long-term cooling phase.

The objective of break selection is to choose a limiting LOCA break location for the GSI-191 long-term cooling evaluation. The break selection considers two aspects: (1) the limiting break, which contributes the most unfiltered debris to the core region causing core flow blockage; and (2) the limiting break for long-term core cooling evaluation, which results in the worst core heatup because of early containment recirculation initiation at a higher decay heat level.

In Section 6.2.1.8.2.6 of this report, the staff discusses the containment debris transport for the DECL break, DEDVI line break, and DEHL break and the evaluation of the percentage of the containment debris entering the reactor vessel for these breaks. The percentage of the debris that might be transported into the reactor vessel without screening by the containment recirculation screens is determined by integrating the relative recirculation flows through the break and through the intact DVI lines of the PXS. Flow split calculation for the DECL break identified that [ ] percent of the water in the containment will come through the DECL break, compared to the DEDVI line break with [ ] percent flow split. Therefore, the applicant determined that the DECL break at the reactor vessel is the limiting break with respect to debris transport to the core, with a flow split conservatively rounded up to 90 percent. The applicant assumed that all of the latent debris in the containment would be in the containment water and, therefore, 90 percent of containment debris would enter the reactor vessel through the submerged DECL break during the post-LOCA recirculation long-term core cooling phase, bypassing the IRWST and containment recirculation screens. This 90 percent debris bypass calculated with a DECL break is the design-basis value used to determine the containment debris bypass to the core for the AP1000 design.

For its long-term cooling evaluations performed in the AP1000 DCD, Revision 17, the applicant selected the DEDVI line break in the PXS room as the limiting long-term cooling case because it minimized the cooling water injection head at the highest decay heat generation rate. The case analyzed in the DCD is the continuation of a small-break LOCA. The DCD long-term cooling evaluations used the PXS valve room as the break location since natural circulation flow losses from the break to the core inlet are greatest, thereby minimizing the amount of flow into the core inlet from the break. The DCD case did not consider the GSI-191 concern that evaluates debris entering the core through the break location. Since the DEDVI break in the PXS room has only a small amount of debris accessible to the break (i.e., only debris in the PXS room floodup water volume can enter the break location), the applicant considered the DEDVI line break in the loop compartment as the limiting break for unfiltered debris entry into the core.

The applicant performed long-term cooling sensitivity studies, described in APP-PXS-GLR-001, Revision 4. The objective of these sensitivity studies was to demonstrate that core cooling margins are maintained when large, arbitrary, nonmechanistic head losses are added to the containment recirculation screens, IRWST screens, and the core inlet. Section 6.2.1.8.2.7 of this report includes additional discussion of these sensitivity studies. As discussed in Section 4 of TR-26, the applicant selected the direct vessel injection (DVI) break for the long-term cooling sensitivity analyses with debris-induced core head loss for the following reasons:

- A DECL break has significantly less resistance to flow than the DVI break; therefore, the DVI break will minimize the water flow to the core. For this reason, only the DVI breaks were analyzed with WCOBRA/TRAC in APP-PXS-GLR-001, Revision 4.

- The lower elevation of the DEDVI break also allows water from the containment to flow into the RCS through the break sooner than for a DECL LOCA; therefore, the debris will start to accumulate sooner with a higher decay heat.

- A DEDVI break results in higher decay heat levels at the time recirculation begins compared to a DECL LOCA. With a DEDVI break, a portion of the IRWST injection flow will spill out of the break into containment, thereby reducing the time of IRWST injection.

In the post-LOCA long-term cooling sensitivity studies, described in APP-PXS-GLR-001, Revision 4, the DEDVI line break in a PXS room and in the loop compartment adjacent to the DVI inlet nozzle, respectively, were assumed from the analysis. In Cases 1 through 5 and Case 7, which have smaller assumed core inlet flow resistances, the DVI line break was assumed in the PXS room, where the floodup level is lower than the floodup level in the loop compartment and is, therefore, more conservative. In other cases with larger core inlet flow resistances simulating a larger amount of debris entering the core, the DVI break is assumed to be in the loop compartment. This is a more realistic assumption because a DVI break in the loop compartment would be exposed to all of the latent debris in the containment to the break location; whereas, a DVI break in the PXS room would only expose the break to the small amount of debris that is located in the PXS room. Therefore, significantly more debris is available to enter the DVI break in the loop compartment. The sensitivity study Case 10, which is a DVI break in the loop compartment with significant flow blockage at the core inlet, was determined to be the limiting break for water flow and debris to the core.

As discussed in Section 6.2.1.8.2.6 of this report, the HL break was determined not to be a significant deterrent for long-term cooling. Based on fuel assembly testing, the debris that enters the top of the core will be broken up by the two-phase flow leaving the core, and core cooling is maintained by the intact DVI flow.

On the basis of its review, the staff finds that the applicant's assumption that 90 percent of the total latent debris in the AP1000 containment can enter the core inlet through the DECL break is conservative, and that the applicant's determination that the DECL break is the design-basis break location for debris transport to the core and for potential debris blockage of the core inlet is acceptable. Additionally, the staff finds that the applicant's use of the DEDVI break in the loop compartment for the long-term core cooling sensitivity studies while using the 90 percent debris bypass obtained from the DECL break to determine the debris-induced core entrance head loss is conservative and acceptable.

6.2.1.8.2.2 Zone of Influence/Debris Generation and Characterization (Excluding Coatings)

The ZOI is the volume about the break in which the LOCA break jet forces would be sufficient to damage materials. Debris generation is the amount of debris generated by these forces, and debris characterization establishes the properties of this debris. The staff considered Section 3.4 of NEI 04-07 and the related safety evaluation when evaluating this section, which addresses all debris types except coatings, which are discussed in the following section.

In the AP1000, metal reflective insulation (MRI) or a suitable equivalent is specifically required on the reactor vessel, RCPs, steam generators, pressurizer, and all ASME Code Class 1 lines. MRI is also required at any location within the insulation ZOI, which is defined in DCD Tier 2, Section 6.3.2.2.7.1, for two situations:

(1) When there are intervening components, supports, structures, or other objects, the ZOI includes the spherical region within a distance equal to 29 IDs of the pipe break for Min-K, Koolphen-K or rigid cellular glass or 20 IDs of the pipe break for other types of insulation.

(2) When there are no intervening components, supports, structures, or other objects, the ZOI is a cylindrical volume extending out from the break a distance of 45 IDs along an axis that is a continuation of the pipe axis and a distance of 5 IDs radial to the pipe axis.

The first ZOI definition is consistent with Section 3.4 of the safety evaluation on NEI 04-07, which considers the spherical ZOI a practical approximation of the jet impingement damage zone and provides appropriate radial values for spherical ZOI for specific insulation types in SER Table 3-2. The spherical radii used to describe the AP1000 ZOI are bounded by the values in this table, except for rigid cellular glass, which NEI 04-07 and the safety evaluation do not address. Since no data are available for rigid cellular glass, the applicant used the maximum ZOI of 29 IDs from Table 3-2 of the safety evaluation on NEI 04-07. The staff accepts this approach, which is further supported by the statements in NUREG/CR-6808, "Knowledge Base for the Effect of Debris on Pressurized Water Reactor Emergency Core Cooling Sump Performance," issued February 2003, that this insulation will float indefinitely even if damaged. The second ZOI definition is identical to that certified in Revision 15 of the DCD. It was evaluated and found to be acceptable in NUREG-1793, Revision 0, based on existing tests and analysis.

If insulation in the AP1000 ZOI is not MRI, it must meet the DCD definition of suitable equivalence, which requires that the insulation be tested at conditions that bound the AP1000 operation and that if debris is generated it must not transported to any of the AP1000 filtering locations. It also requires that the NRC approve the test applicability and any subsequent analysis. This is appropriate because there are no clearly defined protocols for jet impingement testing, and all previous submittals on this type of testing were subject to staff evaluation.

DCD Tier 2, Section 6.3.2.2.7.1, Item 10 prohibits other potential sources of fibrous material, such as ventilation filters or fiber producing fire barrier, in the insulation ZOI. The staff agrees that this design commitment, in combination with the previously discussed insulation commitments, excludes all potential sources of fibrous debris except latent debris from the ZOI.

In RAI-SRP6.2.2-CIB1-28 (and supplements), the staff asked the applicant to clarify how concrete in containment is treated as a debris source, including chemical, coatings, and particulate debris. In letters dated January 10, 2010 and April 26, 2010, and July 30, 2010, the applicant explained that coatings are assumed to fail as particles within the ZOI and transport, and as chips outside the ZOI and not transport. In addition, the applicant explained that all concrete surfaces flooded following a LOCA are assumed to react with the water pool and potentially contribute to chemical debris. The staff found these assumptions acceptable, as discussed in Sections 6.2.1.8.2.3 and 6.2.1.8.2.4 of this report.

With respect to LOCA-generated particulate debris, the applicant explained that concrete is not a likely source of particulate debris for the AP1000 because the only concrete surfaces inside containment impacted by LOCA jets are the concrete floors. The containment walls and ceilings are constructed using steel-lined concrete modules. For AP1000, concrete debris is not considered in the composition of particulate debris based on the proximity of the concrete surfaces to the potential break locations, the orientation of the concrete with respect to the break, and the sharp decrease in the pressure of a LOCA jet as a function of distance.

In the July 30, 2010, letter, the applicant addressed the staff's question regarding the concrete damage apparent in the German HDR test results documented in NUREG/CR-0897, "Steam-Water Mixing and System Hydrodynamics Program, Quarterly Progress Report, Jan.-Mar. 1979". The applicant questioned the applicability of these results, since there is limited information about the testing and multiple tests led to the damage shown in NUREG/CR-0897. The applicant referenced WCAP-7391, "Pressurized Water and Steam Jet Effects on Concrete," as a more relevant study. This report documents results of jet impingement tests that were performed in 1970 by directing a [ ] pounds per square inch gauge (psig), water jet at [ ] concrete slabs. The July 30, 2010, letter also provides jet impingement pressures calculated for double-ended breaks in the limiting case of a pipe parallel to the AP1000 floor. As discussed below, the applicant performed further analysis using the WCAP-7391 test results and jet impingement calculations.

Although Section 1.3.2.4 of RG 1.82, Revision 3, states that erosion of concrete should be considered a potential source of particulate debris, the staff has not developed guidance for a ZOI or quantification of the debris. The applicant assessed the effect of potential concrete erosion debris on the available debris margins in the design basis. In its analysis, the applicant derived a threshold destruction pressure based on the WCAP-7391 jet impingement testing of concrete beams, and then determined whether any double-ended pipe breaks or longitudinal breaks ("split or side breaks") could exceed the threshold pressure. According to WCAP-7391, the tests did not erode the concrete itself, [ ]. In those tests, the minimum value of L/D (the length to diameter ratio which is the distance from the break to the target divided by the pipe inside diameter) was [ ] for the WCAP-7391 test conditions (CL conditions for the AP1000). The L/D ratio is a parameter used to characterize impingement pressure as a function of distance from a jet nozzle. Using the American National Standards Institute/American Nuclear Society (ANSI/ANS) 58.2-1988, "Design Basis for Protection of Light Water Nuclear Power Plants Against the Effects of Postulated Pipe Rupture," jet model to calculate pressure contours for these conditions, the applicant calculated a stagnation pressure of [ ] at the concrete surface. For AP1000 HL conditions and a stagnation pressure of [ ], the corresponding L/D was [ ]. The applicant concluded that these tests demonstrated that jets from double-ended breaks in the AP1000 would not damage concrete at L/D values equal to or greater than [ ] for the HL and [ ] for the CL.

Therefore, for this margin assessment, the applicant set the acceptance criteria for concrete damage at [ ] and applied the same jet model to the double-ended break locations. From these calculations the applicant determined that no locations exceeded the [ ] criterion at the concrete surface, regardless of whether the pipe was oriented perpendicular or parallel to the floor. The staff found this approach acceptable because the WCAP-7391 tests showed no concrete damage and the staff has accepted the ANSI/ANS model as a basis for calculating pressure contours from LOCA jets. The staff evaluated the ANSI/ANS model in the December 2004, safety evaluation of NEI 04-07.

Continuing with the margin assessment, the applicant also evaluated the potential for concrete damage from longitudinal breaks (also referred to as “split breaks” or “side breaks”) at the same locations (module floors). For the geometry of the break, the applicant used one-half of the pipe inside diameter as the width and two times the inside diameter as the length. The applicant used this approach to conform to Branch Technical Position (BTP) 3-4, “Postulated Rupture Locations in Fluid System Piping Inside and Outside Containment.” The applicant then used the ANSI/ANS 58.2-1988 jet model to determine the distance to where the impingement pressure is less than the [ ] acceptance criterion for concrete damage. Based on these calculated pressures for longitudinal breaks, the applicant identified five lines for which the calculated jet impingement pressure on concrete exceeds the [ ] acceptance criterion: [ ].

To estimate the amount of concrete debris generated by these breaks, the applicant assumed that all of the concrete becomes debris where the jet impingement pressure exceeds [ ]. [ ]. The applicant also stated that the ellipsoid shape would be partially filled with steel reinforcement bar rather than concrete, but in this analysis the ellipsoid was assumed to be all concrete.

The applicant then assumed [ ]. The applicant considered this a conservative size distribution relative to the appearance of the concrete damage in photographs of the German HDR test results documented in NUREG/CR-0897. The applicant did not attempt to estimate the size of fine debris in these photographs, but concluded that the concrete debris was mostly in the form of large pieces several inches in length and width. Given the lack of experience with concrete debris generation from impingement, the wide size range of the materials in concrete, and the appearance of the debris generated in the HDR test, the staff found that this size distribution is a reasonable assumption for the concrete debris. The entire concrete debris surface area was assumed to react chemically with the sump fluid.

By summing the concrete, coatings, and latent particle mass at each break location, the applicant concluded that all locations were bounded by the particulate quantities used in the screen and fuel assembly tests. With respect to chemical debris, all of the concrete particulate was assumed to react with the water, potentially generating additional sodium aluminum silicate and calcium phosphate. The applicant determined that the concrete particulate debris added approximately [ ] to the [ ] of concrete already used in chemical debris calculation, for a total of [ ]. (As indicated in Section 6.2.1.8.2.4 of the SER, all concrete in the post-LOCA flood-up zone was assumed, for the design basis analysis, to have the coating removed and, therefore, assumed to react chemically with the sump fluid.) The total calculated amount of chemical debris, including that from the concrete particulate, did not exceed 25.9 kilogram (kg) (57 pounds (lb)), which is the design basis amount of chemical debris that was scaled for use in the screen and fuel assembly testing. The staff performed confirmatory calculations and reached the same conclusion regarding the surface area of the concrete debris and the increase in chemical debris.

Based on this analysis the applicant concluded the following from the margin assessment: (1) the only concrete surfaces potentially exposed to impingement from a LOCA jet are limited floor areas of modules; (2) double-ended breaks of the pipes nearest the concrete do not generate concrete debris, regardless of orientation (perpendicular or parallel); (3) split or side breaks in the pipes nearest the concrete may generate concrete debris from erosion; and, (4) the estimated quantities of concrete particulate and associated chemical reaction debris are bounded by the screen and fuel assembly head loss tests that support the proposed licensing basis.

The staff found the applicant's evaluation acceptable to address Section 1.3.2.4 of RG 1.82, Revision 3, because the evaluation supports the position that concrete debris from jet impingement for the AP1000 plant is unlikely, and because a reasonable estimate of the amount of particulate and chemical debris that could be generated from concrete by a LOCA is within the AP1000 design basis.

Debris Characterization

The next step in the evaluation is to characterize the generated debris for input to the transport analysis. The applicant assumed that MRI in the ZOI degrades to pieces of crumpled foil as small as 1.3 cm by 1.3 cm (0.5 in by 0.5 in), which is consistent with the smallest classification of blast-tested MRI in NUREG/CR-6808. The applicant did not provide a quantity of degraded MRI because the subsequent transport analysis demonstrates that it will not transport to the screens or core.

6.2.1.8.2.3 Coatings

To determine if the AP1000 design meets the requirements of GDC 35, GDC 38, and 10 CFR 50.46(b)(5) with respect to protective coatings (paint) in containment, the staff reviewed the information in the DCD and supporting documents according to the guidance listed in Section 6.2.1.8 of this report. The following are key guidance documents for coatings debris, and the first two are exclusive to coatings debris:

- "Revised Guidance Regarding Coatings Zone of Influence for Review of Final Licensee Responses to Generic Letter 2004-02, 'Potential Impact of Debris Blockage on Emergency Recirculation during Design Basis Accidents at Pressurized-Water Reactors,'" dated April 6, 2010 (ADAMS Accession Number ML100960495)

- Enclosure 2, “NRC Staff Review Guidance Regarding Generic Letter 2004-02 Closure in the Area of Coatings Evaluation,” to “Revised Guidance for Review of Final Licensee Responses to Generic Letter 2004-02, ‘Potential Impact of Debris Blockage on Emergency Recirculation during Design Basis Accidents at Pressurized-Water Reactors,’” dated March 28, 2008 (ADAMS Accession Number ML080230234)

- NEI 04-07, Revision 0 dated December 2004, and the staff’s accompanying safety evaluation

Sections 6.1.2 and 6.3.2 of DCD Revision 17 describe the selection and use of coatings for the AP1000. The three types of paint coatings in containment are epoxy, inorganic zinc, and unspecified manufacturer standard coatings on engineered components. The coatings are applied to three main types of surfaces inside containment: the inside surface of the containment shell, engineered components, and a variety of other surfaces. These other surfaces include both steel structures (walls, ceilings, floors, columns, beams, braces, and plates) and concrete structures (walls, ceilings, and floors). The plant design intentionally limits the amount of painted surface area within the ZOI of a LOCA jet.

The AP1000 design is similar to operating reactors with respect to coatings debris generation and transport. However, design features of the AP1000, such as the lack of containment spray during a LOCA and the low flow rates in the water pool are expected to reduce coatings debris generation and transport relative to operating reactors. For example, stainless steel is used to reduce the need for coatings. According to the descriptions in Section 6.3.2.2.7.3 of the DCD, stainless steel is used rather than coated carbon steel on surfaces within the coatings ZOI near the recirculation screens. The quantity of coatings is also reduced with respect to the originally certified AP1000 design by eliminating inorganic zinc as a primer for epoxy. Instead, inorganic zinc is used in the containment only on the inside surface of the containment shell and where the temperature during normal operating conditions exceeds the limit for epoxy.

The inorganic zinc coating inside containment is classified as safety Service Level I as defined in RG 1.54, Revision 1, which has guidance for procurement, application, inspection, and monitoring based on NRC-approved ASTM standards. The quality assurance program for these coatings meets the relevant requirements of Appendix B, “Quality Assurance Criteria for Nuclear Power Plants and Fuel Reprocessing Plants,” to 10 CFR Part 50. Inside containment, self-priming, high-solids epoxy is used on steel structures (walls, ceilings, floors, columns, beams, braces, and plates) and concrete structures (walls, ceilings, and floors). Appendix B to 10 CFR Part 50 applies to the procurement of these coatings. As described in DCD Sections 6.1.2.1.6 and 6.1.3.2, COL applicants are responsible for the programs to address quality assurance. Section 6.1.3.2 requires COL applicants to provide a program to control the procurement, application, inspection, and monitoring of Service Level I and III coatings, as well as most Service Level II coatings inside containment. The following paragraphs discuss these requirements in more detail below.

The ZOI for coatings conforms to the most recent (April 6, 2010) staff guidance on coatings evaluations for resolution of GSI-191. Specifically, the ZOIs are four times the pipe diameter (4D) for epoxy coatings and 10 times the pipe diameter (10D) for inorganic zinc coatings (DCD Section 6.3.2.2.7.1). The applicant determined the quantity of epoxy and zinc coatings by estimating the surface area with the limiting HL and CL ZOIs, and then applying the thickness and density in the plant specifications already developed. The methodology for selecting pipe break locations to calculate debris quantities is described in Section 6.2.1.8.2.1.1 of this report.

Briefly, the limiting CL location was the terminal end at RCP #2, in the west loop compartment. The limiting HL break was the terminal end at either steam generator, due to similarity between the compartments.

Using plant layout information, the applicant then identified the location of coated surfaces, such as walls, plates, pipes and beams with respect to each postulated ZOI. As explained in its June 30, 2010, Revision 2, response to RAI-SRP6.2.2-SPCV-25, the applicant calculated epoxy coating debris quantities of [ ] and [ ], respectively, for the limiting CL and HL breaks. For these locations, no inorganic zinc coating was located within the 10D ZOI. The staff performed confirmatory calculations based on the applicant's surface area, density, and thickness values. The staff concluded the assumed thickness value (2 coats at 0.01524 cm (0.006 in) each) was conservative for calculating coating weight because it matched the high end of the recommended thickness for nuclear-grade epoxy coatings. The staff also concluded the density value ([ ]) was conservative for calculating coating weight because it was higher than the minimum value (1602 kg/m^3 (100 lb/ft^3)) required by the design.

The applicant's analysis of coating debris quantity is based, in part, on a design change from coated carbon steel to uncoated stainless steel for ASME Code Section III steam generator system instrument piping. This change was described in the June 30, 2010, response, to RAI-SRP6.2.2-SPCV-25 and was submitted to the NRC in a letter dated July 8, 2010. The staff's evaluation of this proposed piping change is described in Section 23.P of this report. The assumed form of the coating debris also conforms to the staff guidance on coatings discussed above. Outside the ZOI, epoxy coatings are assumed to fail as chips and not transport to the screens, as discussed below. Inorganic zinc outside the ZOI is assumed to remain intact because of its Service Level I designation, which conforms to the staff guidance for qualified coatings outside the ZOI. Coatings within the ZOI are assumed to fail in the form of fine particles that transport both to the screens and core. The staff believes it is necessary to treat the coatings in the ZOI as fine particles for two reasons. First, coating chips are assumed not to transport, as discussed below. Therefore, only fine particles of coating would contribute to the debris loading at the screens and fuel assemblies. Second, as explained in the staff's March 28, 2008, guidance for coatings debris, it is important to treat coating debris from the ZOI as particles if there is a possibility of a thin, filtering bed. Since fuel assembly testing indicated head loss resulting from a filtering bed, it was appropriate to consider coating debris as fine particles that transport.

The assumption that Service Level II epoxy outside the ZOI will fail in the form of chips conforms to the guidance because the coatings will be treated as degraded qualified coatings. These coatings are procured (with one exception, as noted in DCD Section 6.1.2.1.6) under Appendix B to 10 CFR Part 50 and are tested under DBA conditions. However, the Service Level II coatings will not have the same level of quality assurance and assessment requirements as fully qualified coatings in containment (i.e., Service Level I). The staff determined that it is appropriate to treat this combination of product qualification and subsequent quality assurance as a degraded qualified coating for debris analysis and assume these coatings in accordance with the staff's March 2008 guidance. The exception to the procurement qualification is for the epoxy coatings in the CVS room that connects to the containment only through a drain line that discharges to the waste processing system below and away from the recirculation screens. As explained in DCD Section 6.1.2.1.6 and Table 6.1-2, the epoxy coatings in this room are not required to be procured under Appendix B to 10 CFR Part 50.

Debris in the form of chips is assumed not to transport to the screens because of the coating's high density, which is a design requirement. Design features of the AP1000 are also expected to keep debris from entering the pool near the screens. Coatings are required to have a density of at least 1.6 grams per cubic centimeter (g/cm^3) (100 lb/ft^3) (Epoxy will be purchased as DBA qualified. Epoxy outside the ZOI is treated according to the Keeler & Long tests for operating reactors and assumed to fail as chips. This testing (Keeler & Long Report No. 06-0413) was performed in support of GSI-191 resolution for operating plants and simulated debris generation from DBA-qualified epoxy and inorganic zinc coatings. The material tested was in the form of epoxy chips with an attached inorganic zinc primer. Nearly all of the epoxy remained as chips larger than 0.79 millimeter (mm) (1/32 in) in diameter, while the inorganic zinc failed as particulate and disbonded from the epoxy. The NRC guidance noted above recommends using these data in conjunction with coating chip transport data to reduce the amount of degraded qualified coatings assumed to transport to the screens.

The staff guidance dated March 28, 2008, states that if less than 100 percent transport of the coatings debris is considered, the basis for the debris settlement should be provided, such as the NRC-sponsored coating chip transport testing described in NUREG/CR-6916, "Hydraulic Transport of Coating Debris," issued December 2006. This testing found that at a steady-state velocity of 0.06096 meters per second (m/s) (0.2 feet per second (ft/s)), most epoxy coating chips with a density (2002 kg/m^3 (125 lb/ft^3)) similar to the specified density for AP1000 coatings ([ ]) did not transport to the end of the test flume at a water velocity of 0.06096 m/s (0.2 ft/s). The calculated maximum approach velocity range for the AP1000 is less than [ ] even for the most limiting case, which occurs [ ]. Therefore, the test conditions in NUREG/CR-6916 bound the AP1000 flows.

With respect to density, Service Level II coatings on structures in the AP1000 containment (except in the CVS room described above) and on engineered components in defined areas are required to have a density of 1602 kg/m^3 (100 lb/ft^3) in order to take credit for settling. The defined areas for engineered components are locations below the maximum flood level of a design-basis LOCA or above the maximum flood level and not inside a cabinet or enclosure. This requirement appears in DCD Tier 1, Table 2.2.3-4. As explained above and in DCD Section 6.3.2.2.7.1, containment recirculation screens have a debris curb as well as protective plates that extend at least 3.04 m (10 ft) in front and 2.13 m (7 ft) to the side of the recirculation screens. Considering these design features, the low fluid approach velocities at the screens, the specified coating density, and the NUREG/CR-6916 test data, the staff finds it reasonable to assume for the AP1000 plant design that coating chips (generated outside the ZOI) will not transport to the containment recirculation screens.

Similarly, for the IRWST, since wetted surfaces inside the IRWST are made of corrosion-resistant materials (e.g., stainless steel); no paint coatings are used on surfaces near the IRWST screens. As described in DCD Section 6.3.2.2.7.2, the IRWST is covered during operation, and the bottom of each vertically oriented screen is 15.24 cm (6 in) above the floor. Therefore, the only route to the IRWST for coatings debris is through the gutter system. However, because of the location of the gutter, the gutter trash rack, and the gutter discharge piping and the high density of the coatings, it is reasonable to assume that coating debris chips will not transport to the IRWST screens. Therefore, based on chip density, transport distance, and water velocity, the staff finds it acceptable to assume for the AP1000 plant that the epoxy chips will not transport to the containment recirculation or IRWST screens.

The staff's evaluation included review of new head loss testing for the recirculation screens, IRWST screens, and fuel assemblies. The testing performed for the screens and fuel assemblies included the amount of ZOI coatings. These tests used silicon carbide particles, with an average size of [ ], as the surrogate for coatings debris. As stated in the safety evaluation for NEI 04-07, the staff found it reasonable to treat coating debris as highly transportable particulates in the size range 10 to 50 microns where there is a possibility of a thin fiber bed. This particle size is based on the basic material constituents for inorganic zinc and epoxy coatings. Section 6.2.1.8.2.8 of this report discusses the test program and results.

For the reasons discussed above, the applicant's assessment using the NRC guidance in RG 1.82, Revision 3, for protective coatings is acceptable with respect to the ZOI, quantity and form of coating debris assumed, and the representation of coatings debris in the screen and fuel assembly testing. On this basis, the staff concludes that the AP1000 plant design meets the requirements of GDC 35, GDC 38, and 10 CFR 50.46(b)(5), as they relate to the effect of protective coatings debris on long-term cooling following a LOCA, including specific consideration of the effects of protective coating debris under accident conditions.

6.2.1.8.2.4 Chemical Effects

To determine the compliance of the AP1000 design with the requirements of GDC 35, GDC 38, and 10 CFR 50.46(b)(5) with respect to chemical debris formed in the post-LOCA containment pool, the staff reviewed the information in the DCD and supporting documents using the guidance listed in Section 6.2.1.8 of this report. The following are the key guidance documents for chemical debris, and the first two are exclusive to chemical debris:

- Enclosure 3, "NRC Staff Review Guidance Regarding Generic Letter 2004-02 Closure in the Area of Plant-Specific Chemical Effect Evaluations," to "Revised Guidance for Review of Final Licensee Responses to Generic Letter 2004-02, 'Potential Impact of Debris Blockage on Emergency Recirculation during Design Basis Accidents at Pressurized-Water Reactors,'" dated March 28, 2008 (ADAMS Accession Number ML080230234)

- "Final Safety Evaluation by the Office of Nuclear Reactor Regulation: TR WCAP-16530-NP, 'Evaluation of Post-Accident Chemical Effects in Containment Sump Fluids To Support GSI-191,'" dated December 21, 2007 (ADAMS Accession Number ML073521294)

- NEI 04-07, Revision 0 and the staff's accompanying safety evaluation.

The staff's review of the applicant's supporting documents included an audit of detailed analyses and a calculation note documenting that applicant determined the chemical debris constituents and quantities using APP-PXS-M3C-052, "AP1000 GSI-191 Chemistry Effects Evaluation," Revision 1, dated May 4, 2009.

The applicant calculated debris from chemical precipitation using the methodology in WCAP-16530-NP. This methodology was developed for operating pressurized-water reactors (PWRs), and the safety evaluation listed above documents the staff's evaluation of the methodology for operating reactors. The staff's review of the methodology finds that the methods of WCAP-16530-NP also apply to the AP1000 based on the containment materials, the sump pH transient, and the pH buffering agent (trisodium phosphate (TSP)). With respect to temperature, however, the applicant noted in Section 2.4 of TR-26 that the predicted sump pool temperature for the AP1000 is briefly outside the range evaluated for WCAP-16530-NP (60 °C to 132.2 °C (140 °F to 270 °F)) but concluded that the methodology was still applicable. The staff reviewed the amount and duration of the temperature deviation during the audit of the calculation note referenced above. The staff estimated that the temperature was between [ ]. The staff concluded that it was appropriate to apply the release rate equations in WCAP-16530 during this period because of the short time relative to the 30-day event and because corrosion data for [ ] did not indicate a sharp increase in the corrosion rate in this temperature range (see Reference 6.2-3 in WCAP-16530-NP).

The amount of chemical precipitation predicted by the applicant was small relative to typical operating plants because of the AP1000's design features. The lack of fiberglass insulation eliminates a potential source of dissolved silica that could precipitate as silicate compounds. Because the AP1000 contains no calcium silicate insulation, there is no precipitation of calcium phosphate resulting from interaction of calcium silicate and the TSP pH buffer. For operating reactors with TSP buffer, calcium phosphate is one of the key chemical effects. The AP1000 analysis assumed calcium phosphate would be generated based on interaction between the dissolved TSP and calcium dissolved from the concrete. The quantity of $Ca_3(PO_4)_2$ precipitate was determined by first calculating the amount of concrete dissolution using the methodology in WCAP-16530-NP and then assuming all of the dissolved calcium precipitated as $Ca_3(PO_4)_2$. In its safety evaluation of WCAP-16530-NP, the staff concluded that this approach is conservative.

Testing and analysis for operating PWRs have shown that aluminum corrosion is a key contributor to chemical debris in the presence of an alkaline water pool. For the AP1000, the only intended use of aluminum is the ex-core detector housings, and the AP1000 design specifies stainless steel or titanium covers to isolate the aluminum from the water. The design includes an ITAAC to verify that the detectors are enclosed in stainless steel or titanium (DCD Tier 1, Table 2.2.3-4, Item 8.c). Although these covers eliminate the potential chemical interaction between aluminum and alkaline water during accident conditions, the applicant anticipated that some quantity of aluminum interacting with the water may be unavoidable in certain engineered components. Therefore, the applicant set an upper limit for this aluminum (27 kg (60 lbs)) in the design (DCD Section 6.1.1.4) and evaluated this quantity for aluminum corrosion and precipitation using the WCAP-16530-NP methodology. In its May 13, 2009, response to RAI-SRP6.2.2-CIB1-21, the applicant stated that the actual quantity of this aluminum would be tracked in accordance with a design calculation note. The staff finds the approach acceptable because the certification documentation in Tier 1 and Tier 2 of the AP1000 DCD limits the amount of wetted aluminum to the amount analyzed for chemical debris.

The applicant's analysis produced the following calculated mass of chemical debris:

Aluminum oxyhydroxide (AlOOH) [ ]
Sodium aluminum silicate ($NaAlSi_3O_8$) [ ]
Calcium phosphate ($Ca(PO_4)_2$) [ ]
TOTAL [ ]

In the WCAP methodology, these precipitates formed from aluminum released from metallic aluminum and concrete, silicon released from silica powder (Min-K insulation) and concrete, and calcium released from concrete. With respect to the total amount of precipitate, WCAP-16530-NP assumes all dissolved calcium, in the presence of phosphate, and all dissolved aluminum form precipitates. In its safety evaluation on WCAP-16530-NP, the staff found that this is a reasonable assumption for calcium and a conservative assumption for aluminum.

The staff reviewed the basis for the release of chemicals and precipitation of debris during its May 7, 2010, audit of APP-PXS-M3C-052, Revision 1. For example, the applicant assumed the coating was removed from all concrete in the flooded zone, and the WCAP release rate equation included the corresponding concrete surface area. For insulation in which silicon is released from silica powder during accident conditions (i.e., Min-K insulation), the release equation assumed that [ ] of the insulation was washed into the pool and subject to chemical release. The staff finds this is a reasonable assumption, since non-reflective metallic insulation (RMI) insulation in containment must be enclosed in seal-welded stainless steel and qualified through NRC-approved testing to show that a LOCA would not generate chemical debris (see DCD Section 6.3.2.2.7.1).

For aluminum, the applicant assumed a surface area of [ ]. The staff considered this a reasonable assumption because it corresponds to a relatively thin sheet of aluminum, on the order of 0.25 cm (0.1 in). This results in a relatively high calculated aluminum release because the release rate is proportional to surface area, and lower thickness corresponds to higher surface area for a given mass. In addition, it is the same conversion factor used in the spreadsheet in Appendix D to WCAP-16530 for calculating the mass of aluminum released. The staff used these assumptions, along with the temperature and pH profile provided in the calculation note, to perform independent confirmatory calculations using the WCAP-16530 spreadsheet. The staff also performed the calculations manually using the release rate equations derived in WCAP-16530-NP and incorporated into the spreadsheet. The staff's calculations produced the same values as the applicant's.

The AP1000 analysis assumes that all chemical debris transports (see Table 3-4 in TR-26). Therefore, the screen and fuel assembly testing included the entire chemical debris load, represented by AlOOH surrogate. The AlOOH precipitate is [ ] of the calculated mass of chemical debris for the AP1000. According to the test reports for screen and fuel assembly testing (WCAP-16914 and WCAP-17028, respectively), the surrogate chemical debris was prepared and added according the WCAP-16530-NP procedures. The staff's safety evaluation on WCAP-16530-NP states that surrogate precipitate prepared in accordance with the directions on WCAP-16530-NP provides adequate settlement and filterability characteristics to represent post-LOCA chemical precipitates in strainer head loss tests. The AlOOH precipitate was generated outside the test loops for the design-basis tests. In some supplemental (engineering) tests, the raw chemical components were added to the loop, and the precipitates formed in situ. The debris was added both sequentially, according to the WCAP, and coincidentally, to address whichever case is more limiting for the AP1000. The quantity of debris is intended to represent the generation and transport rate in the plant and meets the staff's March 28, 2008, guidance on chemical effects.

For the reasons discussed above, the staff concluded that the applicant's assessment of chemical effects conforms to the staff's March 2008 guidance with respect to the type and quantity of chemical debris, as well as the representation of chemical debris in the screen and fuel assembly testing. Therefore, the staff concludes that the AP1000 plant design meets the requirements of GDC 35, GDC 38, and 10 CFR 50.46(b)(5), as they relate to the effect of chemical debris on long-term cooling following a LOCA, including specific consideration of the effects of chemical interaction and formation of debris under accident conditions.

6.2.1.8.2.5 Latent Debris

Latent or resident debris is dirt, dust, lint, and other miscellaneous material that is present inside containment during operation. As stated in DCD Tier 2, Section 6.3.2.2.7.1, Item 12, the design basis for the total amount of resident debris inside the AP1000 containment is 59.0 kg (130 pounds-mass (lbm)), of which up to 3.0 kg (6.6 lbm) is fiber. Additionally, COL Information Item 6.3-1, discussed in DCD Tier 2, Section 6.3.8.1, requires that COL applicants referencing the AP1000 design commit to a cleanliness program that limits the latent debris inside containment to these same quantities.

In TR-26, the applicant explained that limiting the total latent debris inside containment to 59.0 kg (130 lbm) is consistent with the practice for operating reactors. The information regarding latent debris in operating reactors came from publically available responses by individual plants to generic letter (GL) 2004-02, “Potential Impact of Debris Blockage on Emergency Recirculation during Design Basis Accidents at Pressurized-Water Reactors,” dated September 13, 2004. The plants generally identified two quantities for latent debris: a walkdown value representing an estimate of the debris inside the plant based on physical sampling of containment surfaces, and an analysis (or bounding) value used in the GL 2004-02 evaluation. In accordance with Table 2-1 of TR-26, the average amount of latent debris in the 34 cited plants was 40.8 kg (90 lbm) based on walkdown data and 73.5 kg (162 lbm) based on the bounding values. The applicant attempted to correlate the amount of latent debris to the dominant type of insulation used in the plant (RMI or fibrous) and to the plant size, but it determined that neither was a strong predictor for the quantity of latent debris. The applicant concluded that other factors, such as the utilities cleanliness program, would be more indicative of the amount of debris found in the plant but did not provide additional data.

The staff’s review of TR-26, Table 2-1, found that while the values were consistent with the individual plant responses to GL 2004-02, the table only included data from half of the 69 operating PWRs. Therefore, while the reported averages are not representative of the entire PWR fleet, the data demonstrate that some operating PWRs do have latent debris bounding values of less than 59.0 kg (130 lbm). The staff emphasizes the bounding values over the walkdown values because, while some plants performed rigorous walkdowns in accordance with the guidance in the NEI 04-07 safety evaluation, other plants recognized that their walkdown calculations were not bounding; therefore, margin was added to the results before performing the analysis.

Rather than defining the fiber quantity as a mass percentage of total latent debris, the applicant has set the design basis for fiber inside the AP1000 containment to 3.0 kg (6.6 lbm), which is 5.1 percent of the total latent debris. In TR-26, the applicant explained that this is consistent with data from Table 2 of NUREG/CR-6877, “Characterization and Head loss Testing of Latent Debris from Pressurized-Water-Reactor Containment Buildings,” issued July 2005, which shows that the percentage of fiber in two of the four sample plants is less than 4 percent. The NEI 04-07 safety evaluation referenced this same NUREG to support the recommendation to treat 15 percent of the total latent debris mass as fiber. The different conclusions result from two different treatments of the NUREG-reported fiber-to-particulate compositions. In the data referenced by the NEI 04-07 safety evaluation, objects larger than a 0.335-cm (0.132-in) mesh sieve were removed from the sample because they were assumed to be nontransportable. In the data referenced in TR-26, the assumed nontransportable objects were retained because the applicant assumed that all latent debris is transportable and did not anticipate that utilities will remove the larger pieces of debris during sampling. While these assertions seem reasonable, the staff finds the design-basis quantities of total latent debris and fibrous latent debris inside the AP1000 containment to be acceptable because of the COL commitment to limit latent debris to the design-basis amounts. In accordance with the containment cleanliness program, applicants referencing the AP1000 must include a program to limit the amount of latent debris left inside containment following refueling and maintenance outages to 59.0 kg (130 lbm) total latent debris, of which up to 3.0 kg (6.6 lbm) is composed of fibrous material.

As described in Section 3.5.2.2.2 of NEI 04-07 and its related safety evaluation, miscellaneous debris such as equipment tags, tape, and stickers or placards affixed by adhesives that could become transportable should be considered part of latent debris. In accordance with the NEI 04-07 safety evaluation, if the lanyards or adhesives fail and the signs are transported to the screen intact, the available screen surface area should be reduced by an appropriate amount, which is called the sacrificial screen area. No sacrificial screen area is used in the AP1000 evaluation because the DCD requires that all potential sources of transportable material (such as caulking, signs, and equipment tags) be designed so they do not produce debris that will be transported to the filtering areas.

Specifically, unless the items are located inside a cabinet or enclosure, either they must be high density or testing must be performed at conditions that bound the AP1000 to demonstrate that the debris do not transport to any AP1000 filtering location or generate chemical debris. If testing is performed, the NRC must approve it.

6.2.1.8.2.6 Debris Transport

Debris transport is the estimation of the fraction of debris that is transported to each of the filtering locations (screens or core), considering blowdown transport, washdown transport, pool fillup transport, and recirculation transport. In the AP1000 design, washdown transport does not come from containment sprays but from PCS operation, where the majority of the condensed steam runs down the containment walls and the remainder falls from the containment dome. Debris transport is discussed in Section 3 of TR-26 and is evaluated as follows considering Section 3.6 of NEI 04-07 and the related safety evaluation.

All coatings in the ZOI are assumed to fail as fine particles and transport to the screens and core. Coatings outside the ZOI are assumed to remain intact or fail as chips that do not transport because of the high density. Section 6.2.1.8.2.3 describes coatings debris in more detail.

All of the chemical debris is assumed to transport to the screens and core. Section 6.2.1.8.2.4 describes the chemical debris in more detail.

The AP1000 analysis conservatively assumes that 100 percent of the latent debris in the containment will be transported by the fluid streams to the recirculating pool and remain entrained until it reaches the containment recirculation screens. The analysis assumes that 50 percent of the fibrous portion of the latent debris will transport to the IRWST screens. The applicant stated that this is conservative because the only path for debris to enter the closed IRWST tank is through the gutters, located just below the operating deck elevation along the containment walls. Debris transport from the operating deck to the gutter is limited by a border plate around the edge of the operating deck and a physical gap between this border plate and the gutter. Any fluid that makes it past the border plate but not across the gap will drain to the sump. Additionally, the operating deck is flat and has other unobstructed openings where water can spill directly into the containment sump. Because much of the latent debris in the AP1000 containment is located below the operating deck, it is not physically possible for it to be washed into the IRWST gutters. The staff agrees that the assumption of 50 percent transport of fibrous latent debris to the IRWST is conservative based on the IRWST gutter and operating deck configuration. During RNS operation in the recirculation mode, it is possible that some fluid will backflow through the containment recirculation screen to the IRWST. It is expected that the containment recirculation screen will capture the fibrous portion of the debris as it backflows, but not necessarily the particulates. To conservatively account for this phenomenon, the applicant assumed that the IRWST screens see 100 percent of the particulate portion of latent debris.

In the AP1000 design, MRI debris is not transported to the screens or core because of the low velocities of the recirculating water. Based on testing described in NUREG/CR-6808, a velocity of at least 0.061 m/s or 3660 liters per minute per square meter (Lpm/m^2) (0.2 ft/s or 90 gpm/ft^2) is required to move a settled piece of crumpled MRI debris that is 1.3 cm by 1.3 cm (0.5 in by 0.5 in). The maximum fluid approach velocities at the containment recirculation and IRWST screens that occur during RNS operation and as shown in Table 5-2 of WCAP-15914-P are significantly less than this value. The flow through the containment recirculation corridor, which is identified as the limiting area approaching the containment recirculation screen in the Revision 1 response to RAI-SRP6.2.2-SPCV-13, is also below this value.

In order to limit debris introduced during pool fillup, the AP1000 design restricts fibrous material in the containment outside the ZOI but below the maximum floodup level. Insulation located here must be MRI, jacketed fiberglass, or a suitable equivalent. Also, other potential sources of fibrous material such as ventilation filters or fiber-producing fire barriers are not permitted below the floodup level. The MRI and jacketed fiberglass insulation will not be dislodged or eroded by the recirculation flow rates and, thus, will not generate debris. A suitable equivalent insulation is defined as one that has been tested at conditions that bound the AP1000 operation to demonstrate that recirculation flows will not generate chemical debris, and if any other type of debris is generated, it must not be transportable. The NRC must approve test applicability and any subsequent analysis.

Other potential sources of nonfibrous transportable material in containment, such as caulking, signs, and equipment tags, are required to be either made of high-density material, located in an enclosure, or demonstrated to not transport during testing. If they are made of high-density material, which is defined as greater than 1.6 g/cm^3 (100 pounds per cubic foot (lb/ft^3)), it is expected that they will settle and not be carried by the low AP1000 velocities. The minimum 2.5-hour delay between the accident and start of recirculation provides a reasonable amount of time for debris to settle on the containment floor.

While the applicant considered washdown from condensed steam running down the containment walls, it did not consider washdown associated with the containment spray system, which could transport more debris into the fluid stream. The staff agrees that it is not necessary to consider the impact of the containment spray system because it is a nonsafety-related system that will only be used in the event of a severe accident. During a severe accident, core heat removal or coolant has already been lost, and the containment spray's effect in transporting additional debris is not significant. Also, inadvertent actuation of the containment spray system during power operations has previously been found to be noncredible, as described on pages 6-25 of NUREG-1793.

For the AP1000, some break locations will be submerged once the containment has flooded up during the post-LOCA recirculation core cooling phase. When the containment water level is at the elevation of the break, in addition to the flow through the PXS intact DVI recirculation lines, flow carrying unfiltered debris can enter directly into the reactor vessel through the submerged break. A DECL break or DEHL break at the reactor vessel and a DEDVI line break can be submerged when the final containment floodup water level is reached. Any one of these breaks could allow direct transport of unfiltered debris into the reactor, bypassing the containment recirculation screens, during the long-term cooling phase. The DECL break and DEDVI break could allow unfiltered debris into the downcomer, lower plenum, and ultimately into the core, potentially resulting in blocking reactor coolant flow through the core, and the DEHL break allows unfiltered debris into the upper part of the core area.

Of the DEDVI and DECL breaks, the DECL break potentially provides the greatest amount of unfiltered debris to the core inlet and the highest percentage of debris bypass (i.e., the percentage of the debris that could be transported into the RCS without filtering by the IRWST and containment recirculation screens). The applicant determined the percent of debris bypass for the DEDVI break and DECL break by calculating the flow split between the recirculation flows through the break and through the PXS intact DVI lines. Section 3.3 of TR-26 discusses debris transport to the core and calculations to determine the flow split (i.e., the percentage of recirculation flow entering the reactor vessel through the break carrying unfiltered debris). For the flow split calculation, the applicant conservatively assumed that [ ] would transport the entire available debris load to the recirculation screens and into the reactor vessel through the break and ultimately to the core. Therefore, the flow split is determined by integrating the relative recirculation flows through the break and through the PXS for [ ] at the containment floodup water level elevation. Flow rates through the break and through the PXS were obtained from WCOBRA/TRAC long-term cooling cases. The percentage of the water mass that has entered through the flooded break and through the PXS is determined after [ ]. The applicant performed the calculation for a DEDVI LOCA and for a DECL LOCA at the reactor vessel nozzle. In RAI-SRP6.2.2-SRSB-41, the staff asked that the applicant clarify the flow split discussion for the DECL and DEDVI breaks and related calculation presented in TR-26. The applicant responded by revising TR-26 to provide more information concerning the DEDVI and DECL flow splits and break calculations in Tables 3-1 and 3-2, respectively.

For a DECL break, the flow split would be greater than 10 percent flow through the PXS recirculation flowpath and [ ] percent flow through the rupture in the CL, which is greater than [ ] percent for the DEDVI break. The applicant assumed that: (1) 90 percent of the containment water would flow through the break in the CL; and (2) 90 percent of the fiber debris and 100 percent of the particulate debris in the containment would directly enter the reactor core through this DECL break. The applicant used the 90 percent unfiltered fibrous debris assumption in its fuel assembly testing, documented in WCAP-17028-P, by estimating a total fiber load in the containment of 2.99 kg (6.6 lbs) and multiplying that amount by 90 percent, yielding an estimated 2.69 kg (5.94 lb) of fiber directly entering the reactor core.

The staff also evaluated the debris transport through a HL break. In RAI-SRP6.2.2-SRSB-31, the staff asked the applicant to clarify the reasons why the DEHL break is not the most limiting break with respect to debris transport. Through testing and thermal hydraulic evaluations, The applicant developed the probable scenario that occurs during a DEHL break. During a postulated HL break, containment floodup water carrying unfiltered debris begins to enter the top of the core region through the submerged break, and water filtered by the IRWST and recirculation screens also flows into the downcomer and into the reactor core inlet through the two intact DVI lines. The debris that enters the upper core region through the break could block the upper core area, and some could be discharged through the automatic depressurization system (ADS) Stage 4 (ADS-4) valves connected to the HLs. The debris that is not discharged from the RCS through the ADS-4 valves can enter the upper portion of the core and flow down though peripheral low-power fuel assemblies. In its evaluation, the applicant identified that at some point, because of the cross-flow thermal hydraulics in the AP1000, the downflow of water through the peripheral fuel assemblies will cross into the hotter fluid that is rising through the core, and the debris carried by the water that entered the break will mix with the other filtered water flowing into the core. As a result, some of the debris from the HL break could be captured on the upper tie plates of the core.

In its response to RAI-SRP6.2.2-SRSB-31, the applicant further reported that it conducted fuel assembly debris-loading head loss testing to estimate the amount and impact of debris that could be captured in the upper core region. WCAP-17028-P, designating the tests evaluating HL flow conditions as tests 35, 38, and 39. The applicant demonstrated through the fuel assembly testing that on the top of the fuel assembly debris beds will not form in the presence of two-phase flow, which would be prevalent in the AP1000 core during long-term cooling. As a result of this test, the applicant concluded that fibrous debris that enters through a HL break would ultimately be purged and captured by the IRWST and containment recirculation screens, thus purging the upper core region of debris over time during long-term cooling. The applicant further stated that debris that breaks loose from the top of a fuel assembly would likely discharge through ADS-4 valves and subsequently be filtered by the IRWST and containment recirculation screens. Section 6.2.1.8.2.7 of this report presents more discussion of these breaks.

On the basis of its review of the RAI-SRP6.2.2-SRSB-31 response and the associated fuel assembly testing in WCAP-17028-P, the staff finds that debris plugging in the core from a DEHL break is not the most limiting break with respect to debris transport and accumulation.

In summary, in Table 3-4 of TR-26, Revision 8, the applicant presented the AP1000 licensing basis fibrous, particulate, and chemical debris that could be transported into the reactor vessel and potentially reach the fuel assemblies. These debris loads were based on a total latent debris load of 58.96 kg (130 lbs), a total ZOI coating fine particles of 31.75 kg (70 lbs), and a chemical debris load of 25.85 kg (57 lbs). Of the 58.96 kg (130 lbs) of latent debris, no more than 2.99 kg (6.6 lbs) was estimated to be fibrous.

In TR-26, the applicant reported that chemical debris load is based on the type and quantity of chemical precipitates that may form in the post-LOCA recirculation fluid for the AP1000 design. The evaluation presented above identified the DECL break as the worst case break that provides debris to the core.

Based on the DECL break flow split calculation performed by the applicant, 90 percent of the water that enters the reactor vessel during long-term cooling comes through the CL break and 10 percent comes into the reactor as filtered water through the intact DVI lines. For the purpose of these evaluations, the applicant assumed that 90 percent of all fiber and 100 percent of all particulates and chemicals in the containment are transported to the reactor unfiltered.

On the basis of its review of debris transport analysis to the core, the staff finds that the applicant has conservatively evaluated the quantity of debris transported and the minimum transport time to the reactor core.

6.2.1.8.2.7 Availability of Long-Term Core Cooling

The AP1000 PXS and containment system are designed to continuously provide adequate cooling of the reactor following a LOCA. After the initial injection of water from the core makeup tanks (CMTs) and the accumulators, the IRWST provides safety injection by gravity drain. As the IRWST injection continues, the containment sump water floods up above the reactor vessel. After the IRWST level drops to a low setpoint, the containment recirculation valves are open to provide the RCS with recirculation water from the containment sump to maintain core cooling indefinitely. During the long-term cooling phase of the LOCA, steam released from the reactor through the ADS-4 valves is condensed on the inner surface of the steel containment vessel, which is cooled on the outside by the PCS. The condensed water in the containment is collected in a gutter and returned to the IRWST. Both the IRWST and containment recirculation have screens to filter debris and protect the PXS flowpaths into the RCS.

Subsequent to a LOCA that occurs with the break below the post-LOCA water level in the containment, significant unfiltered debris can enter the reactor vessel through the submerged break location.

DCD Tier 2, Section 15.6.5.4C, describes the long-term cooling analysis to demonstrate that the passive safety systems provide adequate emergency core cooling system (ECCS) performance during the IRWST injection and containment recirculation duration. The analysis was performed for a DEDVI line break in the PXS room using the WCOBRA/TRAC code during the IRWST injection phase continuing into containment sump recirculation. When a quasi-steady state was achieved, a WCOBRA/TRAC window mode of calculation was performed. The boundary conditions for the WCOBRA/TRAC analysis, such as the containment pressure and the level and temperatures of the liquid in the containment sump, are based on the WGOTHIC calculations. The long-term cooling analysis demonstrated that: (1) the core remains cooled for the duration of the long-term cooling phase; (2) the boron concentration in the core keeps the core noncritical; and (3) there is no boron precipitation in the core during long-term cooling following a LOCA. Section 15.2.7 of NUREG-1793 describes the staff's evaluation of this long-term cooling analysis. However, the DCD long-term cooling analysis did not consider the effect of debris in the containment on long-term cooling or the GSI-191 evaluation of the AP1000.

As part of the GSI-191 review of the AP1000, the applicant evaluated the effects of containment debris on the long-term core cooling capability. In the AP1000 design, debris could block core flow and adversely affect long-term cooling following a LOCA in three locations: (1) the core inlet; (2) containment recirculation screens; and (3) IRWST screens. Core inlet head loss is the most significant parameter in these analyses because most of the long-term cooling flow and debris goes through the DEDVI and DECL breaks unfiltered into the downcomer and through the core inlet region, and because the AP1000 IRWST and containment recirculation screens are sufficiently large that the debris-induced head loss on the screens is very small. A DEHL break at the reactor vessel adds unfiltered debris into the top of the core region, which does not impact the core inlet loss coefficient. However, it has the potential of flow blockage at the upper part of the core.

The staff's evaluation includes: (1) long-term core cooling analysis sensitivity studies of the effects of the debris-induced head losses at the debris collection locations (i.e., the IRWST and containment recirculation screens) and the reactor core on the long-term cooling analysis and (2) head loss testing of the IRWST and containment recirculation screens and fuel assembly. The applicant's approach is first to perform the long-term cooling sensitivity analysis using the WCOBRA/TRAC code and using arbitrary, nonmechanistic head loss coefficients at the core inlet and the IRWST and containment recirculation screens to determine the maximum allowable head losses in the debris collection locations while still maintaining adequate long-term core cooling. The maximum allowable head losses thus determined serve as the acceptance criteria for the debris-induced head loss tests. The applicant then conducted the debris-induced head loss testing of the IRWST and containment recirculation screens and fuel assembly to demonstrate that, with the amount of debris collected in the IRWST and containment recirculation screens and the core, the respective test acceptance criteria would not be exceeded. Therefore, one can conclude that adequate core cooling is maintained in the presence of the containment debris. The staff's evaluation of the applicant's submittal appears below.

6.2.1.8.2.7.1 LTC Sensitivity Studies to Determine Adequate Core Cooling

The applicant performed long-term cooling sensitivity studies as documented in TR APP-PXS-GLR-001, Revision 4. As discussed in Section 6.2.1.8.2.1 of this report, Westinghouse selected the DEDVI break for Sensitivity Cases 1 through 10 for the long-term cooling evaluation following a LOCA. All cases were performed using the decay heat assumption in Appendix K to 10 CFR Part 50. As the same long-term cooling case analyzed in DCD Section 15.6.5.4C, Case 1 considers a DEDVI line break in the PXS room with a moderate increase in the core and screen pressure drops resulting from debris blockage. The flow resistance of the lower support plate at the core inlet is increased to model a dP of 3 ft of water at the DCD analysis flow rate of 68.9 kilograms per second (kg/s) (152 pounds per second (lb/s)). Cases 2 and 3 increase these pressure drops. Each of these cases includes added pressure drop across the core, recirculation screens, and IRWST screens. Cases 1, 2, and 3 were performed at the start of containment recirculation at 2.6 hours after a LOCA. By this time, only a small portion of the total debris would have been transported into the RCS, and the debris dP would not have increased to its maximum.

In the sensitivity studies and the containment recirculation sump and IRWST screen testing, the applicant also demonstrated that the screen head losses, considering debris amounts and types, flow rates, and screen size and type, were small, or less than a fraction of an inch of water.

For Sensitivity Cases 4 through 10, the core inlet loss coefficient was further increased to represent different levels of debris plugging at the core inlet. Case 10 had the highest core entrance loss coefficient. The IRWST and containment recirculation screen loss coefficients were assumed to be 0 because they are insignificant compared to the core inlet loss coefficient. Sensitivity Cases 4 through 10 were performed at a later time of 8.6 hours after a LOCA, which is considered the earliest time at which all the debris in the water of the containment can be transported from containment into the core, and increased the dP to its maximum.

In RAI-SRP6.2.2-SRSB-36, the staff asked the applicant to clarify its reason for running Sensitivity Cases 4 through 10 at 8.6 hours after a LOCA. In its response dated January 29, 2010, the applicant stated that for Cases 1 through 3, it assumed that peak core dP would occur earlier, before all particles and fibers would be transported to the core. Sensitivity Cases 1 through 3 were analyzed at 2.6 hours after a LOCA. At this time, only a small amount of debris would start to enter the core through the break. For Cases 4 through 10, the applicant assumed, for purposes of core inlet debris accumulation, that the [ ] would transport all of the particles and fibers. As subsequent fuel assembly head loss tests were run, the applicant noted that the maximum core dP occurred later than the evaluation time of 8.6 hours of debris transport. It therefore concluded that using the decay heat level at 8.6 hours after a LOCA in Sensitivity Cases 4 through 10 was conservative for evaluating fuel assembly test results where maximum core dP is reached 9 hours or later post-LOCA. In its response to RAI-SRP6.2.2-SRSB-40, the applicant demonstrated that subsequent fuel assembly concurrent debris addition test results yielded the peak core dP at much later times after the LOCA than

8.6 hours. Table 3-3 of TR-26, Revision 8, showed that for each of the later fuel assembly debris loading tests, peak core dP at an equivalent plant time far exceeded 8.6 hours after LOCA. The equivalent plant time was determined by comparing the amount of chemical addition before the occurrence of the peak dP in the test with the post-accident chemical effects evaluation. The staff agrees that the sensitivity cases calculated at 8.6 hours are conservative for assuming the maximum core inlet blockage because 8.6 hours is far earlier that the time of the peak debris-induced core inlet dP in the plant. As discussed in the Test Acceptance Criteria section, the core inlet dP for Case 10, which was a DEDVI line break in the loop compartment with the largest core inlet resistance among all sensitivity cases, will be used as the acceptance criterion for the fuel assembly debris blockage head loss tests after 9 hours. The core inlet dP for Case 3 will be used as an additional acceptance criterion for the fuel assembly head loss test before 9 hours.

For Sensitivity Case 11, the applicant modeled a DEDVI break in the loop compartment close to the reactor vessel DVI nozzle, simulating significant resistances at the core exit region. The added debris resistance was applied to the core exit in order to provide insights into the impact of containment debris entering the upper part of the core during a postulated HL break LOCA. Because postulated debris would be introduced into the upper plenum during a HL break scenario, no increase in the core entrance flow resistance above the value associated with normal plant power operation was modeled. This case was executed at the decay heat level at 8.6 hours post-LOCA time to transport sump debris into the reactor vessel. The results of Case 11 provide acceptable values of core flow and debris-induced dP for application to fuel assembly head loss testing that evaluated DEHL LOCAs.

The applicant used WCOBRA/TRAC and WGOTHIC for the RCS transient and containment analyses, respectively, of the long-term cooling analysis, as documented in DCD Tier 2, Section 15.6.5.4C, and for the 11 sensitivity cases evaluated in APP-GW-GLR-001. The long-term cooling analysis used a detailed nodalization model to represent the AP1000 core for the WCOBRA/TRAC analysis. WCAP-14776, "WCOBRA/TRAC, OSU Long-Term Cooling Final Validation Report," Revision 4, issued March 1998, documents the code verification for the long-term cooling analyses. The applicant used the WGOTHIC code, described in WCAP-15846, Volume 1, Revision 1, to calculate containment boundary conditions. The fan coolers were assumed to be operating to minimize containment pressure. The staff previously approved the application of WCOBRA/TRAC and WGOTHIC for long-term cooling calculations performed in the AP1000 DCD, as discussed in Chapter 21 of NUREG-1793.

The staff reviewed the application of WCOBRA/TRAC and WGOTHIC for performing the sensitivity studies documented in APP-GW-GLR-001. The staff conducted an audit in Monroeville, Pennsylvania, September 21–22, 2009, and a followup audit March 22–24, 2010. During the September 2009 audit, the staff identified discrepancies between the WCORBRA/TRAC and WGOTHIC calculations for sump water temperature input. In RAI-SRP6.2.2-SRSB-25, the staff asked the applicant to address these inconsistencies.

In its response, the applicant stated that the WGOTHIC containment analysis case was reanalyzed using corrected revised input, and the calculated sump water temperatures were within -17.22 °C (1 °F) of the corresponding values presented in the WCOBRA/TRAC calculation. The applicant stated that since the boundary conditions for WCOBRA/TRAC from the new WGOTHIC case differed minimally, the conclusions of Sensitivity Cases 1 through 3 in APP-PXS-GLR-001 were not affected.

During the audit performed March 22–24, 2010, the staff reviewed the new WGOTHIC analyses and results used for Sensitivity Cases 4 through 10. The applicant also responded to RAI-SRP6.2.2-SRSB-25, Revision 1, which addressed the WGOTHIC containment pressure and sump temperatures used in the Sensitivity Case 1 through 10 long-term cooling analyses. The pressure used in the long-term cooling calculation was 110 kPa (16 pounds per square inch absolute (psia)), which is lower than the pressure calculated by WGOTHIC. The sump temperatures calculated by WGOTHIC were slightly different from the sump temperatures used in the DCD Revision 17 long-term cooling calculations. The applicant has established that a lower pressure is conservative for long-term cooling calculations and that the small changes to the sump temperature do not impact the long-term cooling analysis. Based on its review of the new WGOTHIC analysis and the information provided in response to RAI-SRP6.2.2-SRSB-25, Revision 1, the staff concluded that the analyses were performed in a conservative manner and were acceptable.

The more limiting long-term cooling sensitivity cases in APP-GW-GLR-001 assume large core inlet head losses to simulate extreme core inlet blockage by the containment debris. These cases result in low core flow and high steam quality, which differ from the DCD long-term cooling analysis. The staff, in RAI-SRP6.2.2-SRSB-39, asked the applicant to confirm that the WCOBRA/TRAC code had been validated for the low flow and high steam quality conditions.

In its response dated January 29, 2010 (ADAMS Accession Number ML100330392), the applicant indicated that the validation of WCOBRA/TRAC is provided through the comparison of WCOBRA/TRAC simulations to test data from boiloff tests documented in WCAP-15644-P, “AP1000 Code Applicability Report,” Revision 2, issued March 2004. During the audit performed March 22–24, 2010, the staff reviewed the range of applicability of boiloff tests G1 (WCAP-9764, “Documentation of the Westinghouse Core Uncovery Tests and Small Break Evaluation Model Core Mixture Level Model,” issued July 1980) and G2 (Andreychek, T.S., “Heat Transfer above the Two-Phase Mixture Level under Core Uncovery Conditions in a 336 Rod Bundle,” Volumes 1 and 2, Electric Power Research Institute (EPRI) Report NP-1692, issued January 1981) to the conditions that would be simulated for Sensitivity Cases 4 through 10. In WCAP-15644-P, the applicant used WCOBRA/TRAC to simulate selected G1 and G2 boiloff tests, at low pressure, low flow and a range of power levels typical of AP1000 LTC conditions. WCOBRA/TRAC tended to overpredict the level swell in the core during boiloff scenarios. However, when a multiplier (YDRAD=0.8) is applied to the interfacial drag coefficient computed from the vertical flow regime models in the code, WCOBRA/TRAC generally predicted the level swell to within +/- 20 percent of the measured value. Therefore, the YDRAG=0.8 was selected for use in the WCOBRA/TRAC model for the AP1000 LTC analysis. The staff reviewed the ranges of the G1 and G2 test conditions and found that the conditions simulated for the G1 and G2 tests by WCOBRA/TRAC bounded the conditions calculated in Sensitivity Cases 4 through 10.

The staff noted in its review that the validation evaluations were performed using the WCORBRA/TRAC M7AR4_SB03 code version, whereas the current long-term cooling sensitivity analysis cases were performed using WCORBRA/TRAC M7AR7_AP. The staff asked if the difference in the different code versions could invalidate the conclusions of the previous studies to validate that WCORBRA/TRAC can successfully calculate conditions seen in the high debris blockage conditions of Sensitivity Cases 4 through 10. In Revision 2 of its response to RAI-SRP6.2.2-SRSB-39, dated June 28, 2010, the applicant indicated that it reviewed the differences between the two code versions and found that all but one of the error corrections and code updates can be classified into one of the four categories judged to have no or negligible impact on the applicability of the G1 and G2 validation calculations to the long-term cooling debris sensitivity cases. The only code difference judged to potentially affect the level swell calculations is related to the use of a level sharpener in the WCORBRA/TRAC M7AR4_SB03 code version. The WCOBRA/TRAC_AP code does not contain an explicit mixture level tracking model and, therefore, tracking of two-phase mixture level is accomplished by nodalization and prediction of the axial void gradient between hydraulic cells. The "level sharper" model in WCOBRA/TRAC M7AR4_SB3 code version was developed to locate the mixture level in the hydraulic cells where a sharp void fraction gradient is detected in the vicinity of the two-phase mixture level. The level sharpener logic is only applied to the void fraction used in the fuel rod heat transfer calculations in the hydraulic cells where detailed representation of local void fraction is important to assure that fuel rod heat transfer is computed based on the appropriate fluid condition. The level sharpener does not directly affect the global void fraction distribution. Since the level swell is a measure of two-phase mixture level relative to the collapsed liquid level, and is calculated in terms of the average void fraction, the precise mixture level has minimal effect on the level swell calculation. Therefore, the level sharpener model has negligible effect on the level swell calculation, and its impact on the G1 and G2 simulations is small. In other word, similar conclusions for the WCOBRA/TRAC code validation with the G1 and G2 simulations can be drawn with and without the level sharpener model. Therefore, the staff concludes that the use of the interfacial drag coefficient multiplier identified with the code version with the level sharpener model is applicable to the code version without the level sharpener logic. It should be noted that the WCOBRA/TRAC-M7AR4_AP code version used in the DCD Revision 15 long-term cooling analysis also did not include the level sharpener logic.

Sensitivity Cases 1 through 3 were analyzed with the AP1000 reference core design described in DCD Chapter 4. During the March 22–24, 2010, audit, the staff found that Sensitivity Cases 4 through 11, documented in Westinghouse calculation note APP-SSAR-GSC-732, "AP1000 AFCAP Post-LOCA Long-term Core Cooling Analysis," Revision 0, dated November 12, 2009, were performed with an advanced first core design, which differs from the DCD reference core design. Since the Advanced First Core Analysis Program (AFCAP) core design differs from the core design described in the AP1000 DCD, the staff questioned the applicability of the LTC analysis for cases 4 through 10 to the DCD core design. In response to RAI-SRP6.2.2-SRSB-42, the applicant describes the differences between the AFCAP core design and the DCD core design. The majority of the fuel assembly characteristics are either unchanged or have trivial changes in the AFCAP core design, [ ]. These changes are reflected in the input of the WCOBRA/TRAC AFCAP analysis for LTC sensitivity study Cases 4 through 10 using larger values of the flow resistance form loss coefficients for the mixing vane grids (MVG) and intermediate flow mixer (IFM) grids in the active fuel region. Other parameters in the WCOBRA/TRAC LTC analysis remain unchanged between the AFCAP and the DCD reference core design. The WCOBRA/TRAC LTC analysis was performed with the core geometry and form loss coefficients of fuel assemblies, plus a large non-mechanistic form loss coefficient at the core inlet to simulate possible worst case debris plugging. Since the core inlet flow resistance used in the LTC sensitivity runs are significantly larger than the flow resistances of the MVG and IFM, the differences in the MVG and IFM flow resistance between the AFCAP and DCD core design is not significant. In addition, the use of higher resistances for the MVG and IFM for the AFCAP core design would result in lower core flow rate than the DCD core design with lower MVG and IFM resistances. Since the objective of the LTC sensitivity studies is to establish the flow/pressure drop acceptance criteria for the AP1000 debris-induced core inlet blockage tests, the analysis using the AFCAP core design would result in lower core flow rate and inlet pressure drop. This results in more restrictive acceptance criteria for the fuel assembly debris-induced head loss tests. The use of the more restrictive acceptance criteria from the AFCAP core design for the fuel assembly head loss tests of the DCD referenced core design is conservative and is, therefore, acceptable.

LTC Sensitivity Study Results

Section 3 of APP-GLR-PXS-001, Revision 4, presents the results of the long-term cooling sensitivity analysis. For the DEDVI line break, the effects of increasing the flow resistance at the core entrance are generally reflected in the increase in the downcomer liquid level, a decrease in the core flow rate, a decrease in the core collapsed liquid level, an increase in the upper core void fraction, and an increase in the quality of the discharge flow through the ADS-4 valves. The upper plenum pressure for each case essentially reflects the containment pressure. In all cases analyzed, the collapsed liquid level in the core is higher than or near, the core midplane. The mean HL collapsed liquid level is above the HL centerline. For each sensitivity case, Table 4-1 in APP-GLR-PXS-001, Revision 4, provides the time after LOCA, core inlet loss coefficients, core flow rate, core inlet dP, ADS-4 steam quality, and maximum core boron concentration.

For Sensitivity Case 3, the upper plenum pressure of 22 psia is essentially unchanged from the DCD case. The downcomer liquid level has increased compared to the DCD case because of added core inlet flow resistance. Injection rates through the DVI lines into the vessel are reduced compared to the DCD case values. Flow through the intact DVI line is reduced to 25 kg/s (56 lbm/s) versus 35 kg/s (77.2 lbm/s) in the DCD analysis. Flow into the vessel through the broken DVI line is reduced from 34 kg/s (75 lbm/s) in the DCD analysis to 25 kg/s (55 lbm/s) in Sensitivity Case 3. The core flow is reduced to 50 kg/s (111 lbm/s) with a pressure loss of 24.1 kPa (3.5 pounds per square inch (psi)). The HL collapsed liquid level is above the HL centerline. The quality of the flow discharged through ADS-4 valves in Sensitivity Case 3 is approximately 0.35. The core boron concentration is 4,700 parts per million (ppm).

The thermal hydraulic behavior in the core was shown to be most limiting in Sensitivity Case 10. For Sensitivity Case 10, the downcomer liquid is established at a higher level than in the DCD analysis because of the greater added resistance at the core entrance. Boiling in the core produces steam and a two-phase mixture that flows out of the core into the upper plenum. The core collapsed liquid level is maintained at a mean level above or near the core midplane even with the added core entrance resistance. Boiling causes pressure variations, which in turn cause variations in the core collapsed level and the flow rates of liquid and vapor from the top of the core. The HL collapsed liquid level is around the HL centerline. The peak cladding temperature of the hot rod closely follows the saturation temperature. The flow through the core and out of the RCS provides adequate flushing to preclude the unacceptable concentration of the boric acid solution. Liquid collects above the upper core plate in the upper plenum, where the collapsed liquid level remains well above the active fuel length.

For Sensitivity Case 10, the upper plenum pressure reflects the prevailing containment pressure of 110 kPa (16 psia) calculated at 31,000 seconds. Injection rates through the DVI lines into the vessel are reduced compared to the DCD case values, and the injection flow rate is greater through the lower resistance broken DVI line than it is through the intact DVI line. The core flow is predicted to be 29.5 kg/s (65 lb /s), with a pressure loss of 28.3 kPa (4.1 psi). The steam quality of flow discharged through ADS-4 valves is approximately 0.49. This liquid carryover is adequate to limit the concentration of boric acid in the core water to a value of 6,100 ppm. This is lower than the maximum value of 7,400 ppm at the time of recirculation initiation in the DCD long-term cooling analysis that was shown to be acceptable in DCD Section 15.6.5.4C.4.

The applicant determined that Sensitivity Case 10, which is a DEDVI break in the loop compartment, represented the worst case condition assuming that all the debris will reach the core entrance sometime after one complete recirculation of the entire containment water volume.

The applicant used Cases 3 and 10 to establish the acceptance criteria for the AP1000 fuel assembly debris head loss testing. The staff's evaluation of these acceptance criteria is discussed in the Test Acceptance Criteria section of this SER section.

For Case 11, the resulting injection flow rate through the lower resistance broken DVI line 62.8 kg/s (138.5 lb /s) is greater than it is through the intact DVI line 34.5 kg/s (76 lbm/s). The core flow is predicted to be 97.3 kg/s (214.5 lb /s) with an average pressure loss of 13.8 kPa (2 psid) at the core exit where the added debris resistance was applied. The results of Case 11 also demonstrate long-term cooling performance comparable to the DCD long-term cooling case. The DEHL break acceptance criterion is core exit pressure drop of 13.8 kPa (2 psid) at a flow of 97.3 kg/s (214.5 lbm/s).

It should be noted that the WCOBRA/TRAC long-term cooling analysis did not consider the effects of the potential accumulation of noncondensable gases in high points in the PXS flowpaths. In a letter dated May 25, 2010, the applicant proposed the PXS design changes (Change No. 66), including installation of high point vents, to reduce the potential impact on gas intrusion in the PXS flowpaths. The staff considers that an appropriate PXS design change to prevent potential gas accumulation in the PXS system is an acceptable substitute for not considering the noncondensable gas effects in the long-term cooling analysis. The staff evaluation of DCP Change No. 66 will be addressed in Chapter 23.

6.2.1.8.2.7.2 Fuel Assembly Head loss Testing

The applicant performed a series of experiments to quantify the effect of fibrous and particulate debris and containment chemical effects on the head loss across the fuel assemblies of an AP1000 core during a postulated LOCA, documented in WCAP-17028, Revision 6, and performed in consideration of GSI-191. The objective of these experiments was to demonstrate that there is reasonable assurance that the AP1000 can provide adequate post-LOCA long-term core cooling. The applicant used a fuel assembly design that is consistent with the fuel assembly design described in the AP1000 DCD. The flow rates, debris loadings, and method of debris addition varied from test to test. The ratio of fibrous to particulate debris varied, as did the temperature and chemistry of the coolant. The purpose of the tests was to select a combination of debris variables and simulated plant variables that would bound any AP1000 LOCA and to demonstrate available long-term cooling margin in the AP1000 design such that with the flow blockage caused by the containment debris transported to the reactor vessel, the head losses determined by the fuel assembly testing are bounded by the test acceptance criteria described below.

The applicant performed 39 different experiments. Section 7 and Tables 7-1 through 7-3 of WCAP-17028 summarize the test matrix and initial conditions for the tests. Table 8-1 of WCAP-17028 summarizes the results of experiments that were performed with various debris loads, flow rates, fiber length, chemical effects, and fiber, particulate, and chemical addition sequencing.

The applicant had initially conducted the first 16 fuel assembly tests correlating to long-term cooling Sensitivity Cases 1 through 3. The applicant varied the particulate, fiber, and chemical amounts. The composition of the fibers for these 16 fuel assembly tests also varied. For the subsequent 23 fuel assembly tests, except for tests 35 and 38, the applicant increased fibrous debris loading based on the design-basis fiber amount of 3.0 kg (6.6 lb) in the containment, equivalent to 2.7 kg (6 lb) of fiber to the core inlet, as discussed in Section 6.2.1.8.2.6 of this report. The applicant chose debris loadings in the fuel assembly tests to bound the quantities that could be transported to one fuel assembly in the AP1000. Table 3-4 of TR-26 presents the AP1000 design-basis fibrous, particulate, and chemical debris that could be transported into the reactor vessel and possibly reach the fuel assemblies.

The applicant selected flow rates to bound the conditions expected during post-LOCA recirculation core cooling. Except for Tests 2 and 8 through 11, the first 16 tests were conducted with constant flow rates. Tests 17 through 39 were conducted with variable flow rates, with the flow reduction based on the increase in the dP resulting from debris additions.

Tests 1 through 21 and Test 23 were performed using sequential additions of particles, then fibers, then chemical surrogate. Test 22 and Tests 24 through 39 were performed with concurrent additions of particles, fibers, and chemical surrogate. The applicant prepared fibrous and particulate debris loads and chemical precipitates outside of the test loop and added them to the makeup tank in accordance with the applicant's test plan. All of the experiments included fibrous and particulate debris and chemical reaction products that were added to the makeup tank as water suspensions. The sequential and concurrent debris addition schemes are discussed in the Debris Addition Scheme section below.

The fuel assembly test loop consists of a scaled length of a fuel assembly inside a Plexiglas case, a mixing tank, and the pumps and plumbing required for circulating water and debris. The fuel assembly is consistent with the design described in DCD Section 4.2.2.2. In RAI-SRP6.2.2-SRSB-26, the staff asked the applicant to justify why the test results from the scaled-length, isothermal fuel assembly test facility are applicable to the post-LOCA long-term cooling situation for a full-length assembly in which boiling occurs in the upper portion of the fuel assembly. In its February 26, 2010, response, the applicant stated that most of the AP1000 fuel assembly debris head loss tests were performed with a single fuel assembly and upflow of water. The applicant included a fuel bottom nozzle, p-grid, and spacer grids in the single fuel assembly, simulating the bottom portion of a fuel assembly. The results from the fuel assembly tests have shown that the debris-induced pressure drop (dP) acceptance criteria are met. The upflow fuel assembly tests simulated DEDVI or DECL LOCAs where the debris entered into the downcomer and the core inlet region.

The fuel assembly test results show that the vast majority of the dP was seen across the inlet nozzle and p-grid in the bottom part of the test assembly; therefore, the applicant concluded that the use of a scaled-length test assembly will not change the test results because most of the pressure drop occurs in the first part of the test assembly. On the basis of the test results that show the majority of the dP occurs in the inlet nozzle and p-grid in the bottom part of the test assembly, the staff agrees that the scaled-length test fuel assembly is reasonable to simulate the AP1000 fuel assembly for debris blockage at the core inlet.

The applicant set up a test loop, as described in Appendix C to WCAP-17028, and configured it in two ways: (1) to simulate a DVI break or CL break with break flow through the downcomer and up through the core inlet region; and (2) to simulate a HL break with downflow from the break to the core exit region. The test facility also simulated additional conditions, such as water at higher temperatures and the boiling environment seen in the AP1000 core when there is a high level of debris blockage at the core inlet. The boiling environment in the core is simulated by injection of air during the test. The test loop flow rates were scaled to expected flows seen in the AP1000 to represent the flow rate at the core inlet for a DECL/DVI break with upflow. The selected flow rates were representative of or bounded flows expected through the core during the recirculation phase after a LOCA.

In response to RAI-SRP6.2.2-SRSB-26, the applicant performed additional fuel assembly Tests 36, 37, and 39 to address the applicability of the isothermal scaled test to potential boiling conditions at the full-length fuel assembly. The staff asked whether there are situations where two-phase flow could challenge the single-phase test results and whether a higher liquid temperature or local boiling phenomenon could affect the behavior of the debris plugging the core. Tests 36 and 37 repeated Test 30, with the exception that chemicals were added to the test loop to simulate reactor coolant chemistry and the test loop was heated to a higher temperature than for Test 30. The applicant's test results showed, as before, that the fiber accumulated around the bottom of the p-grid before accumulating around the bottom nozzle. For both tests, near the end of the flow sweeps, the debris bed was very thick and very smooth, yet it did not cause an increase in the steady-state core dP. The pressure drop increase occurred almost exclusively at the bottom nozzle/p-grid location as in the other tests. On the basis of its review, the staff agreed that using the lower temperature water in the test facility in Test 30 was a conservative effect on the measured core inlet dP. As a result, the staff found that testing with lower temperature water was acceptable.

The applicant performed an additional Test 39 in response to RAI-SRP6.2.2-SRSB-26 to observe the effect of adding debris to the test fuel assembly under simulated DEHL break conditions. The conditions simulated in this test were upward flow of coolant with boiling. The debris loadings used were the same as for Test 30. [

]

In the WCOBRA/TRAC analysis, the applicant predicted significant two-phase mixture at the top of the AP1000 core. In APP-GLR-PXS-001, Sensitivity Case 10 was determined to be the worst case debris blockage case simulated by WCOBRA/TRAC. The applicant found that the pressure drop across the core for single-phase flow at the core inlet was larger than the pressure drop across the top part of the core even when two-phase flow at the top of the core causes the flow losses to be much greater.

On the basis of its review, the staff finds that the fuel assembly debris loading head loss testing using single-phase flow appropriately estimates the worst case dP across the core inlet when compared to the two-phase flow predicted in an AP1000 core after a LOCA.

Implicit in the single fuel assembly debris load head loss test is a basic assumption of uniform blockage across the core inlet. In RAI-SRP6.2.2-SRSB-33, the staff requested that the applicant discuss potential effects of non-uniform blockage in the fuel assembly test facility. In its response, dated January 29, 2010, the applicant explained that the AP1000 fuel assembly debris-loading head loss tests indicate that there is non-uniform flow blockage and there is considerable variation in the fuel assembly flow/dP even with the same debris addition. Every test has shown non-uniform blockages within the fuel assembly and gaps in the debris bed. This shows that the debris bed at one fuel assembly will be different from that in others.

The applicant further stated that it is expected that the distribution of debris across the core inlet of all fuel assemblies will be non-uniform. Debris that accumulates at the core inlet is not expected to distribute uniformly across the entire core inlet and, therefore, some fuel assemblies will have more debris buildup than other fuel assemblies. The fuel assemblies with less debris buildup will experience less dP across the fuel assembly and will be able to pass more flow through those fuel assemblies. The higher flows through these low dP fuel assemblies would cross over to assist cooling fuel assemblies that have higher dP and lower flow at the core inlet and provide additional margin for long-term cooling. Therefore, the staff concludes that the single fuel assembly debris-induced head loss test is conservative and acceptable.

Debris Addition Scheme

The manner in which the debris is added has been observed in prior industry testing programs to make a difference in the overall head loss through the fuel assembly. Therefore, it was determined that the order in which particulate, fiber, and chemicals were added was important. the applicant used the following debris addition schemes (i.e., sequential addition and concurrent addition) for the fuel assembly debris loading head loss tests:

- For tests applying the sequential additions of particulate, fiber, and chemicals, an aliquot of the water from the mixing tank was removed and placed in a container for each addition of particulate. The particulate was then well mixed into this water until completely suspended before being added to the mixing tank. The mixing tank volume was allowed to thoroughly mix. Then the fiber was added per the test plan using a similar manner as described above for the particulate. Thirdly, the surrogates for chemical reaction products were added to the test loop after all of the fiber and particulate had been added. The chemical precipitate was mixed outside the test loop per the WCAP-16530-NP-A methodology and then added to the test loop in measured batches. The approach of sequential debris addition into the test loop is consistent with the NRC-approved guidance on head loss testing, WCAP-16406-P-A, Revision 1. The fuel assembly tests using sequential debris addition were set up to determine the maximum dP value that would be achieved under the test condition.

- Tests applying the concurrent addition of particulate, fiber, and chemicals modeled debris addition at start of recirculation after a LOCA. For tests applying concurrent debris addition, an aliquot of the water from the mixing tank was removed and placed in a container and the prescribed amounts of particulate and fiber were added to the container. The particulate and fiber were then well mixed in this water until completely suspended before being added to the mixing tank. Concurrent with the addition of particulate and fiber, chemical surrogate was added directly to the mixing tank in the amount prescribed in the test procedure. Concurrent debris additions were made at times specified in the test procedure.

Test Acceptance Criteria

In the long-term cooling sensitivity studies described above, Case 10 provided the limiting case conditions, which were postulated assuming that all the debris will reach the core entrance after one complete recirculation of the entire containment water volume. For Case 10, the long-term core cooling analysis found that for a CL or DVI break, the limiting dP through the core is 28.3 kPa (4.1 psid) with a corresponding minimum core flow rate of 29.5 kg/s (65.0 lb /s or 480.7 gallons per minute (gpm) core flow rate), or [ ] per fuel assembly. Therefore, the acceptance criterion for the fuel assembly test is 28.3 kPa (4.1 psid) at [ ] per fuel assembly. This is identified as acceptance criterion 1 for all fuel assembly tests not involving a HL break.

The second criterion is based on sensitivity Case 3 in the long-term cooling analysis. In this case, the maximum dP allowed in the core at the beginning of the recirculation phase is 24.1 kPa (3.5 psi) with a flow rate of [ ] per fuel assembly. The second criterion is intended to verify that during the recirculation, for any level of the decay heat between the start of the recirculation phase (long-term cooling Sensitivity Case 3) and 8.6 hours, the core will be satisfactorily cooled, requiring that the head loss through the core at [ ] per fuel assembly must be lower than 24.1 kPa (3.5 psi). It should be noted that the concurrent debris addition fuel assembly tests were set up in order to model the plant timing of debris addition after the start of recirculation. Therefore, the test time can be related to the plant time. In contrast, the sequential debris addition tests were set up to determine the maximum dP value that would be achieved under the test condition, with no reference to the time at which it would occur in the plant. For this reason, the second acceptance criterion is not applicable to the sequential debris addition tests but only to the concurrent debris addition tests.

For those fuel assembly debris head loss tests where the debris is added in a mechanistic, time-dependent sequence for the beginning of recirculation (2.6 hours) after a DECL or DEDVI LOCA, the applicant used Sensitivity Case 3 for the core dP acceptance criteria. This case is conservative because: (1) debris-induced resistance at the core inlet is assumed to occur at the beginning of recirculation, earlier than the time debris would be transported to the core inlet; and (2) the decay heat rate at 2.6 hours post-LOCA is higher than the decay heat rate at 9.0 hours, the time at which the Sensitivity Case 10 acceptance criteria are used.

For a HL break the flow in the upper part of the core is expected to oscillate when the downflow in a low-power assembly becomes low and the steam generation rises upwards. Case 11 from the sensitivity studies found that the limiting dP through the core is 13.8 kPa (2 psid) with a corresponding minimum flow rate of 97.3 kg/s (214.5 lbm/s or 1,602 gpm core flow rate). This is the minimum flow rate that can be maintained for long-term core cooling. The acceptance criterion for the HL break fuel assembly tests is that the dP across the fuel assembly test article must not exceed 13.8 kPa (2 psid) at a flow rate of [ ]. This acceptance criterion will be applied to each of the HL break fuel assembly tests.

As discussed earlier, there are two acceptance criteria for the upflow fuel assembly tests simulating CL and DVI line breaks. The first acceptance criterion for the fuel assembly tests is that dP across the fuel assembly inlet must not exceed 4.1 psid at a flow rate of [ ], which is based on the limiting Case 10 of the long-term cooling sensitivity studies. This acceptance criterion was applied to each of the fuel assembly tests. The second criterion, applied to all concurrent debris addition tests, is intended to verify that during containment recirculation when the debris bed is not completely formed, for any decay heat rate between the start of the recirculation phase at 2.6 hours (long-term cooling Sensitivity Case 3) and the time of 8.6 hours that it takes to recirculate one containment water volume, the core will be adequately cooled, with the core head loss lower than 24.1 kPa (3.5 psid) at fuel assembly flow rates of [ ]. Another test acceptance criterion for a HL break is 13.8 kPa (2 psid) at a flow rate of [ ] through the fuel assembly.

The applicant conducted many CL tests with a constant flow rate higher than [ ] or with variable flow rates where the minimum flows were higher than [ ]. Moreover, in all the concurrent addition tests, the flow rate at a time before 9 hours in plant time was higher than [ ]. To evaluate the test results, the experimental results need to be adjusted to a lower flow rate ([ ] for the first criterion, [ ] for the second one). The applicant developed Equations 5.1.2 and 5.1.3 in WCAP-17028 to calculate the adjusted dP to flow rates of [ ] and [ ], respectively, for the comparison with the first and second acceptance criteria. These equations were developed based on the dP/flow rate relationship developed for each fuel assembly test described in Section 5.2 of WCAP-17028. The exponent "b" in Equations 5.1.2 and 5.1.3 is determined from the fuel assembly head loss tests and summarized in Table 5-1 of WCAP-17028 for each test. In Section 8.39 of WCAP-17028, the applicant described the development of Equations 5.1.2 and 5.1.3, as well as the value of exponent b in these equations.

In RAI-SRP6.2.2-SRSB-27 and RAI-SRP6.2.2-SRSB-29, the staff asked for information about the development of the b exponent in extrapolating the expected pressure differential and the use of the two acceptance criteria for the testing program. In its February 26, 2010 response, the applicant explained that many of the AP1000 tests were conducted with variable flow rates where the flow was changed during the test as the dP increased to simulate the actual behavior of the plant. Therefore, the applicant developed two acceptance criteria for the fuel assembly debris load tests. This was discussed in WCAP-17028 in Sections 5 and 8.

As discussed above, to determine whether a test met the long-term cooling criteria, the maximum dP measured in each test was adjusted, as described below, based on both the flow that existed when the maximum dP occurred and the minimum acceptance flow (i.e., [ ]). This adjusted dP provides a simple way to compare tests and determine whether the test met the acceptance criteria.

The data collected by the tests resulted in the development of Equation 8.39.1 in WCAP-17028, which defines the relationship between head loss and the flow rate. This equation is based on the Darcy formula, and the exponent is determined by test results. When the debris bed is formed and stable, the pressure drop behavior of the debris bed will vary consistently with flow rate. In other words, [ ]. This also means that once the value of the [ ] are known at a particular flow rate, it is possible to evaluate the value of dP at any flow rate.

Since the tests were not conducted at a low flow rate of [ ] as required by the first acceptance criterion, the measured dP must be adjusted as suggested above. For the first acceptance criterion, some of the tests performed flow sweeps to the low flow level. From each of these tests, an exponent was developed and used in Equation 8.39.4 of WCAP-17028 to calculate the pressure differential adjusted to the low flow of [ ]. To illustrate this process, Test 34 will be reviewed below.

Test 34 was performed to investigate the nature of the dP/flow relationship throughout the test to allow comparison of the bed behavior for a fully formed and stable debris bed. Flow sweeps were performed throughout the duration of Test 34, and the experimental results confirm that the dP and the flow are related by a power law relationship as shown in Equation 8.39.1 of WCAP-17028 even in the case of a debris bed not yet fully formed. [ ], which was much lower than the first acceptance criterion of 28.3 kPa (4.1 psid). The test dP at the maximum debris bed resistance as presented in Table 8-1 was used for the first acceptance criterion. Since Test 34 was a concurrent test, the second acceptance criterion must also be applied.

The second criterion is based on long-term cooling Sensitivity Case 3, which assumes the maximum blockage condition in the core at the beginning of the recirculation.

Concerning the applicability of Equation 8.39.3 to the second acceptance criterion, the use of the stable bed exponent would result in a greater underestimation of the adjusted dP. Looking at the results of Test 34, the exponent at [ ], and the bed resistance is still increasing. This suggests that a reduction of about 27 percent should be applied at the stable bed exponent to extrapolate the test results at higher flow rates down to [ ], which is the flow basis for the second criterion. For conservatism, a reduction of [ ] was applied to the exponent b of the second criterion. This reduction is based on the difference between the fully formed bed exponent and the lowest exponent estimated in Test 34. For the second acceptance criterion, the exponent b becomes [ ] because of the reduction applied to the exponent. Applying the second criterion to Test 34, the b exponent for Test 34 was determined to be [ ]; applying Equation 8.39.5 with a measured maximum dP at [ ], which was much lower than the second acceptance criterion of 24.1 kPa (3.5 psid).

For most tests, the value of the exponent applied to flow was determined by the flow/dP data taken from that test. For Tests 18 through 34 and Tests 36 and 37, flow sweeps were conducted at the end of the test that provided many data points (different flows/dPs). The flow sweeps reduced the flow rate to the acceptance criteria flow so that these data are directly applicable. Such data are also available for Tests 8 through 11 because of the use of oscillating flows during the tests. Tests 1 through 6 and 13 through 16 used the average exponent from all tests. Table 9-1 and Figure 9-1 of WCAP-17028 show these results. The data show considerable margin between the scaled dP and the acceptance criterion. For example, for Test Case 33, which has the highest scaled dP, there is close to 50 percent margin from the acceptance criteria.

In the AP1000, debris can transport into the RCS though the flooded HL and possibly into the upper parts of the core. In an actual HL LOCA in an AP1000, the flow in the upper part of the core is expected to oscillate over several minutes. When the downflow in a low-power assembly becomes low, the steam generation rises. The tests before Test 35 were all conducted simulating a CL break scenario and without simulating boiling. In RAI-SRP6.2.2-SRSB-31, the staff asked the applicant for more information and clarification concerning the HL break. In response to this RAI, the applicant performed more testing to simulate the effects of a HL break on the AP1000 core. These tests were conducted to prove that the CL breaks were more limiting even if debris entering the top of the core would occur in a HL break. These conditions were to be tested for an expected HL break LOCA in an AP1000.

In the event of a HL break, the applicant assumed that the post-LOCA containment debris load would be equal to 90.72 kg (200 lbs), consisting of 3.0 kg (6.6 lbs) of fiber, 87.72 kg (193.4 lbs) of particulates, and 25.85 kg (57 lbs) of chemical precipitates. The applicant assumed that all the debris was transported into the core through the outer ring of fuel assemblies.

Tests 35, 38, and 39 represented the HL breaks. The goal of Test 35 was to observe the effects of adding debris to a model fuel assembly under reverse flow conditions that might exist in an AP1000 reactor after a HL break. The test evaluated the distribution of debris blockages within the top portion of the assembly, and the relationship between pressure and flow. To model AP1000 behavior on a HL break, further testing of debris blockage with reverse flow was needed. With the debris load and chemical precipitate tested, the peak head loss recorded for this test was [ ]. The [ ] psid was below the acceptance criteria of [ ].

The purpose of Test 38 was to investigate the debris behavior in the outer fuel assemblies under simulated DEHL LOCA conditions, where flow could be downward and transport debris into the upper part of these fuel assemblies. The test also investigated the impact of changing the direction of flow from the downward to the upward direction, representing steam with boiling present in the upward direction. Test 38 was conducted to represent the downflow in a low-power assembly that produces steam and results in a change in flow from the downward to upward direction. This flow reversal and its effect on a debris bed were explored. The downflow was introduced for approximately 1 hour after one concurrent debris addition. The flow was then reversed to upflow, simulating the steam generation rise, and boiling was introduced at this time.

The reversal of flow did not visibly change the bed a great deal, but when air was introduced to simulate boiling, the [ ]. The air was injected at [ ], which is the maximum allowable air injection for the test rig and is much lower than the steam volume predicted to exist in the upper core region, and proved that this flow rate can quickly disperse any debris that would collect. Therefore any flow rate greater than [ ] would do the same, but more quickly. Based on the test results, the applicant concluded that the brief upflow of steam would be sufficient to break up any accumulated debris in the upper core region. The purpose of Test 39 was to investigate the debris behavior in central fuel assemblies that will be exposed to constant upward flow of water and steam. Test 39 was conducted solely to represent the HL break condition representing the steam in the upward flow direction and the local boiling phenomenon affecting the behavior of the debris plugging the core. The air was injected at the same rate in Rest 38 throughout the duration of the test. [ ].

Tests 38 and 39 had very low pressure drops, [ ].

[ ]. The pressure drops in the core for all three HL tests were less than the acceptance criterion of 13.8 kPa (2 psid).

In RAI-SRP6.2.2-SRSB-28 and RAI-SRP6.2.2-SRSB-30, the staff asked the applicant to explain the large variation in test results for Tests 27, 29, and 30, given they had the same amount of debris and debris addition procedures and appeared to be repeatable tests. The staff also noted that the fuel assembly test results indicate large uncertainties where the peak dP is significantly different for similar flow cases with the same amount of fiber. The staff asked the applicant to justify the acceptability of test results with large uncertainties and to provide an evaluation of the statistical confidence with which the test results could be used to assess the long-term cooling effectiveness based on the fuel assembly debris loading head loss tests.

In its response, the applicant prepared APP-GW-GLR-092, Revision 0, describing its statistical analysis of the fuel assembly debris loading head loss tests. The objective of the statistical analysis was to use available test data to show that there is a low probability that the AP1000 debris bed resistance will exceed the analyzed safety analysis limit from the long-term cooling sensitivity studies, which show acceptable results for the DVI break or CL break scenarios where the debris enters the core from the downcomer and lower plenum. The applicant concluded that, based on the test data and consistent with the statistical evaluation, it had established a conservative distribution of the adjusted pressure drop across the core. Using this conservative distribution, the effective adjusted pressure drop at the core inlet was calculated to be significantly below the safety analysis limit of 28.3 kPa (4.1 psid) with core flow of 29.5 kg/s (65 lbm/s).

The statistical analysis of the tests evaluated in APP-GW-GLR-092, Revision 0, determined that the probability for a single fuel assembly to exceed the acceptance criterion of 28.3 kPa (4.1 psi) is less than [ ]. Therefore, there is a low probability that a few of the 157 fuel assemblies in the AP1000 core could build up a debris bed that could exceed the acceptance criteria. However, many of the fuel assemblies in the core will have debris beds that have lower resistances than the acceptance criterion. The results of the statistical analysis of the AP1000 fuel assembly debris testing show that the effective core inlet adjusted dP would be [ ], using the 95 percent upper bound standard deviation, which demonstrates considerable margin to the acceptance criterion of 28.3 kPa (4.1 psi).

The staff notes that the statistical analysis is not required as a part of the GSI-191 evaluation, and the size of the test dataset is not sufficient to form the basis for a sound statistical analysis. However, the staff finds that the statistical analysis provides useful supporting evidence that the there is low probability that debris entering the core and debris bed buildup would degrade the core cooling margin to the point that the ECCS acceptance criteria were not met.

The staff evaluated the core cooling capability of the AP1000 core during long-term cooling based on the review of the long-term cooling analyses and fuel assembly debris loading head loss testing. The staff concludes the following:

- The design basis of 90 percent debris bypass (i.e., 90 percent of the design basis containment debris entering the core through submerged breaks unfiltered, bypassing the circulation screens), determined by the limiting DECL break, is a conservative assumption for the long-term cooling evaluation. The limiting DECL break was determined to be the worst case break that could allow the maximum amount of unfiltered debris to enter the reactor downcomer.

- The applicant conducted WCOBRA/TRAC long-term cooling sensitivity analyses using large nonmechanistic flow resistance at the core entrance to simulate debris-induced flow blockage to determine adequate core cooling. The limiting core inlet dP and flow results from Sensitivity Cases 3 and 10 were then used to develop acceptance criteria for the fuel assembly debris loading head loss testing.

- The applicant ran 39 fuel assembly tests to show that the worst case debris that would be expected in the AP1000 reactor during long-term cooling would not exceed the dP acceptance criteria. These tests showed that the design-basis AP1000 fibrous and particulate debris and chemical precipitates assumed to exist in the AP1000 containment do not induce a high enough head loss through the fuel assembly to reduce flow into the core to less than the minimum required to provide adequate long-term cooling following a LOCA.

On the basis of its review, the staff finds that the evaluations performed by the applicant showed that, with the design-basis containment debris loading, adequate core cooling in the AP1000 can be maintained during the post-LOCA recirculation long-term cooling period.

6.2.1.8.2.8 Head Loss and Vortexing

The applicant conducted head loss testing using plant-specific debris loads and flow rates to demonstrate the adequacy of the containment recirculation and IRWST screens. The debris types considered were particulate, fiber, and chemical precipitates. WCAP-16914-P and WCAP-16914-NP document the methodology, assumptions, and results. The staff evaluated these documents considering guidance from Enclosure 1, "NRC Staff Review Guidance Regarding Generic Letter 2004-02 Closure in the Area of Strainer Head Loss and Vortexing," and Enclosure 3, "NRC Staff Review Guidance Regarding Generic Letter 2004-02 Closure in the Area of Plant-Specific Chemical Effect Evaluations," to "Revised Guidance for Review of Final Licensee Responses to Generic Letter 2004-02, 'Potential Impact of Debris Blockage on Emergency Recirculation during Design Basis Accidents at Pressurized-Water Reactors,'" dated March 28, 2008.

WCAP-16914-P documents all eight AP1000 screen head loss tests. These experiments were performed over a period of time, capturing different evolutions of the design. Because there were significant changes to the debris source term and screen size over the course of the program, only Tests WE213-4W and WE213-5W are representative of the final AP1000 design. These two tests, which are the focus of the subsequent discussion, were run with nearly identical parameters.

The AP1000 containment recirculation and IRWST screens comprise pockets constructed from perforated plate with holes less than or equal to 1.59 mm (0.0625 in). The screen used in the test is similarly constructed, [

].

The test facility included a large acrylic tank containing the test screen and supporting structure, positioned on the tank floor. Fluid entered the tank through a submerged sparger, located close to the upstream tank end. The flow entered the test screen pockets horizontally and was recirculated through piping connected to the downstream end of the tank. The pump, flow meter, and valves were external to the tank. The temperature of the fluid was maintained just below room temperature via cooling coils wrapped around the sparger.

Tests WE213-4W and WE213-5W began with clean screen head loss measurements at each of the two flow rates designated for use during the test to provide a reference point for the subsequent test results. The flume was then stabilized at the higher flow rate, and the particulate was added by slowly sprinkling the particulate surrogate at the water surface furthest upstream of the screen. The flume was run for five turnovers and stirred to resuspend any settled particulates. The fiber was then added in small batches. For each addition, a portion of the dry fiber was shaken into a solution of flume water and then slowly poured on the water surface furthest upstream of the screen. When fiber addition was complete, the flume was stirred and then allowed to run at a steady state overnight. The next morning, the flow rate was reduced to the minimum value in preparation for chemical addition. The chemical precipitates, created outside the loop, were slowly added to the flume in small batches, at a rate that bounded twice the predicted rate of chemical production in the AP1000, scaled to the limiting screen surface area. Upon completion, the flume water was stirred and again allowed to run at a steady state overnight. The next day, the flow rate was increased to the maximum value and swept back before ending the test. For both Test WE213-4W and test WE213-5W, the head loss remained very close to zero throughout the entire test, from the initial clean screen step through to the final flow sweeps.

The particulate debris comprises the particulate portion of latent debris and the coatings in the ZOI, which fail as fine particles. Coatings that fail as chips are not transported to the screen, as previously discussed. The particulate surrogate was [ ], which is consistent with the description of "dirt" from Appendix V to NEI 04-07. The surrogate for the latent fiber was [ ], which is consistent with the recommendations in Appendix VII to NEI 04-07. It comprised heat-treated fiber that had been either shredded or chipped. For Tests WE213-4W and WE213-5W, the fiber was submersed in a bucket of water and thoroughly shaken. It was not added to the flume until it was confirmed that all fibers were sufficiently fine and individualized. This approach eliminated the fiber agglomeration that was observed in some of the earlier tests. [ ] was used as a surrogate for all three chemical products generated in the postaccident AP1000 sump. As discussed in Section 6.2.1.8.2.4 of this report, this is an appropriate surrogate. The chemical reactant products were formed outside the test loop in accordance with the NRC-approved methodology from WCAP-16530-NP-A. The debris sequencing in Tests WE213-4W and WE213-5W is consistent with the guidance. The flume water was stirred for 1 minute after each debris type was added, which is expected to be sufficient time for all debris to initially reach the screen. Visual confirmation was not possible because the particulates, which were added first, turned the water gray.

For fiber and particulate debris, the loadings for the IRWST and containment recirculation screen are found by dividing the amount of debris transported to each screen by the screen frontal area. The results, based on values taken from the DCD, are presented in Table 5-2 of WCAP-16914-P along with the calculated debris loading from Tests WE213-4W and WE213-5W. As shown, the test debris loadings encompass both the IRWST and containment recirculation screens. Scaling the tested amounts of debris by the more limiting IRWST frontal areas and transport assumptions demonstrates the testing bounds a containment that has [ ] of fiber and [ ] of particulate. The AP1000 design has 3.0 kg (6.6 lb) of fiber and 87.8 kg (193.4 lb) of particulates; thus, there is significant margin in the tested amount of particulates.

A different approach was taken to determine the amount of chemicals added to the test flume. The intended amount, shown in Table 5-2 of WCAP-16914-P, was determined by scaling the chemical debris to screen frontal areas. The applicant claimed this amount of chemicals would result in a chemical concentration in the test flume about [ ] times higher than expected in the AP1000 containment. In order to remove some of this conservatism, the applicant added a termination criterion to the test plan that would allow the test to conclude if the measured [ ]. For both Test WE213-4W and test WE213-5W, the flume was sampled after a portion of the chemical precipitates was added; [

].

The applicant provided additional information about the concentration measurement procedures in response to RAI-SRP6.2.2-CIB1-26 and RAI-SRP6.2.2-SPCV-31. The staff did not conclude that the [ ] provided a conservative alternative to area-based scaling. However, based on the amount of chemical debris added and the measured head loss, the staff did conclude that the test conformed to the staff's guidance with respect to the amount of chemical debris. This is discussed below with the test results.

The procedures for Tests WE213-4W and WE213-5W included minimum and maximum flow rates, originally meant to differentiate the higher IRWST injection flows from the lower recirculation flows. The fiber and particulates were added at the maximum flow rate, representative of injection flow, and the chemicals, which would not precipitate until after start of recirculation, were added at the minimum flow rate. Tests WE213-4W and WE213-5W specified the same maximum flow rate, but the minimum flow rate in Test WE213-5W was slightly higher than in Test WE213-4W in order to encompass the recirculation flow oscillations observed in the long-term cooling analysis, APP-PXS-GLR-001. The highest flows in the AP1000 occur during operation of the nonsafety-related RNS system, which was not intended to be bound in the original test plan. However, the pressure drops remained near zero throughout the testing, indicating a clean screen. This is consistent with photographs from WCAP-16914-P, which clearly show open areas on the screen. Additionally, the calculated fiber bed thickness for these tests is [ ], which is [ ] times thinner than what was demonstrated to produce a thin bed in one of the earlier tests.

As stated above, the staff determined that, although not all of the chemical debris was added to the test, the test conformed to the staff's guidance for test termination with respect to chemical debris. In Section 16 of the March 2008 guidance for GSI-191 chemical effects, the staff stated that tests should be terminated in a way that demonstrates with high confidence that additional time or chemical debris would not significantly change the maximum head loss. In Tests WE213-4W and WE213-5W, the applicant added [ ] percent of the prepared chemical debris, which was scaled to screen frontal area (Table 6-1). The screen area was clean and there was no measured head loss even after adding a substantial fraction of the debris. The staff concluded that the test termination conformed to the staff's guidance.

Because the pressure drop remained negligible during the flow sweeps, the applicant was able to demonstrate that the screen performance was not a function of flow rate and the DCD criterion was changed to require that the testing encompass RNS operation. The test report incorporated this change in Table 5-2, which identifies maximum AP1000 flow rates as those associated with RNS operation. As shown, the maximum tested flow rate bounds the containment recirculation screen, but it is only 94 percent of the IRWST scaled value. The applicant considers this acceptable because a 6-percent difference is small, the scaling was conservatively based on frontal area rather than surface area, and the test results demonstrate a clean screen. The staff agrees that the conservatism in the scaling bounds the minor difference in flow rates and that the resultant clean screen will be insensitive to a 6-percent higher flow rate.

The DCD-specified head loss limit of 1.7 kPa (0.25 psia) was derived from Sensitivity Case 3 of APP-PXS-GLR-001. In APP-PXS-GLR-001, Table 4-1, the containment recirculation screen flow was modeled by the PXS A flow at a temperature of 93.3 °C (200 °F), and the IRWST screen flow was modeled by the PXS B flow at a temperature of 60.6 °C (141 °F). The calculated head loss for the containment recirculation screen was [ ] at a flow rate over the frontal area of [ ], and the calculated head loss for the IRWST screen was [ ] at a flow rate over the frontal area of [ ]. The long-term cooling analysis modeled the pressure drop as proportional to the value of flow squared. Applying this relationship at the minimum test flow from Test WE213-4W gave a pressure drop limit of [ ] at the containment recirculation screen and [ ] at the IRWST screen. The test plan conservatively set the head loss limit to 1.7 kPa (0.25 psia) at all flow rates, which is more restrictive than the calculated value for either screen. The head loss measured throughout the test was negligible, which demonstrates additional margin.

The flume water level was set about [ ] above the top of the screen, bounding both the containment recirculation screens, which have several feet of submergence, and the IRWST screens, which have a minimum submergence of 7.1 cm (2.8 in). As stated in Section 7.3 of WCAP-16914-P, no vortex formation or air entrainment into the screens was observed during any of the testing. [ ]. This experiment is considered bounding as the current design demonstrates a clean screen. The relatively small submergence of the IRWST screens could lead to concerns regarding flashing and deaeration if the pressure drop across the screen approached the head loss limit. However, because the testing demonstrated a clean screen and no vortexing was seen, even during the flow sweeps that encompass RNS operation, there is no concern of voiding or potential entrainment of vapor if potentially saturated liquid passes through the screens. There is also no concern that additional water could be held up in the IRWST as the water level drops below the screen during the wall-to-wall flooding case described in DCD Section 15.6.5.4C.3.

6.2.1.8.2.9 Downstream Effects—In Vessel

During the post-LOCA containment recirculation long-term core cooling phase, the containment debris and chemicals enter the reactor vessel, causing potential core flow blockage, boron precipitation, and plateout of chemical precipitates on the fuel cladding, resulting in degradation of core heat transfer. Section 6 of TR-26, presents an in-vessel evaluation, which assesses the impact of debris in the post-LOCA recirculating water on components inside of the reactor vessel, including the core inlet and fuel assemblies.

The effects of debris in the post-LOCA recirculating water flowing through the fuel assemblies were evaluated through the long-term cooling sensitivity analysis and the fuel assembly head loss testing, as discussed in Section 6.2.1.8.2.7 of this SE. This section provides an evaluation of the effect of potential chemical deposition and scale buildup on the fuel rods on maintaining effective heat transfer from the fuel rods to the coolant.

During post-LOCA long-term cooling, the AP1000 PXS design uses ADS-4 valves connected to the HLs to vent steam and a considerable amount of water from the RCS. The water that leaves through the ADS-4 valves carries boron and other chemicals out of the RCS, which automatically and effectively limits the buildup of these chemicals in the core. Therefore, boron precipitation in the reactor vessel is prevented by sufficient flow of PXS water through the ADS-4 valves to limit the increase in boron concentration of the water remaining in the reactor vessel. DCD Section 15.6.5.4C.4 describes an evaluation of post-LOCA long-term core cooling, as well as core boron concentration and boron precipitation. The analysis results indicated that the ADS-4 venting quality at the initiation of recirculation is about 50 percent and decreases to less than 10 percent at the time of wall-to-wall flooding. At the maximum vent quality, the maximum boron concentration peaks at about 7,400 ppm at the time of recirculation initiation. After this time, the core boron concentration decreases as the ADS-4 vent quality decreases, reaching 5,000 ppm about 9 hours after the accident. The maximum boron solubility temperature is 14.4 °C (58 °F) at 7,400 ppm, which is virtually unattainable in the reactor vessel or the ADS-4 vent pipe. For the containment floodup case, the minimum sump injection head is adequate to maintain core cooling and limit boron concentration. The results show that venting of steam and water ensures that there is adequate liquid flow through the core to cool it and to prevent boron precipitation. Section 15.2.7 of NUREG-1793 discussed the staff's evaluation of the boron precipitation and concluded that: (1) the core remains cooled for the duration of the long-term cooling phase; (2) the boron concentration in the core keeps the core noncritical; and (3) boron precipitation will not occur to obstruct core coolant flow.

However, the long-term cooling analysis presented in the DCD was performed without consideration of containment debris. Because of the flow conditions of the core where there is a significant blockage at the core inlet created by unfiltered debris through the break, The applicant performed a long-term core cooling sensitivity study to evaluate the effects of core inlet blockage. This sensitivity study is described in APP-PXS-GLR-001, Revision 4.

The AP1000 long-term cooling sensitivity study results show that as the core inlet flow resistance increases, the core flow rate decreases, the quality of flow discharged through ADS-4 valves increases, and the boric acid concentration increases. For Sensitivity Case 10, which has the highest core inlet flow resistance, the core flow rate is predicted to be 65 lbm/s with a bounding pressure drop of 4.1 psid, the ADS-4 discharge flow quality is 0.49, and the maximum concentration of boron is 6,100 ppm in the core. This is less than the maximum concentration of 7,400 ppm in the DCD evaluation. Therefore, there is no concern with precipitation in the lower plenum during long-term cooling following a LOCA since the reactor water is not cooled to temperatures lower than the corresponding boron solubility temperature during long-term cooling.

In RAI-SRP6.2.2-SRSB-26, the staff asked if there were any situations where two-phase flow behavior could challenge the single-phase fuel assembly debris-induced head loss test results, and whether a different liquid temperature or local boiling phenomenon affects the behavior of the debris plugging the core. In partial response to RAI-SRP6.2.2-SRSB-26, the applicant provided TR APP-GW-GLR-110, Revision 0, which provides an evaluation of the potential for plateout of unbuffered boric acid or buffered boric acid on the fuel rod surface. The applicant addressed the effect of boron plateout on the core for high steam qualities in the core region that may occur during a significant core inlet blockage by debris. The applicant had previously conducted a series of single-rod bench-scale tests to investigate the nucleate boiling heat transfer characteristics of unbuffered and buffered boric acid solutions. These tests included concentrations of boric acid and buffer agent TSP that were equal to and greater than those concentrations that will occur in the AP1000 following a LOCA. The applicant also reviewed additional PWR heated rod testing in the presence of boric acid solution with decay heat level heat input and low pressure for application to the AP1000. These additional heated rod tests included rod-bundle geometries (Tuunanen, J., et al., "Experimental and Analytical Studies of Boric Acid Concentrations in a VVER-440 Reactor during the Long-Term Cooling Period of Loss of Coolant Accidents," *Nuclear Engineering and Design*, issued 1994) and multirod full-height slab core geometry (W3F1-2005-0007, "Supplement to Amendment Request NPF-38-249, Extended Power Uprate," dated February 5, 2005). These more prototypical geometries of the multirod and rod bundle test displayed precipitation behavior in the heated rod region that was consistent with the single heated rod testing for unbuffered boric acid and boric acid buffered with TSP. These tests generally showed no bulk precipitation in the heated rod region of the core and some local precipitation in the boiling region if the core would become uncovered. The form of boric acid precipitation is usually amorphous and can be redissolved in the presence of a continuous liquid phase. Therefore, the applicant does not expect the deposition of boric acid or boric acid buffered with TSP to occur during post-LOCA conditions in the AP1000 since the heated core region has been shown to be covered at all times by a two-phase mixture.

For the AP1000 design, the boron concentration calculated for the limiting long-term cooling Sensitivity Case 10 is only 6,100 ppm, which has a corresponding low solubility temperature that is not attainable during the long-term core cooling period. Since the available test data demonstrate that, if the boron precipitation occurs at high boron concentration, boron precipitation on the fuel is generally amorphous and would be redissolved in the presence of continuous liquid phase, the staff agrees that potential boric acid solute plateout on the fuel cladding is not likely, and boron precipitation is not a concern for the AP1000 design.

To address the concern that post-LOCA containment debris and chemical precipitates can plate out on fuel rod cladding and impede the heat removal from the fuel rods, The applicant evaluated the impact of post-LOCA deposition of chemical precipitates on fuel rods for the AP1000 design. The source of chemical products is the interaction of the fluid inventory in the post-LOCA containment sump environment with debris and other materials exposed to and submerged in the sump fluid. The purpose of the evaluation is to predict a maximum scale thickness of the resulting cladding deposit buildup and the maximum clad/oxide interface temperature resulting from the deposits during the post-LOCA recirculation long-term core cooling phase.

The evaluation, described in Section 6.2.2 of TR-26, Revision 8, uses the Loss-of-Coolant Accident Deposition Model (LOCADM). LOCADM is a spreadsheet calculation tool developed by the PWR Owners Group to conservatively predict chemical interaction precipitate formation and buildup of chemical deposits on fuel cladding after a LOCA. The details of the LOCADM analysis model appear in Section 7 and Appendix E of WCAP-16793-NP, “Evaluation of Long-Term Cooling Considering Particulate, Fibrous and Chemical Debris in the Recirculating Fluid,” Revision 1, issued April 2009.

WCAP-16793-NP, Revision 1, also proposes the following two acceptance criteria for the post-LOCA evaluation of the chemical deposition on the fuel rods, which the staff accepted for GSI-191 consideration:

(1) The maximum cladding temperature during recirculation from the containment sump will not exceed 426.7 °C (800 °F).

(2) The thickness of the deposition of debris, chemical precipitates, or both on the cladding (oxide + crud + precipitate) will not exceed 50 mils (1270 Micrometer (μm)).

<u>Evaluation of the LOCADM Analysis Model</u>

LOCADM predicts both the deposit thickness and cladding surface temperature as a function of time at a number of core locations. Although the LOCADM analysis model is described in WCAP-16793-NP, Revision 1, there is a link to WCAP-16530-NP-A since the chemical model contained in TR WCAP-16530-NP-A is used to develop the potential source term of species that may enter the reactor vessel. WCAP-16530-NP-A provides a method for evaluating plant-specific chemical effects in a post-LOCA environment, including guidance for how to prepare surrogate chemical precipitates that may be used in strainer head loss tests. The staff reviewed and approved WCAP-16530-NP. WCAP-16530-NP-A, however, does not explicitly address potential chemical effects that may occur in the reactor vessel. WCAP-16793-NP, Revision 1, evaluates potential chemical effects that may occur downstream of the sump strainer in the reactor vessel. The materials tested in WCAP-16530-NP included:

1. commercially pure aluminum and galvanized steel,
2. calcium silicate (Cal-Sil) insulation,
3. NUKON™ fiberglass,
4. other fiberglass - Temp Mat™,
5. Interam™ E-class insulation,
6. powdered concrete,
7. mineral wool insulation,
8. microporous insulation (e.g., Min-K™), and
9. fire-retardant material (e.g., FiberFrax™).

WCAP-16530-NP describes a number of dissolution tests conducted to examine the chemical behavior of various materials found in the sump environment. Sampling times for the dissolution test were set at 30 minutes, 60 minutes, and 90 minutes. The results of the WCAP-16530 test program are consistent with previous work such as the integrated chemical effect test (ICET) program and show that:

1) The predominant materials leached from containment materials are:

    - aluminum ions
    - silicates
    - calcium ions

2) The predominant chemical precipitates formed are:

    - aluminum (oxy) hydroxide
    - sodium aluminum silicate
    - calcium phosphate (for plants using TSP for pH control)

It is possible that other silicate materials may be generated (e.g., calcium aluminum silicate or zinc silicate), but their contribution, based on the referenced studies, will be small (contributing less than 5 percent of the total mass) relative to the predominant precipitates.

The WCAP-16530-NP model considers the release rates of aluminum, calcium and silicate, as these provide the greatest masses of materials that can become insoluble and impacts of other materials are negligible. Given a source term of material from the WCAP-16530-NP model, the staff reviewed the methodology used to determine that these materials:

1. Would not deposit on fuel surfaces to the extent that heat transfer is unacceptably low, and

2. Would not block flow through the fuel channels should the scale materials deposited become dislodged by spalling during fuel cool down.

In evaluating the potential for plate-out of dissolved or suspended chemical compounds on the fuel surface, the WCAP-16793-NP methodology assumes that all of the dissolved species and compounds resulting from the WCAP-16530-NP assessment are transported through the containment sump screen to the reactor vessel. This material represents the source term in WCAP-16793-NP for evaluating plate-out of scale-forming materials on the fuel cladding. The staff finds this source term assumption to be acceptable since the chemical source term is based on WCAP-16530-NP testing, and it is conservative for the reactor vessel fuel analysis to assume that no precipitate settles on the containment floor, no precipitate becomes trapped in a filtering debris bed covering the sump strainer, and material does not deposit in other locations downstream of the strainer (e.g., heat exchangers, reactor vessel lower plenum).

Although the staff finds the use of the chemical model spreadsheet in WCAP-16530-NP to be acceptable for determining the chemical source term for LOCADM, a limitation and condition was provided in the safety evaluation for WCAP-16530-NP related to the aluminum release rate. The WCAP-16530-NP chemical model aluminum release rate is based, in part, on a fit to ICET data using an averaged 30-day release. Actual corrosion of aluminum coupons during the ICET test appeared to occur in two stages; active corrosion for the first half of the test followed by passivation of the aluminum during the second half of the test. Therefore, while the 30-day fit to the ICET data is reasonable, the WCAP-16530-NP model under-predicts aluminum release by about a factor of 2 during the active corrosion part of ICET 1. This is important since the in-core LOCADM chemical deposition rates can be much greater during the initial period following a LOCA, if local conditions predict boiling. To account for potentially greater amounts of aluminum during the initial days following a LOCA, a user's LOCADM input shall apply a 2x increase to the WCAP-16530 spreadsheet predicted aluminum release, not to exceed the total amount of aluminum predicted by the WCAP-16530-NP spreadsheet for 30 days. In other words, the total amount of aluminum released equals that predicted by the WCAP-16530-NP spreadsheet, but the timing of the release is accelerated. Alternately, users may choose to use a different method for determining aluminum release, but users shall not use an aluminum release rate equation that under-predicts the aluminum concentrations measured during the initial 15 days of ICET 1. If a user uses plant-specific refinements to reduce the chemical source term calculated by the WCAP-16530-NP base model, the user shall provide technical justification demonstrating that the refined chemical source term adequately bounds the postulated plant chemical product generation.

WCAP-16793-NP uses various heat transfer computer programs [ANSYS Mechanical Software and WCOBRA/TRAC WCAP-12945-P-A] and a commercially available calculational software package (MATHCAD) for estimating the effects of the plateout of dissolved materials on the increase in fuel clad temperature. WCAP-16793-NP relied on the LOCADM code for its final assessments since the LOCADM calculations address non-uniform chemical deposition due to variation of core power and boiling.

The starting assumption for the LOCADM model with respect to chemical effects is that all the dissolved and suspended chemicals pass through the containment sump screen and into the reactor core. This is a conservative assumption because it maximizes the amount of chemicals available to cause deleterious effects.

The LOCADM model also assumes that some of the fibrous material from destroyed insulation is not removed by the sump strainer and that this material also passes on to the reactor core area. The mass of fiber passing through the strainer is determined on a plant-specific basis, based on bypass testing. LOCADM assumes instantaneous chemical participation of this fiber. Therefore, the fiber bypass quantity is converted to a mass of fiberglass and then to an equivalent mass of elements [calcium + aluminum + silicon] that is immediately available to be deposited in the LOCADM analysis. This increase in the mass of dissolved chemicals is compared to the original mass of dissolved chemicals determined by the WCAP-16530-NP calculations [calcium + aluminum + silicon] and a percent increase is calculated. This increase is on the order of one to two percent, and is referred to as a “Bump-Up Factor.”

These two chemical sources are then used in the plant-specific application of LOCADM. Given the potential plant-specific chemical source term in the reactor vessel, LOCADM determines the amount of scale that deposits on the fuel over time and then calculates maximum fuel clad temperature. An assumption that is very important to the LOCADM calculations is the coefficient of thermal conductivity for the chemical deposits. In order to determine an appropriate thermal conductivity coefficient for the LOCADM calculations, two different thermodynamic equilibrium based codes were used to assess the chemical species that may form in the post-LOCA reactor vessel environment. The applicant performed an analysis using the HSC program by Outokomptu. This thermodynamic equilibrium code was used to evaluate potential differences in the predicted species and to support the choice of a limiting thermal conductivity value for a chemical deposit that may form on the fuel. Using the chemical species predicted by these thermodynamic equilibrium analyses, a lower-bound thermal conductivity value was selected for the LOCADM analysis in WCAP-16793-NP to minimize heat transfer and maximize the temperature rise on the fuel surfaces. A chemical deposit thermal conductivity value of 0.19 watts per meter-degree Celsius (W/m-ºC) (0.11 British thermal unit per foot-hour-degree Fahrenheit (BTU/ft-hr-°F)) was selected based on the possible formation of a postulated sodium aluminum silicate scale. A thermal conductivity value of 0.19 W/m-ºC (0.11 BTU/ft-hr-°F) is the minimum thermal conductivity value reported for sodium aluminum silicate scale. For comparison, the thermal conductivity of dry fiberglass insulation is approximately 8.65×10^{-2} W/m-ºC (0.05 BTU/ft-hr-°F), and, with eight percent of its mass wetted, it increases to approximately 0.173 W/m-ºC (0.1 BTU/ft-hr-°F). The staff questioned if there were any materials from the thermodynamic predictions for fuel clad surface deposits which could have lower thermal conductivity values. The applicant responded that 0.19 W/m-ºC (0.11 BTU/ft-hr-°F) was a bounding thermal conductivity value reported for any of the postulated species that could form a scale deposit on the fuel clad surface. Information provided by the applicant in RAI response number 34 [Schiffley, F. P., PWROG letter to Document Control Desk, NRC, “Response to the NRC for clarification to Requests for Additional Information (RAI) on WCAP-16793-NP,” showed thermal conductivity coefficients of representative calcium-based boiler scale deposits that were in the 0.52 to 0.865 W/m-ºC (0.3 to 0.5 BTU/ft-hr-°F) range, and the thermal conductivity of glass was reported as 1.02 W/m-ºC (0.59 BTU/ft-hr-°F).

Since the LOCADM calculations do not consider the presence of large debris, the staff questioned whether small pieces of insulation (“fines”) incorporated into a deposit could result in a lower thermal conductivity value than the 0.19 W/m-ºC (0.11 BTU/ft-hr-°F) assumed for a sodium aluminum silicate scale. The applicant responded that since core temperatures have decreased by the time the ECCS switches from injection to recirculation mode, which is the time when the first fibrous debris could bypass the sump screens and enter the core, the temperature of the core is insufficient to cause melting of the fiberglass or other fibrous material. Therefore, the presence of fiber fines would not create a different type of scale other than that predicted by the thermodynamic models. The applicant also responded that although dry fiberglass has a lower thermal conductivity than the 0.19 W/m-ºC (0.11 BTU/ft-hr-°F) assumed for the chemical deposit, a fiber deposit would be porous and would allow water to fill in the porosity. Since water has a much higher thermal conductivity than air, the overall thermal conductivity for a deposit containing fiberglass would be bounded by the assumed 0.19 W/m-ºC (0.11 BTU/ft-hr-°F) value. This reasoning is supported by literature [Joint Departments of the

Army and Air Force, USA, Technical Manual TM 5-852-51/AFR 88-19, Volume 5, Article Sub-Arctic Construction: Utilities, Chapter 12] that indicated the fiberglass thermal conductivity constant increases by a factor of two with an eight percent volume of water incorporated into its structure. This is also consistent with insulation manufacturer recommendations to change insulation if it is wetted since the heat conduction through the insulation increases; in other words, it is no longer an effective insulator.

Based on the above discussion, the staff finds that the 0.19 W/m-ºC (0.11 BTU/ft-hr-°F) thermal conductivity value assumed for deposition of scale and particulate represents an acceptably low value to help achieve a conservative prediction of fuel clad temperature increases due to chemical deposits. If plant-specific calculations use a less conservative thermal conductivity value for scale, i.e., greater than 0.19 W/m-ºC (0.11 BTU/ft-hr-°F), the staff expects the licensee to provide a technical justification for the plant-specific thermal conductivity to the staff. This justification should demonstrate why it is not possible to form a sodium aluminum silicate scale or other scales with conductivities below the selected plant value.

Given the potential chemical source term and using a conservative value for thermal conductivity, LOCADM calculates deposit growth over time. The default initial oxide and crud thicknesses assumed by LOCADM are based on the fuel age and the limiting values that have been measured at modern PWRs. Since the boiling deposition mechanism results in the most rapid deposit growth and forms the most tenacious deposits, LOCADM assumes that all deposition occurs through the boiling process if conditions at a core node predict any boiling. The amount of scale calculated to be deposited under boiling assumes that 50 percent of the water present at the clad surface boils and all solutes transported into the deposit by boiling are deposited locally, as liquid evaporates, at a rate proportional to the steaming rate. Subsequent plate-out of solids, once boiling subsides, is estimated from other literature sources (WCAP-16793-NP, Revision 1, RAI Set #2, RAI #8) to be 1/80th of the solids deposition rate during boiling based on the temperatures encountered at the fuel. Once formed, deposits are assumed not to thin by flow attrition, dissolution, or spalling. The sample LOCADM calculation in WCAP-16793-NP, Revision 1, included a 3188 megawatt-thermal PWR with high fiber (198 m^3 (7000 ft^3)) and a large quantity of calcium silicate insulation (2.27 m^3 (80 ft^3)). The staff questioned what additional effect the existing clad crud film and oxide scale (from three cycles) would have on the LOCADM calculations. The applicant responded that the sample LOCADM calculation, for the conditions stated above, including initial fuel clad oxide and crud, showed the maximum chemical scale thickness calculated over 30 days was 10 mils (0.010 in). The maximum clad surface temperature after the start of recirculation was 162.2 °C (324 °F), which meets the acceptance criteria of 426.7 °C (800 °F).

Since LOCADM does not directly account for fiber fines bypassing the sump screen, the staff also questioned how possible effects from fibers depositing in the core are assessed. Analysis of core inlet blockage is discussed elsewhere in this report, but modeling demonstrated that with 99 percent of the core flow blocked, sufficient cooling water would be provided as a result of boiling and back flow from above to prevent clad temperatures exceeding 426.7 °C (800 °F). To model potential local hot spots, heat transfer analysis was provided in Appendix D of WCAP-16793-NP, Revision 1, assuming heat transfer in the radial direction only (i.e., ignoring any axial heat transfer) and using a chemical scale thermal conductivity of 0.173 W/m-ºC (0.1 BTU/ft-hr-°F). These calculations showed that for a chemical scale thickness of 0.127 cm (50 mils or 0.050 in) that formed “instantaneously” at the start of recirculation, the maximum fuel clad surface temperature for a fuel rod diameter of 0.91 cm (0.36 in) is 293.3 °C (560 °F). Additional analyses were performed for larger diameter fuel rods, 1.06 cm (0.416 in) and 1.07 cm (0.422 in) OD rods. The predicted peak clad-oxide interface temperature was less than the acceptance basis value of 426.7 °C (800 °F) in each case. The staff finds this analysis to be acceptable since the assumptions of instantaneous chemical precipitate formation, heat transfer only in the horizontal plane (radial direction), and the assumed thermal conductivity for chemical scale are judged to be conservative for reasons stated in the WCAP.

The staff also questioned whether blockage of core flow channels might occur from scale initially deposited on the fuel surface that would flake off during the cool down process. The applicant responded that the thickness of the scale formed is limited by the amount of solids dissolved in the water. Using scale deposition models the applicant demonstrated that the thickest scale fragment would be insufficient to bridge a fuel rod to fuel rod span to block flow. The staff finds this justification acceptable because the spalling process from the fuel is slow, and experience from spent fuel pool debris generated at PWRs shows these scale materials to be granular and of small size rather than large flakes.

The staff reviewed the LOCADM analysis model as described in WCAP-16793-NP, Revision 1, and finds that:

1. The mass of material used to determine the debris and scale loading is conservative based on the source term calculated from the WCAP-16530-NP tests, along with the assumption that no precipitates settle on the containment floor, are filtered at the sump screen, or deposit in heat exchangers, piping, or in the reactor vessel outside of the core. The mass of materials includes a “bump up factor” to account for fibrous material that bypasses the sump screens. The staff finds this bump up factor to be acceptable for reasons stated in this SER section.

2. The thermal conductivity assumed for chemical scale and debris deposits represents an acceptably low value (0.19 W/m-ºC (0.11 BTU/ft-hr-°F) to help achieve a conservative prediction of fuel clad temperature increase. Wetted insulation allows for better conduction of heat and the thermal conductivity of wetted insulation would be higher. Thus the use of 0.19 W/m-ºC (0.11 BTU/ft-hr-°F) is a conservative assumption.

3. Industry-recognized calculation models were used to predict temperature increases at the fuel surface as a result of chemical plate-out, and these models confirm that the limit of 426.7 °C (800 °F) is not exceeded when these models are used in conjunction with the source term assumptions in WCAP-16530.

4. Blockage of fuel rod spans by spalled fuel scales is unlikely due to the time dependency for spalling and the small thickness of the scale compared to the space between the fuel rods.

Based on the above, the staff concludes that the LOCADM analysis model provides a valid approach to determining potential flow restrictions due to chemical effects of RCS liquid and containment debris and materials, and is both conservative and representative of the post-LOCA conditions based on chemical reactions described in WCAP-16530-NP. Therefore, given the acceptance criteria for fiber bypass, the staff concludes the chemical effects on core cooling resulting from debris and scale deposition following a LOCA are insufficient to create a condition resulting in fuel clad temperatures exceeding the temperature limit of 426.7 °C (800 °F). However, the acceptability of the application of the LOCADM analysis model is contingent upon the following conditions.

1. The aluminum release rate equation used in WCAP-16530-NP provides a reasonable fit to the total aluminum release for the 30-day ICET tests but under-predicts the aluminum concentrations during the initial active corrosion portion of the test. To provide more appropriate levels of aluminum for the LOCADM analysis in the initial days following a LOCA, users shall apply a factor of two to the aluminum release rate as determined by the WCAP-16530-NP spreadsheet. If a user chooses to use a different method for determining the aluminum release, it must demonstrate that the method does not under-predict the aluminum concentrations measured during the initial 15 days of ICET 1.

2. If plant-specific refinements are made to the LOCADM base model to reduce conservatisms, the user shall demonstrate that the results still adequately bound chemical product generation. If a user uses plant-specific refinements to the WCAP-16530-NP-A base model that reduces the chemical source term considered in the downstream analysis, the user shall provide a technical justification that demonstrates that the refined chemical source term adequately bounds chemical product generation. This will provide the basis that the reactor vessel deposition calculations are also bounding.

WCAP-16793-NP, Revision 1, states that the material with the highest insulating value that could deposit from post-LOCA coolant impurities would be sodium aluminum silicate. The WCAP recommends that a thermal conductivity of 0.19 W/m-ºC (0.11 BTU/ft-hr-°F) be used for the sodium aluminum silicate scale and for bounding calculations when there is uncertainty in the type of scale that may form.

To demonstrate acceptable AP1000 long-term core cooling performance, the applicant performed an evaluation using the LOCADM spreadsheet to account for chemical reactions within the coolant that could lead to deposition of material within the core. This evaluation was documented in Section 6.2.2 of TR-26 and Westinghouse calculation note APP-PXS-M3C-057, “Loss of Coolant Accident Deposition Model (LOCADM) Analysis for AP1000 Plant Design,” Revision 1, issued November 2009. The AP1000 LOCADM evaluation makes the following assumptions and simplifications:

- AP1000 Unique Design Features:

  In the AP1000 design, the containment spray system is locked out during a LOCA. Therefore, the containment spray is not considered in the calculation of the post-LOCA debris source release.

  The AP1000 plant design relies on the ADS-4 valves in the HL to vent significant quantities of water along with steam from the core to the containment throughout the LOCA event. This behavior is modeled in the LOCADM spreadsheet by defining core injection flow rates that exceeded the boiloff rate by an amount calculated with the decay heat.

- Treatment of Aluminum:

  Although the AP1000 design precludes a large amount of aluminum from making contact with post-LOCA containment fluids, a mass of 27.2 kg (60 lb) of aluminum is assumed for conservatism. The aluminum surface area is increased to account for the zinc release from galvanized steel, which is not an input for LOCADM. Increasing the aluminum surface area is conservative because the aluminum release rate is greater than that of any other material used in this evaluation.

The aluminum release rate is modified to satisfy NRC concerns about the trend of the predicted aluminum corrosion, by doubling the release rate during the initial portion of the event, yet it holds fixed the total aluminum mass release. This is consistent with the condition of WCAP-16530-NP. It is important because the release rate of aluminum is increased early in the transient when the deposition on the fuel is greatest because of high core decay heat rates and the boiling associated with the removal of that decay heat.

- Use of the Prefilled Reactor and Sump Option

  The LOCADM analysis assumes that the entire sump volume is present in the sump at time 0, precluding the need to specify individual break flow rates. This is conservative, as the entire sump volume is immediately available to react with the submerged debris at the start of the transient, and provides for the calculation of a greater amount of chemical precipitate deposition on the fuel.

- Core deposition is assumed to begin at the start of recirculation (9,300 seconds) and continue for the 30 days evaluated.

- Use of the Bump-Up Factor To Account for Fibrous Debris

  The bump-up factor used in LOCADM accounts for the postulated bypass of latent fibrous debris by increasing the mass of chemical precipitates that may be deposited on the fuel. To implement the bump-up factor in LOCADM, all materials that contribute to the formation of chemical precipitates are increased by a uniform percentage so that the resulting precipitates available for deposition have increased by approximately the amount of latent fibrous debris assumed for the AP1000. This method is independent of the type, diameter, or length of the fiber.

  The bump-up factor as applied to the AP1000 LOCADM evaluation is conservative because it is calculated (in APP-PXS-M3C-053, "AP1000 Latent Debris Calculation," Revision 2, issued November 2009) based on a fibrous debris loading of [ ]. This is the same debris loading used in the ex-vessel downstream effects analysis to evaluate the effects of debris in the recirculating water on pumps, valves, and other components in the post-LOCA recirculation flowpaths. This value is much higher than the design-basis containment residual fiber debris value of 3.0 kg (6.6 lb) and 90 percent transport to the reactor vessel. There are other conservatisms as discussed in TR-26, such as the low value of thermal conductivity (0.19 W/m-ºC (0.11 BTU/ft-hr-°F) assumed in LOCADM for the scale buildup on the fuel rods when considering the latent fiber as part of the fuel rod post-LOCA scale.

  TR-26 indicates that the thermal conductivity of manmade fibers such as nylon and polyester (0.249 and 0.225 W/m-ºC (0.144 and 0.13 BTU/ft-hr-°F) are higher than the assumed thermal conductivity for the scale. The thermal conductivity of natural fiber, such as cotton (3.46E-2 W/m-ºC (0.02 BTU/ft-hr-°F) may be lower, but it will increase significantly when saturated with water, as is the case in a post-LOCA environment. The thermal conductivity of these saturated fibers rises significantly, trending towards the value of water at the ambient conditions saturating the fibrous material (~0.69 W/m-ºC

(0.40 BTU/ft-hr-°F), which is much higher than the heat conductivity used for the chemical scale in the LOCADM evaluation.

TR-26 presented three scenarios evaluated with the LOCADM spreadsheet for the AP1000 design: (1) minimum sump volume case; (2) maximum sump volume case; and (3) minimum sump volume case with a bump-up factor for fiber deposition. The detailed evaluation described in Westinghouse calculation note APP-PXS-M3C-057, Revision 1, includes more sensitivity cases. The results of sensitivity analysis indicate that the minimum sump water volume results in a higher concentration of AP1000 accident chemical products and is therefore more limiting for the chemical deposition evaluation. All three cases described in TR-26 include the doubling of the aluminum release rate as recommended by WCAP-16793, Revision 1. The results show the post-LOCA scale thicknesses of [ ], respectively, for the three cases. With the preaccident oxide thickness of 0.15 mm (5.98 mils) and a crud thickness of 0.14 mm (5.51 mils), the total deposition thicknesses are [ ], respectively. These predicted thicknesses are significantly below the acceptance criterion of 1.27 mm (50 mils). The maximum temperature calculated for the outside diameter of the fuel cladding (at the fuel/oxide interface) is [ ] for all three cases, which is much less than the acceptance value of 426.7 °C (800 °F). This peak cladding temperature occurs at the onset of recirculation before significant debris deposition on the fuel cladding occurs. The chemical deposition appears to have an insignificant effect on the peak cladding temperature because the decay heat is decreasing faster than the chemical deposition rate.

In summary, the LOCADM calculations performed for the AP1000 demonstrate that both acceptance criteria for long-term core cooling identified previously in this report are achieved with significant margin. Specifically, the following is true for the cases evaluated:

- The maximum clad temperature calculated for the AP1000 of [ ] is significantly less than the acceptance value of 426.7 °C (800 °F).

- The total thickness of deposition calculated for the AP1000 fuel cladding is significantly less than the acceptance value for thickness of 0.127 cm (50 mils).

Therefore, the staff concludes that the AP1000 long-term core cooling capability remains viable in the presence of chemical deposition on the fuel cladding.

6.2.1.8.2.10 Debris Source Term

This section evaluates how the plant demonstrates and controls the debris source term. For the AP1000, this includes ITAAC, COL items, and technical specification (TS) surveillance requirements.

ITAAC related to the debris source term are included in DCD Tier 1, Table 2.2.3-4, as part of the 8c) design commitment that the PCS provide safety injection during design-basis events. ITAAC Item ix) verifies by inspection that insulation inside containment within the ZOI is MRI or that a report exists demonstrating that it is a suitable equivalent insulation. ITAAC Item ix) also verifies by inspection that other insulation inside the containment below the maximum DBA flood level is MRI, jacketed fiberglass, or a suitable equivalent insulation. Item x) verifies by inspection that reports exist concluding that tags and signs inside containment that are not inside cabinets or other enclosures have a density greater than or equal to 1.6 g/cm^3 (100 lbm/ft^3) and that ventilation filters and fiber barriers inside containment within the ZOI or below the maximum DBA flood level have a density greater or equal to 1.6 g/cm^3 (100 lbm/ft^3).

The staff finds these ITAAC acceptable because they capture key assumptions made in the long-term cooling analysis regarding debris transport and the amount of fibrous debris and because DCD Tier 2, Section 6.3.2.2.7.1, clearly defines the ZOI, the maximum DBA flood level, and the requirements for a suitably equivalent insulation.

COL Information Item 6.3-1 requires applicants referencing the AP1000 design to develop a cleanliness program that limits the debris left inside the containment following refueling and maintenance outages. Specifically, the amount of latent debris located within the containment must be less than 59.0 kg (130 lb) total latent debris, of which up to 3.0 kg (6.6 lb) is fibrous, and any outage materials stored inside the containment must not produce physical or chemical debris that could be transported to any of the filtering locations. The staff finds this acceptable because it is consistent with the recommendations in RG 1.82, Section C.1.1.2.1, which states that plant procedures should be established to regularly clean the containment and to control and remove foreign materials, and Section C.1.3.2.5, which states that the cleanliness program should be correlated to the amount of debris used in the long-term cooling analysis.

TS Surveillance Requirement 3.5.6.8 requires visual inspection of the IRWST and recirculation screens every 24 months to ensure that they are not restricted by debris. TS Surveillance Requirement 3.5.4.7 requires a similar 24-month inspection of the IRWST gutters. This is consistent with the long-term cooling analysis, which assumes the screens are clean before the LOCA.

6.2.1.8.2.11 Screen Design

ITAAC related to the screen design are included in DCD Tier 1, Table 2.2-3-4, as part of the 8c) design commitment that the PCS provide safety injection during design-basis events. Items vii) and viii) verify by inspection the key design features of the debris screens and barriers, including the existence of plates and debris curbs for the containment recirculation screen and the raised elevation of the IRWST screens. The screen frontal areas, surface areas, and mesh hole sizes are also verified to meet specific design criteria. Because these criteria are consistent with the head loss testing, they demonstrate that the as-built design will perform as expected.

Regulatory Position C.1.1.1.2 of RG 1.82, Revision 3 states that to the extent practical, the sumps should be physically separated from each other and from high energy piping systems by structural barriers to preclude damage by whipping pipes or high velocity jets of water or steam.

While there is physical separation between the IRWST screens, the applicant states that it was necessary to position the containment recirculation screens next to each other due to the location of the PXS subcompartment and the large size of the screens. To address pipe rupture and jet impingement vulnerabilities, the applicant has committed to demonstrate that the containment recirculation screens are protected by pipe whip restraints from the dynamic effects of pipe breaks in DCD Tier 2 Section 3.6.4.1 and DCD Tier 1 Table 3.3-6, Item 8). The staff finds that these restraints will protect the containment recirculation screens such that there are no credible pipe ruptures or jet impingement scenarios capable of causing screen failure. Therefore, this design meets the requirements of GDC 35.

Regulatory Position C.1.1.1.1 of RG 1.82, Revision 3 states that a minimum of two sumps should be provided, each with sufficient capacity to serve one of the redundant emergency core cooling lines. In the AP1000 design, while each PXS subsystem is associated with its own containment recirculation screen, the screens are cross connected. Likewise, each PXS subsystem is associated with its own IRWST screen, which is cross connected to a third IRWST screen. Therefore, if one PXS subsystem does not draw water both containment recirculation screens or all three IRWST screens, will be available to support the functioning subsystem. The NRC recommended providing two sumps to establish clear compliance with GDC 35, which requires long-term mitigation capability of a loss of coolant accident assuming a single failure. However, because the screens are either protected by pipe whip restraints (containment recirculation screens) or not identified as essential targets for the dynamic effects of pipe breaks (IRWST screens), and because the screens and their anchorage are designed to withstand seismic loads and postaccident operating loads, including head loss and debris weight, the staff finds there is no credible chance of failure of the screens, and the design meets the requirements of GDC 35.

NUREG-1793, Section 3.9.3, includes an evaluation of the structural adequacy of the sump screens using guidance from RG 1.82.

6.2.1.8.2.12 Upstream Effects

Any potential effects that debris may have in transit from its source to either the IRWST screens or containment recirculation screens are termed “upstream effects.” An evaluation of upstream effects ensures that flow necessary for recirculation is not held up by debris blockage at drains or other narrow pathways.

The applicant discussed upstream effects in its September 22, 2009, response to RAI-SRP6.2.2-SPCV-23. For ADS-4 discharge and break locations in the loop compartment, the limiting flowpath is the 2.3 m (7.5 ft) wide corridor between loop compartments, which is large enough to preclude debris blockage. For break locations at the maintenance floor elevation, three open stairwells will preferentially drain the break discharge to the sump. Curbs around openings of the two PXS rooms and the CVS room prevent water from entering these rooms. There are no LOCA break locations inside the CVS room, but such locations are present in the PXS room. If a break occurs in the PXS room, the room will fill and overflow onto the maintenance floor elevation, where the water will drain to the sump through the open stairwells. Breaks in the pressurizer line will either flow to the refueling cavity or to the IRWST, while a break in the passive residual heat removal heat exchanger tube will flow to the IRWST. Initially, water in the refueling cavity will drain to the containment sump, but this gravity-driven drain will cease when the water level in the sump increases enough to close the check valves on this line. An increase to the level of water in the IRWST could overflow into the refueling cavity, which will then drain to the containment sump as previously described.

For the AP1000, the potentially significant choke points for flow holdup are the gravity-driven drain lines and check valves in flowpaths between containment compartments. These drain lines and check valves are those in the refueling cavity drain lines, the PXS-A drain line, the PXS-B drain line, and the CVS compartment drain line. If recirculation water flow is restricted by any of these lines or valves, excessive amounts of water may be held up in the compartments and cavities, and the floodup level in the containment, which affects the gravity-driven core cooling flow, could be adversely affected. The staff asked about the issue in RAI-SRP6.2.2-SPCV-27 and RAI-SRP6.2.2-CIB1-31, and the applicant responded in letters dated January 29, 2010, and June 30, 2010. In these responses, the applicant stated that absent a LOCA in the PXS-A, PXS-B, and CVS rooms, there is no forward flow to transport debris to the lines that would prevent closure of the check valves. The staff verified that these valves are periodically stroke tested to ensure that the valves are capable of adequately reseating. The staff finds this acceptable because no debris would exist in these drain lines. Other sources of leakage into the rooms, such as through cracks in the wall, were determined to be insignificant. If an LOCA occurs in one of the PXS rooms (there are no break locations in the CVS room), the room would flood and debris could enter the drain lines. However, in this event the valves do not have to function, because the long-term cooling analysis includes cases that model a lower flood level to specifically account for water holdup resulting from a break in the PXS room. Even though the check valves in the drain lines are not expected to leak any significant amount, the applicant's wall-to-wall flooding analysis assumes that each line leaks 26.5 liters per minute (Lpm) (7 gpm). The staff finds that this is a conservative assessment.

For the refueling cavity drain lines, the check valves may be required to reclose after initially flowing forward following an LOCA and the water in the cavity may contain some debris. The applicant stated that the debris would not excessively erode or plug the valve, because the debris is a limited amount of latent and MRI debris and there is time for significant amounts to settle out. The applicant also stated that the debris could include some MRI fine particles that could pass through the downward-turned elbow drain line inlet and that this debris would not likely collect in the check valves. The staff finds that this is acceptable, because very little of the debris in the refueling cavity would pass into the drain lines and valves and would not significantly impede necessary drainage.

To address the issue of reclosure of these check valves after a period of initially flowing forward with debris in the lines, the applicant performed an analysis demonstrating that adequate long-term cooling was available even with a relatively large back leakage through this line. The analysis included an evaluation of Sensitivity Cases 3 and 10 from APP-PXS-GLR-001, which demonstrated that the margin in the original analysis, coupled with the long time required for the containment sump to leak through the check valve into the reactor cavity, was more than sufficient to remove the decay heat. The staff finds that the assumed leakage for this analysis is acceptable because the valves will be periodically stroke-tested to ensure that they acceptably reseat before debris conditions occur, and because the extent to which each closed check valve would have to be held open for this leakage to occur is significantly greater than what would be expected for these debris conditions. The staff reviewed the supporting calculation notes during its June 1 audit of APP-PXS-M3C-012, Revision 1, "Post-LOCA Refueling Canal Drain Check Valve Leak Evaluation," dated May 2010. The staff found the assumptions used to calculate flood levels, decay heat, and reduced core flow to be appropriate and conservative, and the staff agrees that the analysis demonstrates adequate core cooling flow with the assumed leakage.

The only potential choke point for flow to the IRWST is at the IRWST gutter, which extends around the entire containment circumference and drains to the IRWST through two 10-cm (4 in) pipes. Although there is a rough screen on top of the gutter to prevent large debris from entering, even if both discharge pipes become clogged, the only holdup volume will be water inside the gutter. This is because any excess water will spill over to the containment sump and recirculate through the containment recirculation screens. The applicant stated in its May 13, 2009, response to RAI-SRP6.2.2-SPCV-18 that the gutter volume is 0.96 m^3 (34 ft^3), corresponding to an IRWST water level change of 0.5 cm (0.2 in), which the staff finds is insignificant with respect to the recirculated volume.

In conclusion, the staff finds the applicant's evaluation of upstream effects acceptable.

6.2.1.8.2.13 Ex-Vessel Downstream Effects

In Section 6.2 of the AP1000 DCD, the applicant described the potential effects of sump debris on containment and core cooling, including the ex-vessel downstream effects. The term "downstream effects" refers to the effects of debris that passes through the recirculation screens on systems, structures and components located downstream of the recirculation screens. These effects have been evaluated for operating plants using data and methods developed by the PWR Owners Group. For the AP1000 plant, the applicant performed both an ex-vessel and an in-vessel evaluation for the AP1000 downstream effects. The ex-vessel evaluation describes the effects of debris on the system and components outside the core. This evaluation looks specifically at the disruption of the long-term core cooling flowpath (outside the core) by debris. Section 6.2.1.8.2.9 of this report addresses the staff's evaluation of in-vessel downstream effects (inside the core) for the AP1000.

The staff reviewed several documents, including information provided in the DCD and Westinghouse topical reports, TRs, and other letter reports related to the AP1000 design. Additionally, in an SER dated December 20, 2007, for ANSI/ANS-51.1-1983, "Nuclear Safety Criteria for the Design of Stationary Pressurized Water Reactor Plants," issued 1983, the NRC evaluated the methodology in WCAP-16406-P, Revision 1, for addressing downstream effects (both in-vessel and ex-vessel) of debris on the performance of containment and core cooling systems in existing U.S. PWRs. TR-26 addresses the applicability of WCAP-16406-P, Revision 1, to potential ex-vessel downstream effects for the AP1000 design.

As stated in TR-26, the data and methods used by the applicant to evaluate ex-vessel downstream effects are outlined in Revision 1 of WCAP-16406-P. The applicant stated that the evaluation methods identified in WCAP-16406-P, Revision 1, that are applicable to ex-vessel long-term core cooling recirculation flowpaths associated with the AP1000 design include valve evaluations for plugging and erosive wear, as described in Sections 7 and 8 and Appendix F of WCAP-16406-P, Revision 1. The screening criteria for valves that are identified in Revision 1 to WCAP-16406-P are applicable to valves in the long-term core cooling recirculation flowpath of PWRs. The applicant stated that only the explosively actuated (squib) valves in the post-LOCA flowpath are not covered by the screening criteria, but that once the squib valves are open, they very closely exhibit the characteristics of a standard gate valve.

The applicant stated that the AP1000 has design features that eliminate the need for downstream effects evaluations of components that are included in Revision 1 of WCAP-16406-P. Those evaluations excluded in the applicant's evaluation of the AP1000 design and the bases for their exclusion are as follows:

- Pump evaluations, including hydraulic performance, disaster bushing performance, and vibration analysis. Because of its passive design features, there are no safety-related pumps in the AP1000 passive core cooling flowpaths to evaluate.

- Heat exchanger evaluations for both plugging and erosive wear. There are no safety-related heat exchangers in the AP1000 passive core cooling flowpaths.

- Orifice evaluations for plugging and erosive wear as described in Sections 7 and 8 and Appendix F of WCAP-16406, Revision 1. There are no orifices in the post-LOCA recirculation flowpath of the AP1000 design.

- Settling of debris in instrumentation lines as described in Section 8 of WCAP-16406, Revision 1. There are no instrumentation lines used in the AP1000 post-LOCA containment recirculation flowpath design that are required to support a safety-related function; they are therefore excluded from consideration.

- Containment spray system. The AP1000 does not have a conventional containment spray system. The nonsafety containment spray function is not permitted to be used during a DBA and is therefore excluded from consideration for the AP1000 design.

As documented in TR-26, use of the applicable methods and models in WCAP-16406-P, Revision 1, consistent with the applicable amendments, limits, and conditions of the associated NRC safety evaluation on WCAP-16406-P, demonstrates that the AP1000 PXS equipment used in post-LOCA recirculation is acceptable for the expected debris loading in the recirculating fluid resulting from a postulated LOCA.

The staff finds that the applicant's evaluation of the ex-vessel downstream effects for the AP1000 design addressed the piping and valves in the recirculation path of the PXS. The methodology and acceptance criteria used are described in WCAP-16406-P, Revision 1, and are consistent with the applicable amendments, limits, and conditions of the NRC safety evaluation for WCAP-16406-P, Revision 1, and are, therefore, acceptable to the staff.

The applicant identified equipment in the post-LOCA flowpath using current piping and instrumentation diagrams (P&IDs) for the AP1000 PXS. The AP1000 PXS P&IDs show no pumps, heat exchangers, orifices, and spray nozzles in the PXS. Therefore, although included in the method of WCAP-16406-P, Revision 1, the applicant’s evaluation of the AP1000 PXS does not address pumps, heat exchangers, orifices, spray nozzles, and instrumentation tubing because these components and features are not included in the design of the AP1000 PXS. The applicant listed and described components that are in the AP1000 long-term core cooling flowpath, including both the containment recirculation flowpath and the IRWST injection flowpath.

The downstream path evaluation includes the effects of erosion and wear of the component materials and plugging of the various components. In order to apply erosive and abrasive wear rate models, the debris size and concentration were first assessed. The applicant evaluated the debris types and stated that the debris was composed of latent fibrous and particulate material, with a small amount of coatings debris. In RAI-SRP6.2.2-CIB1-07, the staff raised questions regarding: (1) the results of the applicant’s evaluation of the piping system for plugging and wear; (2) the composition of possible debris other than the evaluated latent and coatings debris; and (3) the effects the composition may have on the downstream flowpath. In a response dated November 11, 2008, the applicant clarified that there is no other debris that would be transported to the recirculation screens. The staff finds that the applicant’s assumed composition of latent and coating debris for the ex-vessel downstream evaluation is consistent with the debris generated from coatings and the chemical effects evaluated by the staff for the AP1000.

Each identified valve in the PXS was evaluated for plugging and wear against the applicable initial screening criteria in WCAP-16406-P, Revision 1. The PXS consists of open gate, check, and squib valves, all of which are greater than 2.54 cm (1 in) based on their individual flow line diameters. Therefore, according to the initial screening criteria, the valves do not need further evaluation for plugging or wear. However, the criterion to be greater than 2.54 cm (1 in) is based on the assumption that only debris of a certain size will pass through the containment recirculation screen because of the size of its holes. For a limiting direct-vessel-injection-line-break LOCA in the AP1000 design, the water level in the containment permits direct entry of debris-laden water into the DVI line at the break location. This could result in a significantly higher concentration of debris and larger pieces of debris entering into the core cooling flowpath than if all cooling water first passed through the screen. Therefore, in RAI-SRP6.2.2-CIB1-08, the staff asked about the assumed concentration and composition of debris for the DVI-line-break LOCA.

In a response dated November 6, 2008, the applicant stated that the only ex-vessel components that would see unfiltered containment water during a DVI line break are the 17.3 cm (6.8 in) ID DVI pipe and the reactor vessel DVI nozzle that has a 10.16 cm (4-in) ID venturi. The applicant stated that these components have openings that are large enough that plugging will not occur and that wear of the venturi is not an issue because the purpose of the venturi is only to limit high-pressure blowdown flow, not to restrict recirculation. The staff finds that the applicant has provided reasonable assurance that plugging and wear of components because of debris-laden water in the ex-vessel PXS flowpaths are not significant concerns for the AP1000 design.

All instrumentation sensors in the PXS recirculation lines are strapped to the outside of the piping. Therefore, there are no instrumentation tubes or sensing lines to evaluate for potential debris collection in the tubes or sensing lines. In RAI-SRP6.2.2-CIB1-09, the staff asked about the possible effects of debris, chemicals, and gases in the recirculation water on the accuracy of these strapped instruments as a result of changing the velocity of sound in the fluid. In a response dated November 6, 2008, the applicant clarified that the only strapped-on instruments are temperature sensors that are not affected by the velocity of sound in the fluid. The staff finds that the applicant's clarification adequately addressed the staff's question.

The applicant also evaluated the potential debris collection in the PXS flowpath piping. Based on the minimum flow rates for the PXS flow lines, the applicant determined that the transverse velocity is sufficient to prevent debris settlement in the PXS flow lines; therefore, blockage in PXS flow lines from the settling out of debris would be precluded. In RAI-SRP6.2.2-CIB1-10, the staff asked about flow rates that could be less than the minimum value assumed (e.g., during system flow initiation or realignment) and whether significant debris settlement could occur that would prevent necessary system core cooling flow. In a response dated November 6, 2008, the applicant responded that with the small amount and low concentration of debris that would be present following a LOCA and the large-diameter piping, any settling out of debris, even during very small flow, such as during startup or realignment, would have a negligible effect on PXS flow resistance. The staff finds this acceptable and agrees that because of the very low concentration of debris in the water, only a very small amount of debris could settle out during low flow conditions and would not cause significant blockage.

The applicant credited only passive systems for core and containment cooling; however, the AP1000 design includes a nonsafety active system (the RNS) that could be used for removing core and containment heat during various plant conditions, including a LOCA. The staff evaluated the possible effects of operation of these nonsafety active system ex-vessel downstream components and their capability to remove heat for long-term core cooling. As a result, in RAI-SRP6.2.2-CIB1-01, the staff asked about the use of these systems and: (1) the effects of possible additional amounts of debris ingested as a result of use of the active systems; (2) how ingested debris could affect the capability of these active systems when relied on for long-term cooling; (3) how ingested debris could affect these active systems for long-term cooling; (4) how ingested debris could affect the pressure integrity, leakage, and containment isolation function of these active systems; and (5) whether leakage through pump seals or other components could increase local dose rates so that credited operator actions, if any, would not be met. In a response dated November 11, 2008, the applicant stated that the evaluation of downstream effects has already included the conservative assumption that all latent containment debris could be ingested.

The applicant also stated that it evaluated the RNS ex-vessel downstream components, including pump seals, for wear, abrasion, and erosion using the evaluation methods of WCAP-16406-P for the assumed debris and found the components to perform their functions for a 30-day period beginning at the time of recirculation from the sump. The applicant further stated that in the event of a large source term (like the design-basis core melt source term), the RNS is automatically (i.e., not manually) isolated from the containment. Additionally, the applicant submitted a response dated May 13, 2009, to the staff's followup RAI-SRP6.2.2-CIB1-23 regarding the capability of the RNS isolation valves to close and not leak excessively under debris-laden conditions after the RNS has been functioning. The applicant performed an evaluation of the effects of wear, abrasion, debris loading, and erosion and concluded that the isolation valves will close and not leak excessively under these conditions. The staff finds that this adequately addresses the concerns regarding the evaluation of ex-vessel downstream RNS components under debris-laden conditions.

In RAI-SRP6.2.2-CIB1-11 and RAI-SRP6.2.2-CIB1-12, the staff asked about possible blockage of the ex-vessel downstream flowpath into the vessel and out of the vessel back to the break location as a result of settling or precipitation of boric acid and other chemicals. In responses dated November 6 and 11, 2009, the applicant stated that the concentration of boron and other chemicals is low enough that their precipitation would not occur over the 30-day mission time. The staff finds that this adequately addresses the issue of potential blockage of ex-vessel core cooling water flowpaths by boron or chemical precipitation.

The applicant performed an evaluation of the effects of the possible collection of noncondensable gases in high points in the PXS flowpath. Gases in sufficient quantities that collect and are trapped at high points could cause unacceptable pressure losses and restriction of system cooling flow, especially in a gravity-driven system. In RAI-SRP6.2.2-CIB1-13, the staff asked about the possible collection of noncondensable gases in the PXS flowpath that could impede cooling flow. In a response dated November 11, 2008, the applicant stated that the CMT and passive residual heat removal heat exchanger circuits are not susceptible to gas accumulation during preaccident standby conditions, except in an engineered high point pipe stub that has redundant level sensors. A low concentration of hydrogen is dissolved in the RCS, which is separated from these circuits by a single valve, but very little pressure is required to maintain the hydrogen in solution. The accumulator circuits are also expected to contain nitrogen dissolved in the water, but there is substantial dP following a LOCA such that any gas pockets would not impede accumulator flow. Once the accumulator water is emptied, nitrogen from the tank will be injected into the RCS. This nitrogen is readily vented from the RCS through the open ADS valves, and integral testing performed for the AP1000 showed that this nitrogen injection did not adversely affect the plant and system performance. The recirculation flowpaths from the IRWST to the RCS or from the recirculation screens to the RCS either contain water all the time or, if they contain air, they are short, straight horizontal pipes, such that the air is expelled and will readily fill with water. The staff finds this acceptable for addressing the possible effects of noncondensable gases, other tha
n those gases that could form as a result of chemical reactions or gases that come out of solution at higher accident-condition temperatures, which are discussed below.

Noncondensable gases that could form in the ex-vessel recirculation flowpath as a result of chemical reactions and additional gases that may come out of solution at higher accident temperatures were also evaluated. In RAI-SRP6.2.2-CIB1-23, the staff asked about the possible effects such gases could have in restricting cooling flow. In a response dated November 11, 2008, the applicant stated that the amount of gas as a result of chemical reactions is small and is limited by the small amount of materials that could react with the coolant. The amount of gases that could form by chemical reactions and that could come out of solution at higher temperatures would have time to bubble to the surface in the pool and be released to the containment. The staff finds this acceptable, because the amount of these gases is limited in quantity or they will have time to come out of solution in the pool water before recirculating in the core cooling flowpath.

Another issue of concern to the staff is how the squib valves may differ from the evaluated gate valves and the effects that squib valve propellant residue or chemicals could have on the ex-vessel downstream flowpath. The staff notes that the actuation of the squib valves occurs when there is no debris in the valve with which these chemicals could interact, such that a combined effect of both chemicals together with debris is not possible. However, the effects of the residue or chemicals as they mix with the system fluid without debris could also be an issue. Therefore, in RAI-SRP6.2.2-CIB1-25, the staff asked about the differences from the gate valve design and the possible effects the residue or chemicals could have in impeding the recirculation flow through the valves. In a response dated September 22, 2009, the applicant stated that both the squib valves and gates valves have sufficiently large flow openings and internal crevices, such that latent and particle debris would not get caught or restrict the flow. Regarding the effects of the residue and chemicals, the applicant stated that each of the 12 squib valves in the plant contains less than approximately 300 g (0.66 lbs) of propellant in which potassium is the predominate constituent. If all of the resulting potassium were mixed with the minimum post-LOCA sump volume, the concentration of potassium would be approximately 0.5 ppm. The applicant stated that this is much less than the concentration of sodium that would be present, which is chemically similar to potassium. The applicant stated that at this concentration, the potassium would stay in solution, and there would be negligible impact on downstream components. The applicant also stated that the remaining constituents of the propellant include gases in concentrations much lower than the potassium concentration, such that they would have no impact on the downstream components.

In reviewing Tier 1 to the AP1000 DCD, the NRC staff found that Table 2.1.2-4, “Inspections, Tests, Analyses, and Acceptance Criteria,” included ITAAC to verify the design and qualification of the as-installed squib valves in the ADS of the AP1000 reactor. However, AP1000 DCD Tier 1, Table 2.2.3-4, “Inspections, Tests, Analyses, and Acceptance Criteria,” did not include ITAAC to verify the design and qualification of the as-built squib valves in the AP1000 PXS. In RAI-SRP6.2.2-CIB1-29, the NRC staff noted that the squib valve design and applications in the AP1000 reactor will not be adequately similar to be represented by the tests or type tests for the ADS squib valves. Therefore, the NRC staff requested that the applicant provide additional ITAAC to verify the capability of the different squib valve designs and sizes and their applications in the AP1000 reactor. In its RAI response dated March 12, 2010, the applicant agreed that ITAAC related to the active safety-related valve functions of the PXS containment recirculation squib valves and IRWST injection squib valves should have been included in AP1000 DCD Tier 1, Table 2.2.3-4. The applicant provided a planned revision to AP1000 DCD Tier 1, Section 2.2.3, “Passive Core Cooling System,” to address the PXS squib valves. The applicant also provided planned ITAAC for the PXS squib valves to be included in AP1000 DCD Tier 1, Table 2.2.3-4, specifying that tests or type tests will be performed that demonstrate the capability of the valve to operate under its design condition, and that an inspection will be performed for the existence of a report verifying that the as-installed squib valves are bounded by the tests or type tests. Revision 18 to the AP1000 DCD included the modifications described in the RAI response. The NRC staff finds that AP1000 DCD Tier 1, Section 2.2.3, and Table 2.2.3-4, provide acceptable ITAAC to verify the design and qualification of the as-built PXS squib valves. Therefore, RAI-SRP6.2.2-CIB1-29 is resolved.

The applicant's evaluation of the effects of the residue and chemicals on the sump pool water is acceptable to the staff, since the concentrations are very small. However, the residue and chemicals from the valve actuation initially would be introduced into a much smaller volume of water inside the valve and in the immediate vicinity of the downstream pipe. To resolve this issue, the staff is reviewing the specific qualification testing of the squib valves being performed by the applicant. The staff has observed actual testing of prototype squib valve designs and will also observe testing of the final squib valve designs before their installation in the plant. Based on the staff's observations, the amount of residue and chemicals entering the flowstream area is small and would not likely restrict the cooling flow through the squib valves. Therefore, the staff finds the applicant's evaluation and the squib valve qualification testing program to adequately address the possible effects of squib valve residue and chemicals on the ex-vessel downstream flowpath.

In conclusion, the staff finds the applicant's evaluation of ex-vessel downstream effects acceptable.

6.2.1.8.3 Conclusion

In summary, the staff reviewed the proposed DCD changes and associated COL requirements to establish the adequacy of the IRWST and containment recirculation sump screen performance. Based on the evaluation described in the foregoing sections, the staff concludes that the design and analyses satisfy the requirements in GDC 35, GDC 38 and 10 CFR 50.46(b)(5).

6.2.2 Passive Containment Cooling System

6.2.2.1 Summary of Technical Information

Revision 17 of the DCD makes several changes to the text and figures in Section 6.2.2, and Change Number 70, included in a letter dated July 6, 2010, proposes further changes to the figures. As a result of these changes, the applicant also revised DCD Tier 1, Figure 2.2.2-1, "Passive Containment Cooling System Piping and Instrumentation Diagram (PCS P&ID)," and Table 2.2.2-2, as described and evaluated below.

6.2.2.2 Evaluation

Changes made to Figure 6.2.2-1 are evaluated as follows:

- Two passive containment cooling water storage tank (PCCWST) discharge lines were combined to a single larger line. TR-103, "Fluid System Changes," issued May 2006, stated that this change was necessary in order to achieve the flow rates required for adequate containment cooling and was not a functional change. In a July 18, 2008, response to RAI-SRP6.2.2-SPCV-01, the applicant confirmed that the flow rates reported in Table 6.2.2-1 were unaffected; therefore, the staff finds this piping change to be acceptable.

- The two PCCWST narrow-range pressure-based level sensors that shared taps with the wide-range level sensors were replaced with two inside wall-mounted ultrasonic, noncontact level sensors. TR-103 reported that this change was made in order to enhance accuracy over the wide-range level measurement at the top of the tank. Based on DCD Tier 1, Table 2.2.2-1, the narrow-range sensors are not safety related; therefore, the change does not impact the safety design basis for the PCS. Additionally, the change to ultrasonic sensors provides diversity in measurement of the PCCWST level because the nonsafety-related ultrasonic sensors now differ from the safety-related dP sensors. The staff finds this change acceptable.

- A second makeup line to the PCS water distribution bucket was added to provide the piping separation required to support a beyond-DBA scenario. Because a safety-related line already exists to supply the water distribution bucket, this new line is nonsafety related. The staff finds this change acceptable because it has no impact on the safety design basis for the PCS.

- As described in TR-103, a nonsafety-related spray system was added to the spent fuel pool (SFP) in response to a National Academy of Sciences study on the potential danger if water were drained from the SFP. The line to the new spray system is branched from the existing PCS makeup line to the SFP, and the location where this existing line stems from the PCCWST is changed from a 15.24 cm (6 in) standpipe to the bottom of the tank. A normally closed manual isolation valve was added to provide a boundary between the ASME Code, Section III Code Class 3 SFP makeup line and the nonsafety-related SFP spray header. Both this valve and the existing normally closed safety-related manual isolation valve must be opened in order to activate the SFP spray. In Revision 0 of its response to RAI-SRP6.2.2-SPCV-02, dated July 18, 2008, the applicant stated that the use of the SFP spray was controlled by procedure and not allowed during a DBA; therefore, there would be no impact on PCS performance. The staff requested additional information to determine if PCCWST inventory could be distributed to the SFP when it was needed for containment cooling. In Revision 1 of its response to RAI-SRP6.2.1.1-SPCV-06, dated August 31, 2009, the applicant added a paragraph to DCD Section 6.2.2.4 stating that the use of the PCCWST to provide water to the SPF spray header would be governed by the Extensive Damage Mitigation Guidelines included in NEI 06-12, "B.5.b Phase 2 & 3 Submittal Guideline," issued December 2006, and this document was added as Reference 33 to DCD Section 6.2.7. The staff finds this acceptable. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

- As described in a letter dated July 6, 2010, Change Number 70 revises the P&ID to accommodate lower than expected efficiency of the PCS recirculation pumps. These changes, which include increasing the size of the recirculation pump piping and associated valves, and adding a line to bypass the pumps, ensure that the ancillary diesel generator does not exceed the steady-state load limit. These changes are acceptable because they have no impact on the system or component design evaluated in NUREG-1793, Section 6.2.2.

- Several changes were made to the P&ID that the staff agrees have no impact on the evaluations made in NUREG-1793, Section 6.2.2. These include moving the recirculation heater from downstream to upstream of the chemical addition tank, standardizing flow orifice flange sets to 1.9 -cm (0.75–in) piping components, and correcting errors in the certified P&ID.

The changes made in the Revision 17 of the DCD to Tier 2, Figure 6.2.2-2, "Simplified Sketch of Passive Containment Cooling System," and Tier 1, Figure 2.2.2-1, are consistent with the items described above. The staff finds them acceptable.

DCD Tier 1, Table 2.2.2-1, identifies the components that perform safety-related functions for the PCS, and Table 2.2.2-2 identifies the PCS safety-related lines. Revision 17 of the DCD added several valves to Table 2.2.2-1 to reflect the P&ID changes previously discussed, but the lines in Table 2.2.2-2 were unaltered. However, the applicant subsequently proposed changes to the lines in this table in its July 18, 2008, and May 27, 2009, responses to RAI-SRP6.2.2-SPCV-04 and RAI-SRP6.2.2-SPCV-20. The changes made to both Tier 1 tables were found to be acceptable because they are consistent with changes made to Tier 2, Figure 6.2.2-1, and with each other. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

In the certified DCD, Section 6.2.2.4 states that the frequency of operational testing of the PCS was consistent with the plant TS and the inservice testing program. Revision 17 of the DCD removes the reference to the plant TS. However, the applicant's May 27, 2009, response to RAI-SRP6.2.2-SPCV-03, Revision 1, withdraws this change. The staff finds this acceptable because the TS are used to define some of the operational test frequencies. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

6.2.2.3 Conclusion

The staff finds the proposed changes to the DCD acceptable because they have no impact on the statements or conclusions of NUREG-1793, Sections 6.2.1.6 and 6.2.2, regarding primary containment testing and inspection and the PCS, respectively.

6.2.3 Shield Building Functional Design

6.2.3.1 Summary of Technical Information

Modifications were made to the shield building to strengthen it against additional external hazards, to make it more robust to seismic events, and to simplify construction. These changes, which include alterations to the inlet and outlet of the air flowpath and the height of the shield building, are expected to impact the air flow rate through the PCS. APP-GW-GLR-096, submitted August 10, 2010 includes a description of these changes and the impact they have on existing test reports. It also documents how the changes were incorporated into a WGOTHIC model that was used to run the limiting DBA and beyond design basis accidents (BDBA) affected by these changes. Appendix A of APP-GW-GLR-096 includes proposed DCD changes.

6.2.3.2 Evaluation

The staff evaluation of APP-GW-GLR-096 will be documented in Chapter 23.

6.2.3.3 Conclusions

The impact of the shield building changes on the containment functional design capability and the staff's conclusion will be provided in Chapter 23.

6.2.4 Containment Isolation System

The major function of the containment isolation system (CIS) is to isolate the containment to allow the normal or emergency passage of fluids through the containment boundary while preserving the integrity of the containment boundary. The CIS consists of the piping, valves, and actuators that isolate the containment.

In a letter dated April 5, 2006, the applicant submitted a request to modify the AP1000 DCD Tier 2 information to incorporate the ability to inject a small quantity of zinc acetate into the RCS. TR-32 describes this proposed change.

Zinc acetate would be added using the same piping and valving as the CVS hydrogen addition piping, which contains two containment isolation valves, CVS-PL-V092 and CVS-PL-V094. This would also require changing the normal position of the outside containment valve, CVS-PL-V092, from normally closed to normally open. The inside containment isolation valve, CVS-PL-V094, is a normally closed check valve. The proposed hardware change would also replace a portion of the 2.54 cm (1 in) pipe (downstream from the inside containment isolation valve) with a heavier wall 1.27 cm (0.5 in) pipe. The staff has reviewed and approved this change (Section 5.2.3 of this report).

6.2.4.1 Summary of Technical Information

The modification described in TR-32 results in changing the outside containment isolation valve, CVS-PL-V092, from normally closed, failed closed to normally open, failed closed.

Revision 17 of the DCD provides four additional overpressure relief valves between two normally closed containment isolation valves, identified in Table 6.2.3-1, “Containment Mechanical Penetrations and Isolation Valves.” These valves have also been added to Tier 1, Figure 2.2.1-1, and identified in Tier 1, Table 2.2.1-1, as CCS-PL-V220, SFS-PL-V067, VWS-PL-V080, and WLS-PL-V058.

6.2.4.2 Evaluation

The normal position of the containment isolation valve, CVS-PL-V092, in the CIS would change from normally closed to normally open. The valve would still fail closed, maintaining its containment isolation function. This change is indicated in Revision 17 of the DCD, Tier 2, Table 6.2.3-1, and shown in Figure 9.3.6-1, Sheet 1 of 2. The following functions and properties are not affected: the containment isolation function signal, the containment isolation design, the valve designation as active (Table 3.9-12 in the DCD), the safety-related mission, the inservice testing type and frequency requirements (Table 3.9-16), and the valve functional requirements for containment isolation (Tier 1, Table 2.3.2-1).

GDC 55, “Reactor Coolant Pressure Boundary Penetrating Containment”; GDC 56, “Primary Containment Isolation”; and GDC 57, “Closed Systems Isolation Valves,” of Appendix A to 10 CFR Part 50 require that containment isolation valves outside containment be located as close to containment as practical. Acceptance Criterion 9 in NUREG-0800 Section 6.2.4, “Containment Isolation System,” Revision 3, issued March 2007, also invokes this requirement. In RAI-SRP6.2.4-SPCV-01, the staff asked the applicant to provide the distances from the containment to the outboard isolation valves, and in RAI-SRP-6.2.4-SPCV-02, the staff asked the applicant to add the approved distances to DCD Tier 2, Table 6.2.3-1. The applicant responded to the RAIs with the distances provided in its letter dated January 13, 2009, and with its commitment in its letter of April 13, 2009, to add these distances to DCD Tier 2, Table 6.2.3-1. The staff found the responses acceptable. The corresponding ITAAC in Table 14.3-7, “Radiological Analysis,” that the containment penetration isolation features be configured as given in Table 6.2.3-1, remains acceptable to the staff as written. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

In Revision 15 of the DCD, additional requirement M in Section 6.2.3.1.3, “Containment Isolation Design,” states the following:

> Containment penetrations with leak-tight barriers, both inboard and outboard, are designed to limit pressure excursions between the barriers due to heating of fluid between the barriers. The penetration will either be fitted with relief or check valves to relieve internal pressure or one of the valves has been designed or oriented to limit pressures to an acceptable value.

Section 6.2.4.2 of NUREG-1793 states, “All overpressure relief valves used as containment isolation valves comply with the SRP acceptance criterion of having a setpoint greater than or equal to 150 percent of the containment design pressure.”

The applicant's response to RAI-SRP6.2.4-SPCV-03 confirms that the four new relief valves comply with the NUREG-0800 Section 6.2.4 acceptance criterion of having a setpoint greater than or equal to 610 kPa (88.5 psig), 150 percent of the containment design pressure. These new relief valves are shown in Revision 17 of the DCD, Tier 1, Figure 2.2.1-1, and listed in Tier 2, Table 6.2.3-1.

In RAI-SRP6.2.4-SPCV-03, the staff also asked whether the CVS letdown line at penetration P06 should be similarly provided with an overpressure relief valve between the two normally closed containment isolation valves, CVS-PL-V045 and CVS-PL-V047. The applicant’s response of May 20, 2009, indicates that it will add relief valve CVS-PL-V058, which will comply with the design requirements of the relief valves already added. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

Among the apparent discrepancies noted in RAI-MISC-SPCV-01 is the fact that the change to the normal position of containment isolation valve CVS-PL-V092 has not been reflected in Section 9.3.6, “Hydrogen Addition Containment Isolation Valve,” which should indicate that the valve is normally open, failing closed. Also, the position of CVS-PL-V092 in Table 9.3.1-1, “Safety-Related Air Operated Valves,” should read “normally opened, failed closed.”

In Revision 16 of the DCD, the applicant also made two editorial changes to Table 6.2.3-1, Sheet 1 of 4. The first identifies containment isolation valves CAS-PL-V015, CCS-PL-V201, CCS-PL-V208, and CCS-PL-V207 and observes the correct naming convention. In addition, for containment isolation valves CCS-PL-V207 and CCS-PL-V208, the applicant corrected the containment isolation signal to “S.” The staff agrees with these two editorial changes.

6.2.4.3 Conclusion

The staff finds that the applicant’s proposed modification to the AP1000 CVS system, approved in Section 9.3.6, does not adversely affect the containment isolation design and is, therefore, acceptable. The five thermal relief valves provided for overpressure protection are in accordance with regulatory guidance, consistent with DCD commitments, and are acceptable to the staff.

The editorial changes are acceptable.

6.2.5 Containment Hydrogen Control System

The containment hydrogen control system is provided to limit the hydrogen concentration in the containment so that containment integrity is not endangered.

On September 2004, the staff provided its assessment of the AP1000 hydrogen ignition subsystem design in Section 6.2.5.1 of NUREG-1793. As stated in paragraphs 3 and 9 of Section 6.2.5.1, adequate igniter coverage was provided based on implementation of the igniter location criteria in DCD Table 6.2.4-6.

DCD Tier 2, Table 6.2.4-6, provides the criteria used in the evaluation and the application of the criteria to specific compartments. On the basis of the staff's review and the applicant's implementation of the igniter location criteria as listed in DCD Tier 2, Table 6.2.4-6, the staff concluded that adequate igniter coverage had been provided.

6.2.5.1 Summary of Technical Information

In APP-GW-GLN-003 (TR-37), "Hydrogen Igniter Locations," Revision 1, the applicant modified the elevations or locations of certain hydrogen igniters within the AP1000 hydrogen control system. The applicant stated that the modifications were necessary because either the polar crane elevation or the pressurizer height had been changed, or in order to place the igniters in more easily accessible locations or to avoid trip hazards.

In Revision 16 of the DCD, Figures 6.2.4-5 through 6.2.4-13 show the proposed locations of the hydrogen igniters, and Tables 6.2.4-6 and 6.2.4-7 identify the proposed hydrogen igniter locations. The number of igniters is unchanged at 64.

6.2.5.2 Evaluation

Revision 16 of the DCD, Table 6.2.4-6, provides the criteria used in the evaluation and the application of the criteria to specific compartments. The changes to igniter locations as a result of the continuing COL and detailed design activities for the AP1000 satisfy the igniter location criteria identified in DCD Table 6.2.4-6 (Sheet 1 of 3) that were used for the DC review of the hydrogen igniter subsystem and referenced in the AP1000 SER. Therefore, changes in the placement of the hydrogen igniters that are consistent with the criteria in Table 6.2.4-6 do not alter the design function of the igniters, have no effect on any analysis or analysis method, and do not affect the performance or controls of hydrogen control functions.

On the basis of the staff's review and the applicant's implementation of the igniter location criteria as listed in DCD Tier 2, Table 6.2.4-6, the staff concludes that adequate igniter coverage has been provided.

6.2.5.3 Conclusion

The staff finds that the applicant's proposed modification to the AP1000 hydrogen control system design with respect to the change in hydrogen igniter locations, as described in TR-37, is consistent with the previously approved criteria and, therefore, acceptable.

6.2.6 Containment Leak Rate Test System

The containment leak rate test system is designed to verify that leakage from the containment remains within limits established in the TS.

6.2.6.1 Summary of Technical Information

The containment penetrations, including electrical penetrations, subject to Type B testing appear in Figure 6.2.5-1, "Containment Leak Rate Test System Piping and Instrumentation Diagram." The applicant has added the test connection assembly for the newly added electrical penetration, P03, to the list of electrical penetrations test connections in Figure 6.2.5-1.

6.2.6.2 Evaluation

The design commitment to provide a test assembly for Type B leak rate testing for the newly added electrical penetration, P03, is acceptable.

6.2.6.3 Conclusion

Based on its review, the staff finds the proposed addition of a Type B leak rate test assembly for the new electrical penetration, P03, acceptable.

6.2.8 Tier 1, Chapter 2.2.1, Containment System

6.2.8.1 Summary of Technical Information

In TR-97, APP-GW-GLN-022, Revision 1, "DAS Platform Technology and Remote Indication Change" dated May 2007, the applicant identifies and justifies standard changes to Revision 15 of the DCD. These changes include relocating the diverse actuation system (DAS) squib valve control cabinet (DAS-J3-003) and adding the DAS instrumentation cabinet (DAS-JD-004) to the southern section of the auxiliary building. The DAS is a nonsafety-related system. These changes necessitate the addition of a containment electrical penetration, P03. In a letter dated May 14, 2007, the applicant submitted responses to all the NRC RAIs on TR-97.

6.2.8.2 Evaluation

The staff's assessment of the CIS design was provided in Section 6.2.4 of NUREG-1793. As stated in the NUREG-1793 section, the containment penetration design of isolation barriers met the following acceptance criteria of NUREG-0800 Section 6.2.4.

Containment isolation equipment may be subject to potentially harsh conditions resulting from pressure, temperature, flooding, jet impingement, radiation, missile impact, and seismic response. The staff's review confirmed that the CIS had been properly classified to ensure that protection from these environmental hazards is encompassed by the mechanical and electrical design bases and quality standards of the isolation system.

The CIS will be designed to ASME Code Section III, Class 2 criteria. Containment penetrations are classified as Quality Group B, as defined in RG 1.26, "Quality Group Classifications and Standards for Water-, Steam-, and Radioactive-Waste-Containing Components of Nuclear Power Plants," Revision 4 and seismic Category I. The containment penetrations are identified as Class B, equivalent to ANS safety Class 2. The staff concluded that the applicant had selected the appropriate mechanical design classification for the CIS.

The staff determined that the CIS met the acceptance criteria of Section 6.2.4 of NUREG-0800, including the relevant requirements of GDC 1, "Quality Standards and Records"; GDC 4; and GDC 16, "Containment Design."

The acceptable design standards for electrical penetrations, namely ASME Code Section III, seismic Category I, non-Class 1E qualified, harsh environment qualified, will also apply to the new electrical penetration, P03, as shown in DCD, Revision 17, Tier 1, Table 2.2.1-1. The addition of the new electrical penetration, P03, is shown in DCD Revision 17, Figure 2.2.1-1 where it is included in the note "1 of 24 and one spare." This is inconsistent with TR-97 and in RAI-SRP6.2.4-SPCV-04, the staff requested the note be corrected. In a letter dated May 17, 2010, the applicant agreed to revise the note to state "1 of 25." In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

Tier 1, Table 2.2.3-4, Inspections, Tests, Analyses, and Acceptance Criteria, describes the equipment listed in Tier 1, Table 2.2.3-6, including all electrical penetrations, as having sufficient thermal lag to withstand the effects of hydrogen burns associated with severe accidents. The newly added electrical penetration, P03, has been added to the list of electrical penetrations in Tier 1, Table 2.2.3-6. The design commitment to provide the thermal lag to the newly added electrical penetration, P03, is acceptable.

6.2.8.3 Conclusion

Based on its review, the staff finds the proposed change as described in TR-97, Revision 1, which adds an additional containment electrical penetration in accordance with previously acceptable design criteria for electrical penetrations, namely ASME Code Section III, seismic Category I, non-Class 1E qualified, harsh environment qualified, will also apply to the new electrical penetration, P03. The staff finds that the applicant's proposed modification to the AP1000 CIS design with respect to the addition of an electrical penetration, as described in TR-97, is consistent with the previously approved criteria and is, therefore, acceptable.

6.4 Control Room Habitability Systems

6.4.1 Summary of Technical Information

Section 6.4 of the AP1000 DCD has undergone significant revision. The revisions include a major redesign of the AP1000 main control room (MCR) emergency habitability system (VES). The VES is a passive system design that consists of safety-related canisters of air that supply the control room with fresh, uncontaminated breathing air. The system does not require alternating current (ac) power to function and is required to function for 72 hours. After 72 hours, nonsafety systems can be credited for control room habitability. In the certified design, the COL applicant was responsible for the testing frequency associated with the control room integrity program. Additionally, the certified design provided no filters to remove radioactivity from the control room environment. The system only replaced the contaminated control room air with bottled air that was uncontaminated. In the amendment, the applicant removed the COL information item and provided a general description of the control room integrity program with the testing frequency. Additionally, to permit the use of the AP1000 design at more sites, the radiation dispersion factors were also expanded. In developing a control room integrity program, which includes in-leakage testing for the control room envelope (CRE), the applicant was unable to establish achievable acceptance criteria for the in-leakage testing with the new radiation dispersion factors. As a result, the applicant made a series of significant design changes to add margin to the control room dose calculations.

The changes included reducing control room in-leakage through various design provisions, including precluding ductwork from penetrating the CRE and reconfiguring the vestibule. A filter train was added to the passive system as well. The filter train consists of an eductor with ductwork, silencers, a particulate filter, and a high-efficiency particulate air (HEPA) filter. The design change resulted in changes to Tier 1, Tier 2, TS, and ITAAC. Additionally, the applicant has made a number of other unrelated changes, including the redesignation of the technical support area to the control support area. This allows COL applicants more flexibility in designating a technical support area. The design of this system has evolved over the course of the review, and numerous applicant submittals describe the changes. The applicant consolidated all the changes into a response to RAI-SRP6.4-SPCV-15 Revision 1, which was submitted in a letter dated May 24, 2010.

The changes can be grouped into six broad categories. The first includes changes associated with addressing the control room integrity program in the DCD. The approved version of the DCD made this the responsibility of the COL applicant and documented it as a COL information item. The second involves changes associated with the new passive filter train. Third are changes associated with the design changes to reduce the unfiltered in-leakage. The second and third categories of changes were necessary because the applicant revised the radiation dispersion factors to expand the scope of sites that would be covered by the certification. The higher dispersion factors required less leakage and more effective control room fission product removal. The fourth category includes changes associated with the redesignation of the technical support center (TSC) as the control support area. The fifth involves changes intended to improve operational flexibility of the system by including four isolable banks of compressed air canister banks rather than a single bank. Last, there are editorial changes.

A number of changes are associated with the removal of the COL information item on the control room integrity program. The applicant provided a description of the control room integrity program in the final safety analysis report (FSAR) using tracer gas testing. The applicant also included TS implementing the program.

A number of changes are associated with the introduction of a passive filter train. An innovative single passive filter train was added to the existing compressed air system. An eductor was designed to connect to the existing compressed air system. The eductor draws in unfiltered control room air and circulates it through a filter train. The filters are designed and tested to meet the intent of RG 1.52, “Design, Inspection, and Testing Criteria for Air Filtration and Adsorption Units of Post-Accident Engineered-Safety-Feature Atmosphere Cleanup Systems in Light-Water-Cooled Nuclear Power Plants,” Revision 3, issued June 2001, and design provisions were made to demonstrate that the single passive train meets the single failure criteria.

A number of design changes are intended to reduce unfiltered in-leakage. The control room air exhaust was moved to vent through the vestibule. This created a sort of purge, reducing unfiltered air ingress from the MCR doors. Additionally, the applicant made design commitments to preclude ductwork from penetrating the CRE. Other material changes were made as well.

Changes are associated with the redesignation of the TSC as the control support area. The applicant changed the description in DCD Tier 2, Section 6.4, and the Tier 2 description in Chapter 18.

The applicant made changes to improve operational flexibility. For example, it divided the existing air tanks into four isolable headers to allow maintenance work to be done on some of the tanks while the remainder of the system remains functional. TS were added to address the situation where one bank of compressed air tanks is out of service. The applicant also performed the dose analysis for the fuel handling accident with a shorter time to reactor shutdown. This permits fuel movement earlier than was previously analyzed.

The applicant also made a number of editorial changes. For example, it changed the general information for onsite chemicals identified in Table 6.4-1. The list of chemicals is general and does not provide the quantity of material or the distance to the control room intake. Additionally, the COL applicant is responsible for identifying and evaluating the onsite and offsite chemicals. As a result, the staff considers this change to be editorial. This SER does not describe these types of changes in detail. With the exception of the editorial changes, a more detailed evaluation of the major changes is provided below.

6.4.2 Evaluation

6.4.2.1 Evaluation of Control Room In-Leakage Testing

In developing a control room integrity program, the applicant had difficulty establishing an achievable in-leakage that could be demonstrated through testing. Originally, the applicant proposed a total effective in-leakage of 0.0425 cubic meters per minute (m^3/min) (1.5 cubic feet per minute (cfm)). This would account for both unfiltered in-leakage as well as effective in-leakage though the doors. The staff issued a number of RAIs to determine how this design limit would be demonstrated. In response, the applicant made a major redesign of the VES. In a letter dated May 24, 2010, the applicant responded to RAI-SRP6.4-SPCV-15 R1 and included all the DCD changes associated with the VES redesign. The applicant has removed the analysis assumption of 1.5 cfm effective unfiltered in-leakage from the MCR dose analysis. The analysis assumption was revised to assume 5 cfm unfiltered in-leakage into the control room as a result of ingress/egress activities. An unfiltered in-leakage of 5 cfm is appropriate for the AP1000 control room because of the incorporation of a two-door vestibule. The control room doses with this increased effective in-leakage assumption required the addition of a passive filtration line to the VES to remain below regulatory limits.

The NRC issued GL 2003-1, "Control Room Habitability," dated June 12, 2003, to alert addressees to findings that the control room licensing and design bases and applicable regulatory requirements may not be met, and that existing specification surveillance requirements may not be adequate. In 2006, the staff approved a modification to the Standard Technical Specifications (STS) (NUREG-1430, "Standard Technical Specifications-Babcock and Wilcox Plants"; NUREG-1431, "Standard Technical Specifications-Westinghouse Plants"; NUREG-1432, "Standard Technical Specifications-Combustion Engineering Plants";

NUREG-1433, "Standard Technical Specifications-General Electric Plants (BWR/4)"; and NUREG–1434, "Standard Technical Specifications-General Electric Plants (BWR/6)") that were proposed by the PWR and boiling-water reactor (BWR) owners groups' Technical Specification Task Force (TSTF) in STS change traveler TSTF-448, Revision 3. The notice of availability for adopting TSTF-448, Revision 3, using the consolidated line item improvement process was published in the *Federal Register* on January 17, 2007 (72 FR 2022). TSTF-448, Revision 3, addresses the tracer gas surveillance, adding a TS action for an inoperable CRE and instituting a CRE habitability program that will ensure that CRE habitability is maintained.

In Revision 17 of DCD Tier 2, Sections 6.4.5.1 and 6.4.5.4 commit to performing tracer gas testing during preoperational inspection and testing, and periodically during the life of the unit in accordance with RG 1.197, "Demonstrating Control Room Envelope Integrity at Nuclear Power Reactors," issued May 2003; they also commit to performing followup self-assessments. However, the AP1000 generic TS did not include a surveillance requirement to measure unfiltered in-leakage into the CRE (the tracer gas test), and required actions for an inoperable CRE boundary and a CRE habitability program as approved by the NRC in STS generic change TSTF-448, Revision 3.

In RAI-SRP6.4-SPCV-01, the staff asked the applicant to incorporate the changes to the STS made by TSTF-448 in AP1000 DCD Tier 2, Chapter 16, "Technical Specifications." In a letter dated May 4, 2009, the applicant responded to incorporate the DCD changes according to the staff's request.

Additionally, the staff raised questions with the applicant about a demonstrable control room in-leakage design basis. VES is a passive system design. There is no safety-related emergency electric diesel to provide electrical power during DBAs accompanied by a loss of outside power. Therefore, there is not enough Class 1E power to drive fans to recirculate control room ventilation air through filters to remove activity during radiological accidents. There is a limited supply of bottled compressed air to maintain control room habitability during DBAs. Based on DCD Revision 17, the VES design had no filtration trains to recirculate and filter the air in the CRE. The bottled air can only supply 1.84 m^3/min (65 cfm) for 72 hours. To meet the dose limits, the unit could only accept 0.0425 m^3/min (1.5 cfm) MCR in-leakage (MCR unfiltered in-leakage and MCR doors ingress/egress combined) to maintain operator dose rates below the required levels. Safety class calculation "AP1000-LOCA Dose Analysis" is the key analysis to demonstrate that MCR operator dose is below 5 roentgen equivalent man (rem) total effective dose equivalent (TEDE), as dictated by GDC 19, "Control Room," in Appendix A to 10 CFR Part 50. Should the MCR in-leakage exceed the 0.0425 m^3/min (1.5 cfm) design limit by a small amount, the 5 rem TEDE limit would be exceeded. The safety margin for this configuration was very small.

The applicant chose to ease the safety margin issue for the VES passive system design by installing a passive filtration line to the VES system. The bottled air will provide 1.84 m^3/min (65 cfm) to an eductor to induce at least 17.0 m^3/min (600 cfm) of air from the MCR into a filter bank to remove radionuclides. This will allow 0.425 (15 cfm) MCR in-leakage and keep MCR operator dose below the required 5 rem TEDE. By doing this, the safety margin issue of the VES passive system design is relaxed. The resulting system is a single safety Class 3, passive filtration line, which is new to the ASME Code. Using the passive filtration line, the VES is able to maintain operator dose below the GDC 19 requirements assuming a total in-leakage of 0.425 m^3/min (15 cfm). The dose analysis assumes that 5 cfm results from ingress/egress activities and up to 0.283 m^3/min (10 cfm) of in-leakage can occur from all other sources. The 0.283 m^3/min (10 cfm) in-leakage is verified through the control room integrity leakage program.

As a result, the applicant has established an achievable design basis in-leakage, and it has properly accounted for effective in-leakage through the doors. Additionally, there is a control room integrity program that meets the recommendations in RG 1.197, and there are TS consistent with TSTF-448. Therefore, the staff finds the applicant's approach acceptable.

6.4.2.2 Evaluation of the Passive Filter Train

The VES uses a bank of compressed air storage tanks to provide the MCR with breathable air and maintain a positive pressure relative to its adjacent areas during accident conditions. The system is designed to deliver a constant flow of 1.84 ± 0.14 standard m^3/min (65 ± 5 standard cubic feet per minute (scfm)) for 72 hours. Using the current VES design, the applicant developed a passive air filtration line that uses an eductor to induce a filtration flow through the MCR of at least 17.0 standard m^3/min (600 scfm). The components that comprise the passive filtration portion of the VES are located entirely within the MCR envelope.

To the extent applicable, the filtration line is designed in accordance with RG 1.52, Revision 3. The applicant added a conformance assessment to Appendix 1A to the DCD to compare the passive filtration line to the requirements defined in RG 1.52, Revision 3, and added this RG to DCD Table 1.9-1. In the conformance assessment, the applicant took an exception to Regulatory Position C.6.1. The staff asked the applicant to explain why it needed an exception to this regulatory position. In a letter dated May 24, 2010, the applicant provided a revision to its response to RAI-SRP6.4-SPCV-15 that stated that the filtration line conforms to Regulatory Position C.6.1. It included the associated changes to Appendix 1A to the DCD to reflect this conformance. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

The filtration line comprises an intake grill located near the inner vestibule door inside the MCR envelope. This location was chosen because it is expected to be the location where the greatest amount of in-leakage occurs as a result of ingress/egress activities. Flow is then directed through safety-related ductwork and a silencer into the eductor. The VES supply line is connected to the eductor. The VES bottle air supply is the motive force that drives at least 600 cfm of air flow through the intake duct. The eductor works by directing a small amount of compressed air through a nozzle along the walls of the opening. When released into the nozzle, this small amount of compressed air is moving at near sonic speeds and creates a powerful vacuum in the area upstream of the nozzle. This vacuum draws air in through the surrounding duct and pulls it through the nozzle. The compressed air then carries it downstream away from the eductor. The eductor then directs the flow through a second silencer, a HEPA filter, a charcoal filter, and a postfilter. The filtration units work to remove particulates and iodine from the air to reduce the potential MCR dose. Redundant flow instruments are located downstream of the filtration units to ensure that adequate flow is passing through the filtration units during testing activities. The new flow instrumentation has high and low alarms to alert the operator of possible filtration issues during testing. After passing the flow instrumentation, the filtered air is discharged to three locations inside the MCR envelope. Approximately 1.70 to 1.98 m^3/min (60–70 cfm) would be discharged in the vicinity of the shift supervisor’s officer or operator break room, and the remaining 17.0 m^3/min (600 cfm) would be discharged into the main control area through two discharge paths on the opposite side of the control room from the air intake located in the operations work area. Two flow dampers located downstream of the postfilter control the flow distribution.

Although each of the components in the filter train arrangement has been used before, this particular application is novel in the nuclear industry. The applicant constructed a scale model to demonstrate that the system would function. The scale model was tested, and the test results were presented to the NRC in a public meeting on December 15, 2009. The tests demonstrated that the system would function as designed.

The existing pressure-regulating valves in the VES control pressure and flow from the emergency air storage tanks into the eductor. The pressure at the outlet of the valve is controlled via a two-stage, self-contained pressure control operator. A failure of either stage of the pressure-regulating valve will not cause the valve to fail completely open. A failure of the second stage of the pressure-regulating valve will increase flow from the emergency air storage tanks. There is adequate margin in the emergency air storage tanks such that an operator has time to isolate the line and manually actuate the alternative delivery line.

To reduce the overall noise, the silencers, eductor, and filtration unit must all be located behind the main control area. The applicant added an ITAAC to DCD Tier 1, Section 2.2.5, to verify that the noise levels in the MCR remain below the recommended guidelines in NUREG-0700, "Human-System Interface Design Review Guidelines," issued May 2002. The ITAAC will verify that the noise level at the operator work station will remain below 65 decibels when the VES is in operation.

A filtration flow of at least 17.0 m^3/min (600 cfm) resolves the original difficulty in having a control room design in-leakage that could be demonstrated through testing. At a filtration flow rate of 17.0 m^3/min (600 cfm), 0.425 m^3/min (15 cfm) is an acceptable MCR in-leakage to maintain operator dose rates below the required levels. (The total flow at the outlet of the filters must be at least 17.0 m^3/min (600 cfm) plus the flow from the compressed air tanks.) This allows the dose analysis to assume a constant 0.142 m^3/min (5-cfm) in-leakage through the vestibule and up to 0.283 m^3/min (10 cfm) of in-leakage from sources other than through the vestibule. Using a tracer gas test, it would be possible to verify that the in-leakage from sources other than the vestibule is less than 0.283 m^3/min (10 cfm). The applicant revised the existing ITAAC related to tracer gas testing (ITTAC 7b in Section 2.2.5-5 of the DCD) to reflect the appropriate acceptance criteria of less than or equal to 0.283 m^3/min (10 scfm). A technical specification has been added to the AP1000 technical specifications to incorporate the requirements of TSTF-448 for a CRE habitability program.

The staff raised a number of technical issues in its review of the passive filter system, as described below.

6.4.2.2.1 Evaluation of Issues Associated with the Eductor in the Passive Filtration Line

Nuclear power plant applications have limited operational and maintenance experience with the eductor. The frequency of the technical specifications surveillance test of the eductor should be based on experience with eductor system degradation. However, the frequency chosen for the surveillance was not supported by a technical rationale or data on the degradation of eductors. Therefore, in RAI-SRP6.4-SPCV-09, the staff asked the applicant to justify the surveillance frequency with a technical rationale that is based on data associated with eductor degradation.

The applicant responded in a letter dated December 9, 2009, stating that the "frequency of Technical Specification Surveillance Testing for the Main Control Room Emergency Habitability System (VES) eductor was chosen to align with the Ventilation Filter Testing Program (VFTP) identified in Surveillance Requirement 3.7.6.11 of the AP1000 Technical Specifications as revised by RAI-SRP-6.4-SPCV-06." Additionally, the applicant provided examples of operational data on eductors in industrial applications. This information supports the applicant's claims, and the staff finds the applicant's proposed TS surveillance testing frequency for the eductor reasonable.

6.4.2.2.2 Evaluation of Issues Associated with the HEPA Filter in the Passive Filtration Line

Section 6.3, regarding HEPA filter in-place leak testing, of RG 1.52 shows the acceptable combined penetration and leakage (or bypass) to be less than 0.05 percent of the challenge aerosol. The applicant's proposed TS 5.5.13 shows this value to be 0.5 percent. In its response to RAI-SRP6.4-SPCV-06 received in a letter dated May 4, 2009, the applicant stated that each HEPA filter cell is individually shop-tested to verify an efficiency of at least 99.97 percent in accordance with ASME AG-1, Section FC. The staff asked the applicant to provide a technical basis to credit 99.97 percent HEPA filter efficiency at 0.5 percent penetration and system bypass conditions.

The applicant responded in a letter date May 24, 2010 that the markup of the TS that indicates the combined penetration and leakage of less than 0.5 percent is an editorial error. The applicant corrected TS 5.5.13 in the draft DCD revision pages to indicate a leakage value of less than 0.05 percent.

In accordance with Section 6.3 of RG 1.52, to be credited with 99 percent removal efficiency for particulate matter in accident dose evaluation, a HEPA filter bank should demonstrate an aerosol leak test result of less than 0.05 percent of the challenge aerosol. It its response to RAI-SRP6.4-SPCV-06, the applicant stated that the HEPA filters will remove 99 percent of particulates consistent with the guidance in RG 1.52. The staff asked the applicant to provide a technical basis to credit 99 percent HEPA filter efficiency for particulate matter in accident dose evaluation at 0.5 percent penetration and system bypass conditions.

In a letter dated February 25, 2010, the applicant responded to RAI-SRP6.4-SPCV-10, Revision 2, by stating that it intends to comply with Section 6.3 of RG 1.52, Revision 3, as indicated in the markup of Appendix 1A in RAI-SRP6.4-SPCV-06, Revision 0. The staff found the DCD changes provided in the response to RAI-SRP6.4-SPCV-15, Revision 1 to be in alignment with the guidance and acceptable.

Section 6 of RG 1.52, Section 9.5 of ASME N510-2007, "Testing of Nuclear Air Treatment Systems," and Section 5.7 of ASME N511-2007, "In-Service Testing of Nuclear Air Treatment, Heating, Ventilating, and Air-Conditioning Systems," specify dP testing across the HEPA filter bank. However, proposed TS 5.5.13 did not specify the dP testing across the HEPA filter bank. The staff asked the applicant to explain why the technical specifications did not specify the rationale for the dP testing across the HEPA filter bank.

The applicant responded in a letter dated May 24, 2010 in RAI-SRP6.4-SPCV-15, Revision 1 that it would include dP testing across the combined HEPA filter, charcoal adsorber, and the postfilter in the ventilation filter testing program. The staff verified that the draft DCD revisions included this. As a result, the staff finds the applicant's approach acceptable.

6.4.2.2.3 Evaluation of Issues Related to the Adsorber in the Passive Filtration Line

Section 6.4, regarding adsorber in-place leak testing, of RG 1.52, Revision 3, shows the acceptable combined penetration and leakage (or bypass) to be less than 0.05 percent of the challenge gas. The applicant's response to RAI-SRP6.4-SPCV-15, provided in a letter dated February 25, 2010, proposed TS 5.5.13, which shows this value to be 0.5 percent. In its response to RAI-SRP6.4-SPCV-06, the applicant stated that the charcoal adsorber is designed, constructed, qualified, and tested in accordance with ASME AG-1 and RG 1.140, "Design, Inspection, and Testing Criteria for Air Filtration and Adsorption Units of Normal Atmosphere Cleanup Systems in Light-Water-Cooled Nuclear Power Plants," Revision 2, issued June 2001. Both RG 1.52 and RG 1.140 specify a combined penetration and leakage (or bypass) adsorber in-place leak test criterion of 0.05 percent or less of the challenge gas. The staff asked the applicant to provide the technical basis for the exception taken to relax the adsorber penetration and system bypass criterion from 0.05 percent to 0.5 percent.

The applicant responded to RAI-SRP6.4-SPCV-11, Revision 1 in a letter dated December 3, 2009, by stating that it intends to comply with Section 6.3 of RG 1.52, Revision 3, as indicated in the markup of Appendix 1A in RAI-SRP6.4-SPCV-06. The applicant noted an editorial error in the markup of the technical specifications that indicates combined penetration and leakage of less than 0.5 percent. The applicant corrected TS 5.5.13 in Reference 13 to indicate a leakage value of less than 0.05 percent. As a result, the staff finds the approach acceptable.

For maximum assigned credit for active carbon decontamination efficiencies of 95 percent (elemental iodine and organic iodide), RG 1.52, Revision 3, Section 7, regarding laboratory testing of charcoal samples, shows an acceptable penetration of less than 2.5 percent for a 5.08 cm (2-in)-deep charcoal bed. For maximum assigned credit for active carbon decontamination efficiencies of 99 percent (elemental iodine and organic iodide), Section 7 shows an acceptable penetration of less than 0.5 percent for a 10.16 cm (4-in) bed. In its response to RAI-SRP-6.4-SPCV-06, the applicant stated that the charcoal filters would remove 90 percent of the elemental iodine and 30 percent of the organic iodine, claiming to be consistent with RG 1.52, Revision 2, issued March 1978. For the assigned activated carbon decontamination efficiencies of 90 percent (elemental iodine) and 30 percent (organic iodide), RG 1.52, Revision 2, Section 6, related to laboratory testing criteria for activated carbon, shows an acceptable laboratory testing criterion for a methyl iodide penetration of less than 10 percent for a 5.08 cm (2-in)-deep charcoal bed. The applicant's proposed TS 5.5.13 shows a value of 35 percent. The 35-percent allowable penetration should be calculated from a safety factor of 2 recommended by GL 99-02, "Laboratory Testing of Nuclear-Grade Activated Charcoal," dated June 3, 1999, (100 percent – organic iodide efficiency)/safety factor = (100 percent – 30 percent)/2 = 35 percent). The staff asked the applicant to provide the technical basis for assigning a credit for active carbon decontamination efficiencies of 90 percent (elemental iodine) and 30 percent (organic iodide) charcoal carbon efficiency at 35 percent penetration conditions.

The applicant responded to RAI-SRP6.4-SPCV-11, Revision 1 by stating that the "technical basis for assigning activated carbon decontamination efficiencies of 90 percent (elemental iodine) and 30 percent (organic iodine) for charcoal carbon efficiency at 35 percent penetration conditions should have been identified as Reference 1." Reference 1 identifies a methodology described in GL 99-02 to calculate the allowable penetration percentage based on assumed organic iodine efficiency and a defined safety factor. Using the provided methodology, a 35 percent penetration condition is calculated assuming a 30 percent organic iodine efficiency and a safety factor of 2. The staff noted that the values in the table were generated for specific penetration, elemental and organic efficiencies, and residence times. The use of the 35 percent penetration value was not specifically approved by the staff in the RG and further justification would be needed to apply the methodology.

The applicant stated that it would revise TS 5.5.13 to show an in-place test of the charcoal adsorber with a penetration and system bypass less than 0.05 percent (RAI-SRP6.4-SPCV-10, Revision 2). Additionally, the applicant included the residence time as a design parameter in the DCD. RG 1.52, Revision 3, specifies the value of less than 0.05 percent. The applicant demonstrated that the value chosen for penetration relative to the efficiencies used in the dose analysis is conservative. The staff verified that the applicant included the change in the response to RAI-SRP6.4-SPCV-15, Revision 1 in the draft DCD revisions and finds the approach acceptable.

Section 6 of RG 1.52, Section 10.5 of ASME N510-2007, and Section 5.8 of ASME N511-2007 specify dP testing across adsorber banks. However, proposed TS 5.5.13 did not specify the dP testing across adsorber banks. The staff asked the applicant to provide the rationale for not specifying the dP testing across the charcoal filter bank in the TS.

The applicant responded to RAI-SRP6.4-SPCV-15, Revision 1 by stating that it would include dP testing across the combined HEPA filter, charcoal adsorber, and postfilter in the ventilation filter testing program. The staff verified that this was included in the draft DCD revisions. As a result, the staff finds the applicant’s approach acceptable.

The staff noted in Section 6.4.2.3 of NUREG-1793 that the applicant referenced RG 1.140 for the design, construction, and qualification of the charcoal adsorber. The staff notes that it cited RG 1.52, Revision 3, for all other aspects of the design. The staff is unclear why the applicant would use RG 1.140 for this specific aspect of the application rather than RG 1.52, Revision 3. In a letter dated May 24, 2010, the applicant revised its response to RAI-SRP6.4-SPCV-15 to state that RG 1.52, Revision 3, is the correct reference and provided an associated DCD change. The staff found the response acceptable.

6.4.2.2.4 Evaluation of the Test Frequency of the Combined Filters Pressure Drop

TS 5.5.13, which the applicant submitted in response to RAI-SRP6.4-SPCV-15, Revision 0, states that a "program shall be established to implement the following required testing of Engineered Safety Feature (ESF) filter ventilation systems at the frequencies specified in accordance with regulatory guide 1.52, Revision 3, ASME N510-1989, and AG-1." Item d of TS 5.5.13 requires a test of "the pressure drop across the combined HEPA filter, the charcoal adsorber, and the post filter." However, RG 1.52, Revision 3, ASME N510-1989, and AG-1 do not have a clearly defined combined pressure drop test frequency. This dP measure is a surveillance test made at regular intervals to detect deterioration that may develop under service conditions. Regular in-place testing is necessary because deterioration may take place even when the system is not being operated.

For the combined HEPA filter, charcoal adsorber, and postfilter pressure drop test in TS 5.5.13.d, the staff asked the applicant to provide a specific citation and reference for performing this test and to provide the required test frequency. The applicant responded in a letter dated June 2, 2010, to RAI-SRP6.4-SPCV-16 by stating that it would revise the proposed TS 5.5.13 to list the frequencies for each test listed in TS 5.5.13.a, b, c, and d. It removed the reference to RG 1.52, Revision 3, and ASME N510-1989 from TS 5.5.13.d that were proposed in the response to RAI-SRP6.4-SPCV-15. The frequencies provided for Section 5.5.13.a, b, and c are the same as the frequencies listed in RG 1.52, Revision 2. As a result, the staff finds these frequencies acceptable. The test in TS 5.5.13.d will be conducted every 24 months, which aligns with the frequencies for the HEPA filter and charcoal adsorber inplace tests and the charcoal adsorber sampling and analysis (TS 5.5.13.a, b, and c). A specific RG or standard citation is not needed with the revised TS 5.5.13.d, since the test is described by the TS itself and the frequency is specified.

Because the frequencies given in TS 5.5.13.a, b, and c are those specified in RG 1.52 and the frequency given in TS 5.5.13 d is aligned with the frequencies in the RG, the staff finds the DCD changes identified in the response to RAI-SRP6.4-SPCV-16 acceptable. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

6.4.2.2.5 Evaluation of the Safety Class of Passive Filtration Flow Instrumentation

Redundant flow instruments are located downstream of the filtration units to ensure that adequate flow is passing through the filtration units during testing activities. The instrumentation is not safety-related. The applicant's rationale is that the instrument does not perform a safety function. An existing VES safety flow instrument indicates whether there is sufficient flow coming from the compressed air tanks to induce the passive filtration flow. The new flow instrumentation has high and low alarms to alert the operator of possible filtration issues during testing.

Section 3.3.1.3 of ANSI/ANS-51.1-1983 (Reference 2) states the following:

> safety class 3 (SC-3) shall apply to equipment, not included in SC-1 or -2, that is designed and relied upon to accomplish the following nuclear safety functions:
>
>> k. Ensure nuclear safety functions provided by SC-1,-2, or -3 equipment, m. Provide information or controls to ensure capability for manual or automatic actuation of nuclear safety functions required of SC-1, -2, or -3 equipment"

At a filtration flow rate of 17.0 m^3/min (600 cfm), 0.425 m^3/min (15 cfm) is an acceptable MCR in-leakage level to maintain operator dose rates below the required levels. (The total flow at the outlet of the filters must be at least 17.0 m^3/min (600 cfm) plus the flow from the compressed air tanks.) This allows the dose analysis to assume a constant 0.142 m^3/min (5-cfm) in-leakage through the vestibule and up to 0.283 m^3/min (10 cfm) of in-leakage from sources other than through the vestibule. The 17.0 m^3/min (600 cfm) flow induced by the eductor is the design basis used by the dose calculation to make sure filtration units in the passive air filtration line will work to remove particulate and iodine from the air to reduce the potential MCR dose. This dose calculation is required to satisfy GDC 19 in Appendix A to 10 CFR Part 50.

The two flow instruments in the filtration line provide information to ensure the capability of the eductor to draw at least 17.0 m^3/min (600 cfm) so the VES system safety function (MCR habitability during radiological accidents) can be achieved. The existing VES safety flow instrumentation to indicate whether there is sufficient flow (1.84 m^3/min (65 cfm)) coming from the compressed air tanks to induce the passive filtration is not a direct indication of the performance of the eductor.

The operators would rely on this instrumentation during an accident to ensure that the safety-related filtration train was functioning. Based on ANSI/ANS-51.1-1983, the staff asked that at least one flow instrument in the passive air filtration line be safety related. The staff also asked the applicant to provide additional justification that the operators would not rely on this instrumentation during an accident or else make one of the instruments safety related.

The applicant responded in a letter dated February 25, 2010, to RAI-SRP6.4-SPCV-15, Revision 0, by stating that the operator would not rely on this instrumentation during an accident. Rather, the operator would rely on the flow instrumentation directly from the compressed air tanks. The staff noted that this instrumentation would not notify the operator of a clogged or partially blocked component in the filter train and that flow blockage was a credible failure after 24 hours. The applicant responded by making design changes demonstrating compliance with the single failure criteria. Further discussion of the single failure criteria appears below. Given that the applicant eliminated all credible single failures, the staff agrees that reliance on the flow instrumentation from the compressed air tanks during an accident is acceptable. As a result, the two redundant flow instruments that are located downstream of the filtration units to ensure that adequate flow is passing through the filtration units during testing activities do not need to be safety-related.

6.4.2.2.6 Evaluation of the Single Failure of the Passive Filtration Line

The applicant stated that redundant passive filtration lines are not required because the passive filtration line has no electrical power requirements, contains no moving parts, and requires no maintenance such as adjusting setpoints or lubricating bearings. The applicant stated that adequate design margin is provided to prevent the likelihood of a passive failure.

Section 3.2.1.c of ANSI/ANS-51.1-1983 states that fluid systems required to support, directly or indirectly, the three nuclear safety functions stated above shall be capable of performing these functions as provided in ANSI/ANS-58.9-1981, “American National Standard Single Failure Criteria for Light Water Reactor Safety-Related Fluid Systems.”

ANSI/ANS-58.9-1981 defines “passive failure” as “a failure of a component to maintain its structural integrity or the blockage of a process flow path.” In this standard, the term refers to a random failure, its consequential effects assumed in addition to an initiating event, and its consequential effects for the purpose of safety-related fluid system design and analysis. This standard defines rules for application of the single failure criteria. During the short term, the single failure considered may be limited to an active failure. During the long term, assuming no prior failure during the short term, the limiting single failure considered can be either active or passive. “Long term” is defined as that period of safety-related fluid system operation following the short term, during which the safety function of the system is required. “Short term” is defined as that period of operation up to 24 hours following an initiating event.

Additionally, TSTF-448 and the associated TS Bases describe the expectation to consider passive failures. Specifically the TSTF states, “No single active or passive failure will cause the loss of outside or recirculated air from the CRE [control room envelope].”

The VES passive filtration line is required to meet single failure criteria. The single active or passive failure of a component in the VES passive filtration line, assuming a loss of outside power, shall not impair the ability of the system to perform its design function. The staff noted that if the present passive filtration design proposed by the applicant has a passive failure (e.g., the nozzle section of the eductor fails to induce the minimum 17.0 m^3/min (600 cfm) flow), the safety function of the filtration may not be achievable. The proposed VES passive filtration line does not have independent, redundant trains to recirculate and filter the CRE. The staff asked the applicant to provide a justification that the described system meets the single failure criteria or to provide a redundant filter train. The applicant responded to RAI-SRP6.4-SPCV-13, Revision 0 in a letter dated December 11, 2009 by stating the following:

> The primary components that comprise the main control room habitability system (VES) passive filtration line are duct work, two silencers, an eductor, and a filtration unit. The passive filtration line has no active components. The only active components in the VES are in the air delivery portion of the system that provides the motive flow to induce to the filtration flow. The air delivery portion of the system also provides breathable air for main control room occupants during abnormal scenarios. In the air delivery portion of the system, there are redundant flow paths. The redundant flow paths prevent a single active or passive failure from impairing the ability of the system to perform its design function. Based on the guidance in SECY-77-439, the passive filtration portion of the system must be evaluated for a credible passive failure 24 hours after the start of an event. SECY-77-439 defines a passive failure as events such as a line blockage or structural failure of a static component that limits the effectiveness of the component. Though a passive failure in the passive filtration portion of the VES is highly unlikely, it would not impair main control room habitability. Dose analysis for the AP1000 main control room was performed to verify that in the event of a passive failure in the passive filtration portion of the VES 24 hours after the initiation of the event operator doses would remain below 5 rem TEDE. The limiting AP1000 main control room dose scenarios were evaluated for a loss of filtration flow 24 hours into an accident. These scenarios are limiting since they involve a release 24 hours after the initiation of the event. The analysis showed the following acceptable increases in dose rates compared to the scenarios when filtration is available for 72 hours. Therefore, the passive filtration portion of the VES can sustain a single passive failure without impairing main control room habitability for the first 72 hours following a design basis accident.

The applicant demonstrated that filtration was not needed in the long term or after 24 hours. The staff noted that this response adequately addressed the blockage of the filter or ductwork. However, it did not address the potential blockage of the eductor, which would prevent the required breathable air from entering the control room. These concerns were brought to the attention of the applicant. In a letter dated February 25, 2010, the applicant submitted a response to RAI-SRP6.4-SPCV-13, Revision 2, which incorporate a bypass line for the eductor and thereby provides operators with the ability to deliver the air flow from the emergency air storage tanks following the highly unlikely passive single failure of the eductor. The design addition added a flow control orifice and normally closed manual valve to allow the 65 scfm of breathable air to flow into the MCR without passing through the eductor. Also, the applicant added a normally open manual valve upstream from the eductor to provide full isolation of the flowpath to the educator. The revised dose analysis demonstrates that air filtration is not necessary in the long term. The manual bypass valves with the safety-related flow meter from the compressed air tanks allow the air delivery function to be accomplished if there is a blockage. As a result, the staff finds the applicant’s response acceptable because the design is capable of withstanding the unlikely credible single failures in the passive filter train.

The applicant has designed a filter system that meets, to the extent practicable, the guidance of RG 1.52. The applicant proposed surveillance and testing consistent with the intent of RG 1.52 and the STS. The design was demonstrated to function in scale-model testing. The applicant has addressed all credible single failures. As a result, the staff finds the single filter train acceptable.

6.4.2.3 Evaluation of Design Changes To Reduce Unfiltered In-Leakage

The applicant changed the MCR envelope purge design. The VES discharge air flow is now directed into the entry vestibule to provide a continuous vestibule purge. This helps to reduce the radioactivity introduced into the MCR each time there is access to or from the MCR during a radiological accident. The VES discharge dampers originally discharged through the MCR wall directly to the atmosphere outside the MCR. This design change redirects the damper discharge flow into the MCR vestibule and adds openings to allow free passage from the vestibule to the hallway.

The applicant made a number of other changes to the design of the CRE. For example, the applicant eliminated ductwork penetrating the CRE. The applicant also installed isolation capability for various control room penetrations, like the sanitary system and normal vents. Additionally, the applicant proposed different materials for the control room. Each of these changes improves the overall design, and the staff finds them acceptable. The staff notes that the overall effectiveness of the CRE is demonstrated through the testing associated with the control room integrity program.

During the course of the review, the applicant proposed a number of other changes. For example, the applicant proposed an additional actuation to isolate the normal control room ventilation system. The applicant also proposed to remove the dose calculations associated with the normal ventilation system. According to TR-122, “AP1000 COL Standard Technical Report Submittal of APP-GW-GLN-122 (TR-122),” Revision 0, dated July 27, 2007; the DCD did not report the dose analysis for the nuclear island non-radioactive ventilation system (VBS) operating cases because the VBS does not continue to operate if a high-2 radioactivity level is detected. The staff was concerned that the normally operating active ventilation system (VBS) in the supplemental air filtration mode should not be isolated early and should be demonstrated to meet the regulatory limits. With active systems, the VBS is the preferable system to function because it will provide greater comfort to the operators and will provide active cooling for the control room equipment. In response to RAI-TR122-SPCV-01, the applicant stated that it will update the DCD to present the results for the case with the VBS operating for the duration of the accident and remove the earlier isolation of the VBS.

The applicant also proposed to procedurally delay access into the control room. According to TR-122, Revision 0, the AP1000 requires procedurally delaying access to the control room in order to meet the operator dose limits. The staff was concerned that GDC 19 requires that adequate radiation protection shall “be provided to permit access and occupancy of the control room under accident conditions.” The AP1000 control room, as proposed by TR-122, did not seem to provide adequate radiation protection to permit access under accident conditions because of the access control process. In its response to RAI-TR122-SPCV-01, submitted in a letter dated December 17, 2008, the applicant stated that it would update the DCD to present the results for the case without consideration for an MCR entry time delay. The results will show that the AP1000 design with the vestibule purge configuration fully satisfies GDC 19, with or without credit for the use of the entry time delay. The staff finds this response acceptable.

6.4.2.4 Redesignation of Technical Support Center

The applicant proposed to redesignate what was referred to as the TSC in the certified design to the control support area. The change removed the TSC from the Section 6.4 description in Tier 2. If a reactor is being built on a site that already has an operating reactor and a functioning TSC, it is reasonable for the COL applicant to want a single TSC. The applicant added a statement to Tier 2* that requires the TSC to be located in the control support area. As a result, if a COL applicant would like to locate the TSC somewhere other than in the control support area, a Tier 2* departure requiring NRC approval would be necessary. In a subsequent letter dated January 27, 2010, the applicant removed the Tier 2* information and included a statement in DCD Chapter 18 indicating that the location of the TSC would be in the control support area. Section 13.3 of this report approves this change. Because the information is Tier 2, rather than Tier 2*, a departure may not require prior NRC approval. However, the location of the TSC is part of the Emergency Plan, which a COL application is required to include under 10 CFR 52.79(a)(21), "Contents of applications; technical information in final safety analysis report." As a result, regardless of whether the Tier 2 departure would require NRC approval, the Emergency Plan and the location of the TSC therein would be subject to prior NRC review and approval. The analysis showing that the control support area remains habitable following an accident, if the nonsafety-related VBS system is available, remains in the DCD. The analyses were redone in the amendment with the higher dispersion factors, and the results remain within regulatory limits. Although these values were removed from the DCD in one of the intervening revisions, the DCD now refers to these analyses as the "VBS Operating" dose results. Because there are no impacts from a safety perspective associated with this change, the staff finds the change acceptable.

6.4.2.5 Changes to Improve Operational Flexibility

TS 3.9.7 specifies that the minimum radioactive decay time ensures that the radiological consequences of a postulated fuel handling accident inside containment or in the fuel handling area inside the auxiliary building are consistent with the assumptions in AP1000 DCD Tier 2, Chapter 15.

In TR-122, the applicant changed the minimum decay time mandated in the TS to 48 hours. This TS change affects the convenience of plant operations; there are no system design concerns. The staff finds this change acceptable based on an acceptable finding associated with the related dose calculations that are being reviewed by the Office of New Reactors, Division of Site and Environmental Reviews, Technical Specification Branch.

Supplementary changes have also been made to VES to increase the reliability of the system and provide a safe environment for workers performing maintenance on the system. Because there was concern about isolating this system for repair or maintenance with a single valve, double isolation valves have been added to the banks of air tanks and the supply lines. Individual fill and vent lines have also been added to each bank of tanks to allow one bank to be taken out of service and be recharged while keeping the other three banks of tanks online and ready for service at all times. Revised Figure 6.4-2 in the DCD depicts these changes.

The applicant modified the condition in TS 3.7.6 for "VES inoperable" to specify a condition for "One bank of VES air tanks (8 tanks) inoperable." The completion time to increase pressure in the operable tanks to the upper portion of the system operating band is 12 hours. The completion time is 7 days to restore the VES to operable status.

In the revised TS bases (B 3.7.6), the applicant stated the following:

> If one bank of VES air tanks (8 tanks out of 32 total) is inoperable, then VES is able to supply air to the MCR for 54 hours (75 percent of the required 72 hours). If VES is actuated, operator must take actions to maintain habitability of the MCR once the air in the tanks has been exhausted. The VBS supplemental filtration mode or MCR ancillary fans are both capable of maintaining the habitability of the MCR after 54 hours.
>
> Increasing the pressure in the OPERABLE tanks from the minimum pressure of 3400 psig to the upper portion of the system operating band maximizes the time the VES will be able to supply air to the MCR. The 12-hour Completion Time provides sufficient time to achieve the increased pressure.
>
> With one bank of VES air tanks inoperable, action must be taken to restore OPERABLE status within 7 days. In this Condition, the remaining OPERABLE VES air tanks, along with compensatory operator actions, are adequate to protect the main control room envelope habitability. The 7 day Completion Time is based on engineering judgment, considering the low probability of an accident that would result in a significant radiation release from the reactor core, the low probability radioactivity release, and that the remaining components and compensatory systems can provide the required capability.

The staff reviewed the rationale. At 75 percent VES air capacity (54 hours); the system no longer accomplishes the safety function for 72 hours. Additionally, the VBS supplemental filtration is not safety-related. The applicant's regulatory treatment of non-safety systems (RTNSS) (ancillary fans) may not be available in 54 hours. Additionally, increasing the pressure in the operable tanks is not a reviewed operating condition and may not be advisable with a degraded system. Further, restoring or replacing an inoperable tank is a relatively simple evolution, and it is not clear why 7 days is needed to complete this action.

The 72-hour design basis for passive safety system capability and operator actions 72 hours after accident initiation has been evaluated as part of the RTNSS process. The safety-related design basis for the VES is to operate for 72 hours. The 54-hour VES air capacity is in a condition outside the accident analysis. If one bank of VES air tanks (8 tanks out of 32 total) is inoperable, the loss of safety function would merit more immediate action.

The staff asked the applicant to explain why such a long completion time is appropriate for the loss of a safety function to restore operability.

The applicant responded in a letter dated December 3, 2009, to RAI-SRP6.4-SPCV-14, Revision 0 by stating the following:

> Any leakage that would cause the system to enter the Technical Specification of "One bank of VES air tanks (eight tanks) inoperable" would most likely be at the safety-relief valves (V040A/B/C/D). The air bank with the excessively leaking relief valve will be individually isolated and depressurized to allow the safety-relief valve to be replaced. Because only the air bank with the leaking safety-relief valve is isolated, the remaining three air banks will be at or above the minimum operating pressure of the system. The maintenance on an individual air bank can be done without affecting the other 3 banks in any way.

> The pressure in the operable tanks will not be increased. The operable tanks are credited as maintaining a normal minimum pressure of 3400 psig.
>
> The time limit of 7 days for this Technical Specification is acceptable based on engineering considerations with regard to the low probability of an accident that would result in a significant radiation release from the fuel, the low probability of not containing the radiation, and that the remaining components and compensatory systems can provide the required capability to maintain the MCRE [ ] habitable. If one bank of tanks is taken out of service, 75 percent of the system will still be available to supply air to the control room in the event of an accident. Dose calculations have been performed to verify that the MCR dose limits will remain within the requirements of GDC 19 if 75 percent (54 hour supply of breathable compressed air) of VES is available and compensatory measures, through the use of the ancillary fans, are taken at 54 hours for the remainder of the event. The MCR ancillary fans are located in the auxiliary building as indicated in Tier 1 Table 2.7.1-5 of the DCD and will be available if required 54 hours after the initiation of VES.
>
> The Tech Spec Bases 3.7.6 as submitted in RAI-SRP6.4-SPCV-06, Revision 0 are marked up to include that GDC 19 requirements are met with 54 hours of VES with compensatory measures taken at 54 hours.

Based on discussions with the staff at a public meeting on December 15, 2009, the applicant revised this response in a letter dated March 25, 2010. RAI-SRP6.4-SPCV-14, Revision 2, included additional required actions in Limiting Condition for Operation (LCO) 3.7.6, Condition D, to provide greater confidence that the MCR envelope can be maintained habitable for 72 hours following a DBA during a condition where one bank of VES emergency air storage tanks is not available. The additional action requires confirmation that the VBS MCR ancillary fans and supporting equipment are available within 24 hours of a bank of VES emergency air tanks going out of service.

Action D.1 has also been clarified. The applicant revised action D.1 to require verification of the pressure in the unaffected banks of air tanks. The pressure in the affected tanks should be verified to be above 23.4 MPa (3,400 psig) within 2 hours and once every 12 hours thereafter. The applicant removed the reference to increasing the pressure in the operable tanks above 23.4 MPa (3,400 psig) to the upper portion of the system operating band from action D.1 and the associated bases. Based on the discussion above and an acceptable finding from the Office of New Reactors Technical Specification Branch, the staff finds the applicant's TS adequate.

6.4.3 Conclusion

The staff has reviewed the applicant's changes to the DCD on the VES system. On the basis of the evaluation described in NUREG-1793 and this report, the staff concludes that the portion of the DCD on the VES system is acceptable and that the application to amend the DC meets the requirements of Subpart B, "Standard Design Certifications," of 10 CFR Part 52, "Licenses, Certifications, and Approvals for Nuclear Power Plants," that are applicable and technically relevant to the AP1000 standard plant design. This conclusion is based on acceptable findings by the other responsible NRC branches. Notably, there are related changes in Chapters 3, 7, 9, 15, and 16, which are the responsibility of other branches. Additionally, the DCD revisions reviewed by the staff were submitted as draft.

In a letter dated July 29, 2010, the applicant submitted Change Notice 73. In the letter the applicant identified that the design change noted in this section required a higher pressure at the pressure regulator. As a result, the minimum pressure in the canistered air tanks also needs to be higher. The technical evaluation of this aspect of the design change is included in Chapter 23 of this report.

6.5.2 Containment Spray System

6.5.2.1 Summary of Technical Information

In Revision 17 of the DCD, the applicant changed the description of the nonsafety-related containment spray system in Section 6.5.2.1 and Figure 9.5.1, "Fire Protection System P&ID," in order to correct errors.

6.5.2.2 Evaluation

Revision 15 of DCD Tier 2, Section 6.5.2.1.1, states that the remotely operated valve (FPS-V701) downstream of the manual isolation valve in the spray riser is normally closed, but Figure 9.5.1 shows it as open. In Revision 17 of the DCD, the applicant changed the text to describe this valve as open to match Figure 9.5.1. However, as described in the applicant's January 8, 2009, response to RAI-SRP6.0-SPCV-02, Revision 1, this valve is actually normally closed; therefore, the applicant proposed changes to Section 6.5.2.1.1 and Figure 9.5.1 of the DCD to describe it as such. The staff finds the changes acceptable because the text will revert to the Revision 15 description of the valve and the original error in Figure 9.5.1, which showed the valve as open, will be corrected.

Revision 15 of DCD Tier 2, Section 6.5.2.1.1, incorrectly states that closing the passive containment cooling water system fire header isolation valve (PCS-V005) isolates the primary fire water tank, when it actually isolates the PCCWST. Revision 17 corrects this error, and the text is now consistent with Tier 1, Figure 2.3.4-1, "Fire Protection System," and Figure 6.2.2.1, "PCS P&ID."

6.5.2.3 Conclusion

These changes are acceptable and have no impact on the evaluation of the nonsafety-related containment spray system reported in NUREG-1793, Section 6.5.2.

6.6 Inservice Inspection of Class 2, 3, and MC Components

6.6.1 Summary of Technical Information

In Revision 16 to the AP1000 DCD, the applicant added metallic containment (Class MC) components to the scope of the preservice inspection (PSI) and inservice inspection (ISI) programs. Furthermore, the changes defined the responsibilities for preparation of the PSI and ISI programs and removed the ISI program discussion from Section 3.8.2, "Steel Containment," which is dedicated to the design, rather than the inspection of the containment.

In Revision 17, the applicant revised Section 6.6.2 to delete the phrases that there are no Quality Group B and C components that require ISI during operation and that relief from Section XI requirements for the baseline DC code will not be required.

6.6.2 Evaluation

In Revision 16 of the AP1000 DCD, the applicant proposed to add Class MC components to the scope of the PSI and ISI programs. 10 CFR 50.55a(b)(2)(vi), “Codes and standards,” provides requirements for licensees to select their effective Edition and Addenda of Subsections IWE and IWL for ASME Code Section XI, as modified and supplemented by the requirements in paragraphs (b)(2)(viii) and (b)(2)(ix). ASME Code Section XI, Subsection IWE is dedicated to the PSI and ISI of Class MC components. The AP1000 DCD, Revision 16 changes ensure that the metallic containment integrity is maintained through periodic inspection and testing as defined under the regulations and ASME Code Section XI. In addition, the inclusion of Class MC components as part of the PSI/ISI program provides heightened visibility of the operational program by including Class MC components along with ASME Code Class 2 and 3 components, which receive PSI/ISI. The staff concludes that the change to include Class MC components within the PSI and ISI program is in compliance with the requirements of 10 CFR 50.55a and ASME Code Section XI, and is, therefore, acceptable.

In Revision 17 of the AP1000 DCD, Section 6.6.2, the applicant proposed to remove the phrase that there are no Quality Group B and C components that require ISI during operation.

In the AP1000 DCD, Section 6.6.2, the applicant states that ASME Code Class 2, 3, and MC components are designed so that access is provided in the installed condition for visual, surface and volumetric examinations specified by the ASME Code. Furthermore, it states that considerable experience has been used in designing, locating, and supporting Quality Group B and C (ASME Code Class 2 and 3) pressure-retaining components to permit PSI and ISI. The applicant’s removal of the statement that there are no Quality Group B and C components that require ISI during reactor operation does not eliminate the performance of ISI. Furthermore, neither 10 CFR 50.55a nor ASME Code Section XI prohibits the performance of ISI during plant operation. Since the proposed changes would allow the possibility to expand the performance of ISI during operational conditions rather than eliminate the ISI examinations, the staff concludes that this portion of the proposed change is acceptable.

In Revision 17 of the AP1000 DCD, Section 6.6.2, the applicant proposed to remove the sentence: “Relief from Section XI requirements will not be required for ASME Section III, Class 2, 3, and MC pressure retaining components in the AP1000 plant for the baseline design certification code.”

In the AP1000 DCD, Section 6.6.2, the applicant states that ASME Code Class 2, 3, and MC components are designed so that access is provided in the installed condition for visual, surface and volumetric examinations specified by the ASME Code. Furthermore, it states that considerable experience has been used in designing, locating, and supporting Quality Group B and C (ASME Code Class 2 and 3) pressure-retaining components to permit PSI and ISI. The AP1000 DCD also states that the goal of designing for inspectability is to provide for the inspectability, access and conformance of component design with available inspection equipment and techniques. Factors such as examination requirements, examination techniques, accessibility, component geometry and material selection are used in evaluating component designs, as stated by the applicant.

In addition, the regulations under 10 CFR 50.55a(g)(3)(ii) require that Class 1, 2, and 3 components and supports be designed and provided with access to enable the performance of both PSI and ISI requirements set forth in the Editions and Addenda of Section XI of the ASME

Code incorporated by reference in paragraph (b) of this section applied to the construction of the particular component. However, 10 CFR 50.55a recognizes that inaccessible areas for the containment cannot be eliminated completely. 10 CFR 50.55a(b)(2)(ix)(A) states that for Class MC applications, the licensee shall evaluate the acceptability of inaccessible areas when conditions exist in accessible areas that could indicate the presence of or result in degradation to such inaccessible areas. The staff concludes that proposed changes recognize that inaccessible areas may be present in the design of Class MC components and that sufficient effort will be incorporated into the design of Class 1, 2, and 3 components to meet the requirements under 10 CFR 50.55a. The staff concludes that the change is in compliance with the regulations and is, therefore, acceptable.

6.6.3 Conclusion

Based on the above evaluation, the staff concludes that the AP1000 DCD changes as proposed in Revisions 16 and 17 meet the requirements of 10 CFR 50.55a and ASME Code Section XI for Class 2, 3, and MC components and are, therefore, acceptable. Therefore, the proposed DCD changes are acceptable pursuant to 10 CFR 52.63(a)(1)(vii) on the basis that they contribute to the increased standardization of the certification information.

7. INSTRUMENTATION AND CONTROL

Westinghouse (the applicant) has submitted information in support of its design certification (DC) amendment application that the applicant considers “proprietary” within the meaning of the definition provided in Title 10 of the *Code of Federal Regulations* (10 CFR) 2.390(b)(5), “Public inspections, exemptions, requests for withholding.” The applicant has requested that this information be withheld from public disclosure and the Nuclear Regulatory Commission (NRC) staff agrees that the submitted information sought to be withheld includes proprietary commercial information and should be withheld from public disclosure. This chapter of the NRC staff’s evaluation includes proprietary information that has been redacted in order to make the evaluation available to the public. The redacted information appears in “square brackets” as follows:

[ ]

The complete text of this chapter, including proprietary information, can be found at Agencywide Documents Access and Management System (ADAMS) Accession Number ML112091879 and can be accessed by those who have specific authorization to access Westinghouse proprietary information.

7.1 Introduction

Chapter 7 of the AP1000 design control document (DCD) includes changes to the descriptions of commitments pertaining to the primary instrumentation and control (I&C) systems of the AP1000 design, as evaluated in NUREG-1793, “Final Safety Evaluation Report Related to the Certification of the AP1000 Standard Design,” issued by the NRC in September 2004. Additionally, AP1000 DCD Tier 1, Section 2.5, includes changes to the proposed design description and inspections, tests, analyses, and acceptance criteria (ITAAC) for I&C systems. This report must be used in concert with the original version of NUREG-1793 and Supplement 1 to completely understand the full evaluation of the AP1000 I&C systems standard design. The sections identified and addressed below have had additions, alterations, or deletions incorporated into the technical information presented previously in the certified design of Revision 15 of the AP1000 DCD. The sections not listed below had no appreciable technical changes and, thus, are not included in this report.

Although all open items have been resolved prior to the final issuance of this supplement of the safety evaluation report (SER), this report discusses what open items were generated when it considered an applicant’s original submittal and response to be inadequate.

In the proposed changes to the AP1000 DCD, the applicant provided additional information related to the architecture of its safety-related I&C protection system, referred to as the protection and safety monitoring system (PMS); the diverse back-up system to the PMS, the diverse actuation system (DAS); and data communications protocols and methods utilized to ensure a secure development and operational environment (SDOE). The applicant also proposed minor modifications to some of the interlock and control systems.

7.1.3.1 Compliance with Standard Review Plan (SRP) Criteria

The staff reviewed the additional and amended information provided by the applicant, using the guidance in Chapter 7, “Instrumentation and Control Systems,” of NUREG-0800, “Standard

Review Plan [SRP] for the Review of Safety Analysis Reports for Nuclear Power Plants: Light Water Reactor Edition," Revision 5. The NRC developed NUREG-1793 using the guidance of Revision 4 of NUREG-0800, which did not include Section 7.8, "Diverse Instrumentation and Control Systems," or Section 7.9, "Data Communication Systems." Therefore, although this supplement follows the format of NUREG-1793, the NRC added Section 7.8, "Diverse Instrumentation and Control Systems," and Section 7.9, "Data Communication Systems," to discuss the staff's review of these issues. Where necessary, the staff correlated the information in Sections 7.8 and 7.9 with other pre-existing Chapter 7 sections.

7.1.3.2 Compliance with Industry Standards

The applicant submitted a number of technical reports (TR) associated with I&C systems, which it incorporated by reference into the AP1000 DCD. Based upon the letter, "Secondary References in a Design Certification Rule," dated May 3, 1994, the staff determined with the concurrence of utility representatives and other members of the commercial nuclear industry that documents referenced in Tier 1 and Tier 2 information in the AP1000 DCD should be considered part of the licensing basis. Therefore, the addition of these documents is deemed acceptable to the staff.

In several cases, the applicant referenced revisions of the same industry standards and other regulations in its TRs different from those referenced in DCD Revision 15. The applicant stated that all newly created or revised technical documents that do not refer to the guidance or standards certified in Revision 15 of the AP1000 DCD will reference currently issued guidance or standards provided the newly referenced guidance or standards include all acceptance criteria to those references certified in the Revision 15. The staff found the response acceptable.

7.1.3.3 Compliance with 10 CFR Part 52

Based upon the discussion in Section 7.1.3.3 of NUREG-1793, the standardized power plant designer or combined license (COL) applicant will satisfactorily demonstrate that "the digital I&C system design development process, as documented in the DCD, will ensure that the digital I&C system, as designed, will satisfactorily accomplish its safety functions."

All newly submitted documentation is to support and agree with all previously submitted design documents to enable the NRC to reach the same conclusion as in NUREG-1793.

The regulations in 10 CFR 52.63, "Finality of standard design certifications," are applicable to modifications addressed in this chapter, which supplements NUREG-1793 to address the applicant's amendment request.

7.1.4 Tier 1 Material

Revision 19 of AP1000 DCD Tier 1, Section 2.5, includes information associated with the DAS and the PMS within the first two phases of the software, logic-based, or programmable technology design processes. The proposed alteration to the DAS design allows the use of technology other than microprocessor-based systems (i.e., firmware or analog technology) and the selection of the specific PMS design platform, the Common Q platform. Revision 19 of the DCD also proposes to remove part of the design acceptance criteria (DAC), which is a subset of ITAAC, in Tier 1, Section 2.5. Sections 7.2 and 7.8 of this report discuss these changes.

The applicant classifies the first two phases of the PMS and DAS lifecycles as the design requirements (or conceptual) phase and system definition phase, for both the PMS and the DAS in the certified design. Branch Technical Position (BTP) 7-14, Revision 5 as well as Branch Technical Position HICB-14, to which the AP1000 DCD was certified, in Chapter 7 of NUREG-0800 refers to these two phases of development as the “Planning Activities” phase and the “Requirements Activities” phase of the PMS software lifecycle (SLC) and the DAS programmable technology lifecycle, respectively.

AP1000 DCD Tier 1, Section 2.5.1, identifies the ITAAC for the DAS, and Section 2.5.2 identifies the ITAAC for the PMS. Section 2.5.1, Design Description 4, and Table 2.5.1-4, “Inspections, Tests, Analyses and Acceptance Criteria,” discuss Design Commitment 4, which identifies the phases of the programmable technology development life cycle for the DAS. Likewise, Section 2.5.2, Design Description 11, and Table 2.5.2-8, “Inspections, Tests, Analyses and Acceptance Criteria,” discuss Design Commitment 11, which identifies all phases of the SLC for the PMS. Based on the cover letter received with Revision 17 of the AP1000 DCD, the applicant considers both of these items DAC.

To address the DAC, the applicant provided design information related to the design requirements and system definition phases of the PMS SLC and the DAS programmable technology lifecycle. For both the DAS and PMS sections (Sections 2.5.1 and 2.5.2, respectively) of the Tier 1 document, the applicant proposed the removal of the first two phases of the SLC processes in Revision 17 of the AP1000 DCD. Sections 7.2.5 and 7.2.8 of this report provide further discussion of this topic as it relates to the PMS, and Sections 7.8.2 and 7.8.3 discuss the lifecycle development process for the DAS.

The additional detailed design information for the I&C architecture and communications results in increased standardization of this aspect of the design. Therefore, the change meets the finality criterion for changes in 10 CFR 52.63(a)(1)(vii).

7.1.5 Instrumentation and Control System Architecture

In support of the proposed changes to the AP1000 DCD, the staff reviewed the following TRs:

- APP-GW-GLR-071/ Westinghouse Commercial Atomic Power (WCAP)-16675-P, “AP1000 Protection and Safety Monitoring System Architecture Technical Report,” Revision 5 (TR-89). This report describes how the PMS will function. Section 7.2.2, “Protection and Safety Monitoring System Description,” and Section 7.9, “Data Communications Systems,” discuss this report.

- APP-GW-GLR-065/WCAP-16674-P, “AP1000 I&C Data Communication and Manual Control of Safety Systems and Components,” Revision 4 (TR-88). This report provides critical design aspects of the communications methodology and various protocols when dealing with inter- and intra-division communications and safety-related to nonsafety-related communications methods. The report also includes key information related to the manual operation of the AP1000 safety systems. Sections 7.2.2, 7.5.3, 7.9.3, and 7.9.4 of this report discuss WCAP-16674-P in greater detail.

- APP-GW-GLN-022, “AP1000 Standard Combined License Technical Report DAS Platform Technology and Remote Indication Change,” Revision 1 (TR-97), dated May 2007. This report provides information associated with the relocation of DAS equipment, and it also incorporates changes to allow a microprocessor-based or alternative technology to serve as the principal design of the DAS platform. Section 7.1.6, “Diversity and Defense in Depth Assessment of the AP1000 Protection System,” and Section 7.8, “Diverse Instrumentation and Control Systems,” of this report provide additional discussion on APP-GW-GLN-022.

- APP-GW-GLR-017, “AP1000 Standard Combined License Technical Report,” Revision 0 (TR-42). This report summarizes the applicant’s proposed resolution of the 10 generic open items (GOIs) and 14 plant-specific action items (PSAIs) associated with the NRC review of the Westinghouse Common Q platform. Section 7.2.3 includes more information on this document.

- APP-GW-GLR-024/WCAP-16361-P, “AP1000 Setpoint Calculations for Protective Functions,” Revision 1 (TR-28). This report discusses the calculation of setpoints and setpoint methodology for the PMS. Section 7.2.7 addresses additional information on setpoint methodology in AP1000 I&C systems.

- APP-GW-GLR-018, “Failure Modes and Effects Analysis and Software Hazards Analysis for AP1000 Protection System,” Revision 0 (TR-43). This report summarizes the steps taken to perform the failure modes and effects analysis (FMEA) and software hazards analysis (SHA) and serves primarily as a pointer to the AP1000 FMEA and SHA reports.

- APP-GW-JJ-002/WCAP-16438-P, “FMEA of AP1000 Protection and Safety Monitoring System,” Revision 3. This report provides the postulated failure modes and effects the PMS will undergo as a result of the given failures.

- APP-PMS-GER-001/WCAP-16592-P, “Software Hazard Analysis of AP1000 Protection and Safety Monitoring System,” Revision 2. This report discusses the risks associated with the use of software or programmable technology in protection and control systems. The report will be discussed further in Section 7.2.

- APP-GW-GLN-004, “Instrument and Control Design Change,” Revision 0 (TR-39), incorporates signal and other name changes to the post-accident monitoring system (PAMS), which interfaces with the qualified data processing system (QDPS).

- WCAP-17179, “AP1000 Component Interface Module Technical Report,” Revision 2. This report discusses the design of the component interface module (CIM) within the PMS in greater detail than in the WCAP-16675-P report. The report is discussed further in Sections 7.2 and 7.9.

- WCAP-17184-P, “AP1000 Diverse Actuation System Planning and Functional Design Summary Technical Report,” Revision 2. The report defines the planning process and other design attributes of the DAS. The report will be discussed in greater detail in Section 7.8.

- WCAP-17201-P, "AC160 High Speed Link Communication Compliance to DI&C-ISG-04 Staff Positions 9, 12, 13 and 15 Technical Report," Revision 0. This report discusses how the PMS will comply with certain acceptance criteria in the digital instrumentation and controls (DI&C) Interim Staff Guidance (ISG)-04. The TR will be further evaluated in Section 7.9.

- WCAP-17226-P, “Self-Powered Detector Signals in the AP1000 In-Core Instrumentation System", Revision 2. This report discusses the interactions between the nonsafety-related in-core instrumentation system (IIS) and the safety-related core exit thermocouples (CETs). As the report covers the interaction of safety-related CETs and the IIS, this report will be covered in Section 7.5.7.

- APP-GW-J0R-012, “AP1000 Protection and Safety Monitoring System (PMS) Computer Security Plan,” Revision 1. This report discusses how the PMS is constructed in an SDOE and will be discussed further in Section 7.9

- APP-GW-GLR-137, “Bases of Digital Overpower and Overtemperature Delta-T (OP∆T/OT∆T) Reactor Trips,” Revision 1. This report, also known as APP-GW-GLR-005, discusses the changes associated with how the PMS calculates its OP∆T and OT∆T signals. In addition to the content in Section 7.2, Appendix 7A provides additional information regarding this TR.

The staff reviewed WCAP-16592-P, Revision 2, and determined the information in the report adequately addresses the subject matter related to hazards or risks associated with the use of software or programmable technology in the PMS with one notable exception. Revision 1 of the report fails to discuss the potential hazards and/or risks associated with utilizing a firmware-based device, such as the CIM or safety remote node controller (SRNC) within the CIM subsystem of the PMS. While the CIM and SRNC will not use any software during their operation, the use of a programming language and other similar protocols during device development must be addressed and any hazards associated with the CIM and SRNC development process must be adequately mitigated or eliminated prior to their use within the PMS. Based upon the additional information required by the staff to make a determination of acceptability, the applicant submitted a response to request for additional information (RAI)-SRPSHA-01, Revision 1, on June 28, 2010. The staff finds the commitments to update the SHA, including the removal of text stating that since the CIM and SRNC execute no software when operating, there is no need to cover their development or operation in the SHA, are acceptable. Additionally, in the response, the applicant committed to adding several potential hazards and mitigation strategies based upon the use of the CIM system in the PMS in Section 5 of the SHA. The staff previously identified this issue as Open Item OI-SRP7.1-ICE-02. In a subsequent revision to the SHA, the applicant included the potential hazards and mitigation strategies, which resolves this issue.

The applicant replaced the remote shutdown workstation with the remote shutdown room (RSR). The staff finds that the change complies with all applicable acceptance criteria. Specifically, according to design drawings presented to the staff, the RSR transfer switch exists in a hallway located between the main control room (MCR) and the RSR. The staff asked the applicant to explain how it provides positive control of the reactor at all times, in accordance with 10 CFR 50.54(k), “Conditions of licenses.” The applicant responded to RAI-SRP7.1-ICE-13 by stating that control of the RSR switch would be primarily through administrative or procedural control. In a “normal” evacuation of the MCR, licensed operators would pre-staff the RSR before transferring reactor control. In an extreme life-threatening emergency, the licensed operators would be directed to manually scram the reactor before exiting the MCR, and, during the short journey to the RSR, move the transfer switch to RSR control and execute the necessary operator actions that follow a reactor scram. The staff finds this approach acceptable.

In response to RAI-SRP7.1-ICE-14, the applicant provided additional information regarding the overall makeup of its electrical distribution system. The staff reviewed the proposed grounding system for instrumentation and computer systems. Section 8.3.1.1.7 of the AP1000 DCD describes the four primary grounding systems for the AP1000. In particular, the instrument and computer systems use a separate radial grounding system. Based upon the information in the referenced section and the diagrams in Chapter 8 for the Class 1E instrumentation power distribution system, the staff finds the grounded, three-phase wye transformer configuration acceptable for the I&C systems.

In Section 7.1.7, "References," of Revision 17 of the AP1000 DCD, the applicant deleted several references from the certified reference section without sufficient basis. As a result, the staff identified this as Open Item OI-SRP7.1-ICE-03. In its response to Open Item OI-SRP7.1-ICE-03, dated June 22, 2010, the applicant committed to update key reference documents in Chapter 7 of the AP1000 DCD, Tier 2, as well as update Tier 2, Table 1.6-1. Additionally, the applicant committed to update its Tier 2* document list with WCAP-16361-P and WCAP-17179-P, and restore WCAP-15927, Revision 2, to the Tier 2* list as well. In addition, the applicant committed to remove all references to APP-GW-GLR-104, and other associated references to cyber security, as the staff's review under 10 CFR Part 50, "Domestic licensing of production and utilization facilities," does not encompass a cyber security review. Further information on cyber security is provided in Chapter 13 of the SER for the respective COL. Based upon the staff's review of the applicant's commitments in the Open Item OI-SRP7.1-ICE-03 response, the staff finds the changes are acceptable. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

The staff could not identify several of the abbreviations the applicant used in some of its originally amended TRs. In RAI-SRP7.1-ICE-25, the staff asked the applicant to define all abbreviations in the text and diagrams in TR-89, and similar documents, as well as terms such as "hardwired," "bypass function," "partial trip mode," and "failsafe trip." The NRC discussed these issues with the applicant's technical staff on January 29-30, 2009, at its Rockville, Maryland office. The staff received adequate responses to RAI-SRP7.1-ICE-24, RAI-SRP7.1-ICE-25, RAI-SRP7.2-ICE-02, RAI-SRP7.2-ICE-03, and RAI-SRP7.2-ICE-06; which the applicant has incorporated into the current revision of WCAP-16675-P and other affected TRs.

The additional detailed design information for the I&C architecture and communications results in increased standardization of this aspect of the design. Therefore, the change meets the finality criterion for changes in 10 CFR 52.63(a)(1)(vii).

7.1.6 Defense-in-Depth and Diversity Assessment of the AP1000 Protection System

Section 7.8 of this report discusses the safety evaluation of changes to the approved PRA-based diversity and defense-in-depth (D3) design.

7.2 Reactor Trip System

7.2.2 Protection and Safety Monitoring System Description

As described in Revision 17 of the AP1000 DCD, the applicant identified the Common Q platform as its safety-related protection system platform, negating the reference to WCAP-13383, “AP600 Instrumentation and Control Hardware and Software Design Verification and Validation Process Report,” since that report primarily dealt with the use of the Eagle 21 platform, which will not be used in the AP1000 design. Specifically, in Section 7.1 of the AP1000 DCD Tier 2, the applicant removed references to the use of the Eagle 21 protection system hardware and committed to use the Common Q platform. This change was verified in the applicant’s response to Open Item OI-SRP7.1-ICE-03, dated June 22, 2010, which the staff finds acceptable. As a result, removal of WCAP-13883 from the AP1000 DCD, Tier 2, Chapter 7, is acceptable.

In WCAP-16675-P, Revision 5, the applicant provided design information on the AP1000 PMS. Additionally, the applicant submitted WCAP-16674-P, Revision 4, which addressed data communications and manual component control of safety-related systems, and WCAP-17179-P, Revision 2, which discussed a subsystem within the PMS responsible for allowing nonsafety-related control of safety-related components during normal plant operation known as the CIM system. In the event of a PMS actuation, the PMS overrides nonsafety-related control through the CIM and takes the safety-related components to their safe state. This task is accomplished through priority logic within the CIM. The CIM system resides within the engineering safety features actuation system (ESFAS) portion of the PMS. The CIM system’s primary active components are the CIM and SRNC.

The staff reviewed the design and architecture of the PMS to assess how it meets regulatory requirements and addresses the acceptance criteria associated with an I&C safety system. The PMS encompasses the functions of the reactor trip system (RTS), ESFAS, PAMS, and QDPS. Section 7.5 of this report includes additional information regarding the QDPS.

The discussion of the PMS in the following sections includes information presented in the publicly available, non-proprietary version of the following reports:

- APP-GW-GLR-137, Revision 1 (also known as APP-GW-GLR-005)
- WCAP-16674-NP, “AP1000TM I&C Data Communication and Manual Control of Safety Systems and Components,” Revision 4
- WCAP-16675-NP, “AP IOOOTM Protection and Safety Monitoring System Architecture Technical Report,” Revision 5
- WCAP-17179-NP, Revision 2
- WCAP-16438-NP, APP-GW-JJ-002-NP, “FMEA of AP 1000 Protection and Safety Monitoring System,” Revision 2
- WCAP-16592-NP, Revision 2

7.2.2.1 PMS Functional Requirements

The PMS performs the functions of the RTS, ESFAS, PAMS, and QDPS. During normal operation, administrative procedures and plant control systems maintain the reactor in a safe state, preventing damage to the three barriers (fuel clad, reactor coolant system (RCS), and reactor containment building) that prevent the spread of radioactive material to the environment. Accident conditions causing one or more of the barriers to be threatened could occur. Thus, the PMS monitors key plant parameters and automatically initiates various protective functions to prevent the violation of any of the three barriers. When violation of a barrier cannot be prevented, PMS will attempt to maintain the integrity of the remaining barriers. This ensures that, given a design-basis event, the site boundary radiation releases will be maintained below the limits in 10 CFR Part 100, “Reactor site criteria.” The system functions by actuating a variety of equipment and by monitoring the plant process using a variety of sensors and operations that perform calculations, comparisons, and logic functions, based on those sensor inputs. The PMS functional requirements documents discuss the protective functions of the system and the requirements these functions place on the equipment that performs them.

7.2.2.1.1 Reactor Trip Functions

The PMS generates an automatic reactor trip for the following conditions:

- source range high neutron flux trip
- intermediate range high neutron flux trip
- power range high neutron flux trip (low setpoint)
- power range high neutron flux trip (high setpoint)
- power range high positive flux rate reactor trip
- overtemperature delta-T (OTΔT) reactor trip
- overpower delta-T (OPΔT) reactor trip
- reactor trip on low pressurizer pressure
- reactor trip on low reactor coolant flow
- reactor trip on reactor coolant pump (RCP) underspeed
- RCP bearing water temperature
- pressurizer high-pressure reactor trip
- pressurizer high-water-level reactor trip
- reactor trip on low-water level in any steam generator
- high-2 steam generator water level in any steam generator
- automatic depressurization systems (ADSs) actuation reactor trip
- core makeup tank (CMT) actuation reactor trip
- reactor trip on safeguards actuation
- manual reactor trip

Revision 15 of the AP1000 DCD identified the reactor trip functions listed above. The applicant modified the design description of several reactor trip functions in Revisions 16 and 17 of the AP1000 DCD. Specifically, the applicant proposed the following modifications:

- The source range high neutron flux trip is delayed when the detector’s high-voltage power supply is energized to prevent a spurious trip. The staff finds this acceptable, since the detector would be energized before being declared operable.

- The equations for performing the OTΔT and OPΔT reactor trips were modified. The staff determined, through an examination of TR, APP-GW-GLR-137, Revision 1, and associated RAIs and satisfactory applicant responses, that the new equations were equivalent to the previous equations but in a different format. Therefore, the changes are acceptable. Appendix 7A provides a more detailed evaluation of APP-GW-GLR-137. The revision of the WCAP-16361-P report will be addressed in Section 7.2.7 of this report.

- Reference to Permissive P-8 (power range nuclear power above setpoint) was removed, as Permissive P-10 made it redundant. The staff finds the change acceptable.

- Reactor Trip on High RCP Bearing Water Temperature. The trip has been modified to occur if any RCP experiences a high bearing water temperature without the P-10 interlock being able to block the trip when reactor power is below the P-10 setpoint. As this modification is conservative in nature, in that the number of permissives needing to be satisfied before the trip occurs has been reduced, the change is deemed acceptable.

- The applicant removed the automatic rod withdrawal block, which prevents rod withdrawal if the negative flux rate setpoint is exceeded, in Revision 16 of the AP1000 DCD. As a result, based upon the removal of the associated text and table information in Chapter 7 of Revision 17 of the AP1000 DCD, the staff understands the previously discussed P-17 interlock to have been removed from use in the PMS. Since this control action utilized the nonsafety-related rod control system for its actuation or, in the case of the block signal, the lack of actuation, the removal of the block action is beyond design basis as it pertains to this evaluation and is, therefore, acceptable.

The NRC determined that the other changes to the reactor trip functions, such as editorial changes or changes that added conservatism to the design, were minor; therefore, this chapter does not discuss them further.

7.2.2.1.2 Engineered Safety Features Actuation System Functions

The PMS performs both reactor trip and ESFAS functions. The AP1000 design provides I&C to sense accident situations and initiate engineered safety features (ESFs). The occurrence of a limiting fault, such as a loss-of-coolant accident (LOCA) or a secondary system break, requires a reactor trip plus actuation of one or more of the ESFs. This combination of events prevents or mitigates damage to the core and RCS components and provides containment integrity.

The PMS is actuated when safety system setpoints are reached for selected plant parameters. The selected combination of process parameter setpoint violations is indicative of primary or secondary system boundary challenges. Once the system receives the required logic combination, the PMS equipment sends the signals to actuate appropriate ESF components.

The PMS initiates the following ESF system-level actuations:

- safeguards actuation
- containment isolation
- in-containment refueling water storage tank (IRWST) injection
- CMT injection
- ADS

- RCP trip
- main feedwater isolation
- passive residual heat removal actuation
- turbine trip
- containment recirculation
- steamline isolation
- steam generator blowdown system isolation
- passive containment cooling actuation
- startup feedwater isolation
- boron dilution block
- chemical and volume control system (CVS) isolation
- steam dump control
- MCR isolation
- auxiliary spray and purification line isolation
- containment air filtration isolation
- refueling cavity isolation
- CVS letdown isolation
- pressurizer heater block
- steam generator relief isolation
- normal residual heat removal containment isolation
- demineralized-water transfer and storage system isolation
- reactor vessel head vent valve control

Revision 15 of the AP1000 DCD identified the ESF system-level actuations listed above. The applicant incorporated several minor changes related to the ESF functions into Section 7.3 of the AP1000 DCD, and the staff finds the changes acceptable.

7.2.2.1.3 Component Control Functions

The applicant provides control of individual safety-related components that perform Class 1E functions. Component-level control consists of the following functions:

- resolution of multiple demands (priority logic) for a given component from various systems

- application of manual component demands

- performance of the component protection logic (e.g., torque limit, antipump latch)

- reporting of component status to the plant information system

- local component control

The following inputs are required for control of individual components:

- automatic system-level actuation commands from the reactor trip and ESF actuation logic

- manual system-level actuation commands from the fixed position switches in the MCR and RSR

- individual safety component control commands from the nonsafety-related plant control system (PLS) for component actuations with no onerous consequences (for test, maintenance, restoration, and noncredited actuations)

- individual safety component control commands from the safety and QDPS displays in the MCR for component actuations with onerous consequences

- component feedback signals from the individual safety components to the PMS

The outputs to individual safety-related components consist of hardwired control signals to open or close a solenoid valve, motor-operated valve (MOV), or circuit breaker.

7.2.2.2 AP1000 Protection and Safety Monitoring System Operation

The PMS detects off-nominal conditions and actuates appropriate safety-related functions necessary to achieve and maintain the plant in a safe-shutdown condition. The PMS controls safety-related components in the plant that are operated from the MCR or RSR workstation. In addition, the PMS provides the equipment necessary in its QDPS subsystem to monitor the plant's safety-related functions during and following an accident, as identified in regulatory guide (RG) 1.97, "Criteria for Accident Monitoring Instrumentation for Nuclear Power Plants," Revision 3.

The AP1000 PMS consists of four redundant divisions, designated A, B, C, and D. The PMS performs the necessary safety-related signal acquisition, calculations, setpoint comparison, coincidence logic, reactor trip and ESF actuation functions, and component control functions to achieve and maintain the plant in a safe shutdown condition. The PMS also contains maintenance and test functions to verify proper operation of the system. The PMS includes four redundant safety displays, one for each division and two QDPS displays, located on the primary dedicated safety panel (PDSP) in the MCR. Only two of the four divisions contain software to drive QDPS displays and to provide PAMS information to the operator, on Divisions B and C. The system's use of four redundant divisions is one of the mechanisms employed to satisfy single-failure criteria and improve system availability.

The I&C equipment performing reactor trip and ESF actuation functions, its related sensors, and the reactor trip switchgear are, for the most part, four-way redundant. This redundancy permits the use of bypass logic, so that a division or an individual channel within a division taken out of service can be accommodated by the operating portions of the protection system that revert to a two-out-of-three (2oo3) logic function from a two-out-of-four (2oo4) logic function. Additional discussion related to bypasses and the indication of inoperable channels within the PMS can be found in Section 7.5.6 of this report.

Four redundant measurements, using four separate sensors, are made for each variable used for reactor trip or ESF actuation within a single division. Each division, which is comprised of two redundant channels, processes one measurement. Analog signals are converted from remote sensor outputs to digital form by analog-to-digital converters within the division's bistable processor logic (BPL) modules - one per channel. Signal conditioning is applied to selected inputs to the BPL, after the digital conversion. Following necessary calculations and processing, the measurements are compared against the applicable setpoint for that variable. A partial trip signal for a parameter is generated in the BPL if the channel's measurement exceeds its predetermined or calculated limit. Processing of variables for a reactor trip is identical in each of the four redundant divisions of the protection system.

Two local coincidence logic (LCL) processors within each division receive the output signal from each division's BPLs. The LCL subsystem acts to initiate a reactor trip or ESF actuation when a predetermined condition in 2oo4 independent safety divisions reaches a partial trip or partial actuation state. The LCL also provides for the bypass of trip or actuation functions to accommodate periodic tests and maintenance.

7.2.2.2.1 Reactor Trip Operation

The reactor trip coincidence logic performs the logic function to combine the partial trip signals from the BPL subsystems and generates a failsafe trip output signal to the reactor trip switchgear. The reactor trip signal from each of the four divisions of the PMS is sent to the division's reactor trip circuit breakers (RTCBs). Each division controls two RTCBs. The design of the RTCB placement ensures that the reactor trip would still occur, even in the presence of a failure of one of the division's two RTCBs. The reactor is tripped when two or more divisions actuate, thereby generating a reactor trip signal opening their breakers. The automatic trip demand signal initiates the following two actions: it deenergizes the undervoltage trip coils on the RTCBs, and it energizes the shunt trip devices on the RTCBs. Either action causes the breakers to trip. Opening the appropriate trip breakers by any two divisions removes power to the rod drive mechanism coils, allowing the rods to fall into the core. This rapid negative reactivity insertion causes the reactor to shut down. Section 7.2.2.3.7, "Capability for Test and Calibration," provides further information on testing RTCBs.

7.2.2.2.2 ESF Actuation

The ESF coincidence logic processors perform the logic function to combine the partial actuation signals from the BPL subsystems, along with automatic and manual permissives, blocks, and resets, to generate a fault tolerant actuation output signal to the integrated logic processor (ILP) subsystems.

The primary functions of the ESF logic processors are to process inputs, calculate system-level actuation, combine the automatic actuation with the manual actuation and manual bypass data, and transmit the data to the ILPs. To perform the ESF coincidence logic calculations, the ESF processors require data from the BPL subsystems and also use manual inputs (such as setpoints and system-level blocks and resets) from the MCR and the RSR workstation.

The ESF logic processors perform the following functions:

- Receive bistable data supplied by the four divisions of BPL subsystems and perform 2oo4 voting on this data.
- Implement system-level logic and transmit the output to the ILP processors for ESF component fan-out and actuation.
- Process manual system-level actuation commands received from the MCR and/or RSR.

The ESF component control function uses redundant ILPs, which serve as LCL output control signal “fan-out” devices, which distribute the activate signal to the various SRNCs that forward their given output to their respective CIMs. The CIMs provide a distributed interface between the safety system and plant equipment for control of non-modulating safety-related plant components. The safety-related input to the CIM comes from both of its respective SRNCs within the PMS, while the nonsafety-related input enters the CIM through the nonsafety-related remote node controller (RNC). Non-modulating control relates to the opening or closing of solenoid valves and solenoid pilot valves and the opening or closing of MOVs and dampers. It also provides the plant operator with information on the equipment status, such as an indication of component position (full closed, full open, valve moving), component control modes (manual, automatic, local, remote), or abnormal operating conditions (power not available, failure detected).

The staff approved the Common Q platform portion of the AP1000 PMS, previously based on information in the Common Q topical report. However, regarding the use of the ESFAS functions, the PMS design uses distribution devices known as ILPs, SRNCs, and CIMs, which had not been previously evaluated in the Common Q platform. The applicant provided design information detailing the functions of each of the aforementioned components. Sections 7.2.2.3.13 through 7.2.2.3.15 include the technical discussion regarding the additional information the staff reviewed for each of these components before determining their acceptability. The ILP is an intra-divisional device that receives its input from the LCL and distributes its outputs to a given SRNCs which forward their outputs to their assigned CIM. Besides distributing the activate signals to non-modulating safety-related devices, the CIM serves as an interface control device, as it receives inputs from both the safety-related PMS and the nonsafety-related PLS to actuate the requested vital components of the safety-related ESFAS.

7.2.2.3 PMS Evaluation

The staff evaluated the technical requirements of the PMS design against the requirements and acceptance criteria in the following documents:

- 10 CFR 50.49, “Environmental qualification of electric equipment important to safety for nuclear power plants”

- 10 CFR 50.55a(h), “Codes and standards,” which incorporates by reference Institute of Electrical and Electronic Engineers (IEEE) Standard (Std.) 603-1991, “IEEE Standard Criteria for Safety Systems for Nuclear Power Generating Stations” (NOTE: The clauses of IEEE Std. 603-1991 not referenced in the topical-based discussion below are unaffected by the proposed changes described in Revision 19 of the AP1000 DCD).

- 10 CFR Part 50, Appendix A, “General Design Criteria [GDC] for Nuclear Power Plants”

    – GDC 13, “Instrumentation and Control”
    – GDC 20, “Protection System Functions”
    – GDC 21, “Protection System Reliability and Testability”
    – GDC 22, “Protection System Independence”
    – GDC 23, “Protection System Failure Modes”
    – GDC 24, “Separation of Protection and Control Systems”
    – GDC 29, “Protection Against Anticipated Operational Occurrences”

The industry and staff guidance in Chapter 7 of NUREG-0800 applies to the PMS review.

The staff evaluated the PMS architecture against those requirements affected by the additional or modified design information provided on the PMS. Those requirements include single-failure protection, quality, equipment qualification, system integrity, independence, capability for test and calibration, information displays, control of access, repair, automatic and manual control, and bypasses. Section 7.2.7 discusses setpoints. The staff determined that other requirements for I&C systems were not affected by changes in Revision 19 of the AP1000 DCD, compared to those approved in Revision 15. Specifically, the applicant uses the Common Q platform as a major portion of the PMS. This report evaluated major subcomponents of the PMS, including those that were not previously developed at the time of the staff's original SER for the AP1000 such as the ILP, SRNC, and CIM. Sections 7.2.2.3.13 through 7.2.2.3.15 discuss those evaluations.

7.2.2.3.1 Common Q Evaluation

The staff previously approved the use of the Common Q platform for generic nuclear power plant (NPP) applications. Section 7.2.2.2.2 of this report includes reference material related to the Common Q topical report and the associated safety evaluations. The applicant presented additional planning and design information related to the use of the Common Q platform in the AP1000 design in the form of the newly submitted TRs related to the PMS that are discussed in Section 7.1.5.

7.2.2.3.2 Single-Failure Protection

The staff evaluated the single-failure protection characteristics of the Common Q and PMS against requirements in IEEE Std. 603-1991, Clause 5.1, "Single Failure Criterion," and GDC 21. The staff used the guidance in RG 1.53, "Application of the Single-Failure Criterion to Nuclear Power Plant Protection Systems," which endorses IEEE Std. 379-1988, "Standard Application of the Single-Failure Criterion to Nuclear Power Generating Station Safety Systems."

To address the guidance in RG 1.53, the applicant presented the NRC with an FMEA and an SHA to demonstrate the system's capability to withstand a single-failure event. WCAP-16438-P, Revision 2, describes the FMEA, and WCAP-16592-P, Revision 2 describes the SHA for the PMS. The staff's evaluation of the PMS SHA is described in Section 7.1.5, "Instrumentation and Control System Architecture."

The staff examined the AP1000 FMEA against the guidance of IEEE Std. 352-1998, "IEEE Guide for General Principles of Reliability Analysis of Nuclear Power Generating Station Safety Systems," and IEEE Std. 379-1988. The staff finds the report provides a satisfactory demonstration of the system's fault tolerance under various scenarios. Several technical questions were identified regarding specific system responses in the presence of certain failure types and required resolution as shown in the following examples:

- Five CIMs possess a mean time between failure (MTBF) that did not meet the design reliability targets for the PMS. However, the text gave no explanation or analysis as to how the system will minimize, mitigate, or eliminate these failure types. To address this issue, the applicant issued a response to RAI-SRP7.1-FMEA-01 in December 2009, stating that an MTBF analysis would be conducted and was expected to be completed by July 2010. The response further discusses how, once the MTBF analysis report is completed, if the failure rates were not in line with the expected failure rate of at least 200,000 hours, the applicant's design change process would be utilized to modify the equipment to reach the MTBF goal or adequately explain why the higher rate of failure is acceptable. The staff finds the use of an MTBF analysis to verify a sufficiently low level of failures of the CIM and SRNC to be acceptable.

- According to the FMEA, when the check sum verification process fails, the setpoints are not updated; however, this condition would be restricted to one division only. The FMEA then discusses how the division may trip erroneously or not trip due to the setpoints not being properly updated. In its response dated December 1, 2009, the applicant stated, in part, that the cyclic redundancy check (CRC) verification mechanism can fail and the correct setpoint value still be monitored by the maintenance and test panel (MTP). Although the MTP may not receive the updates due to a failure of the CRC, there are continuous lower level diagnostics that provide alarm and indication informing the operators that a fault has occurred between the LCL and the MTP. Additionally, even though the diagnostics and self-tests that are executing continuously are not credited, the fault would be limited to a single division's MTP and is, therefore, acceptable.

The FMEA describes how the PMS, through the MTP, periodically adjusts setpoints automatically. This automatic adjustment of setpoints, without operator control, would not meet the requirements in Criterion III, "Design Control," in 10 CFR Part 50, Appendix B, "Quality Assurance Criteria for Nuclear Power Plants and Fuel Reprocessing Plants." In its response dated November 9, 2009, the applicant related the "periodic refreshing" of data was part of the inherent communications in a deterministic format utilized between the AC160 (Common Q processor) and the MTP. The response stated further that the setpoints within the AC160 can only be altered manually by the operator of the MTP. The applicant submitted Revision 3 of the FMEA to more clearly state that the system is not continually sending "new" updated setpoints to the AC160, but simply performing its communication function. The staff finds this revision acceptable.

When comparing the requirements in Clause 5.1 of IEEE Std. 603-1991 and GDC 21 to the information in WCAP-16675-P and WCAP-16438-P, and after reviewing the responses provided by the applicant related to the FMEA, the staff determined the single failure requirements related to IEEE Std. 603-1991 have been adequately addressed. The NRC staff previously identified these issues as Open Item OI-SRP7.2-ICE-01, and as a result of the staff's review of the responses provided by the applicant and its commitment to update the next revision of the FMEA based upon their responses to RAI-SRP7.1-FMEA-02, RAI-SRP7.1-FMEA-04, RAI-SRP7.1-FMEA-05 and RAI-SRP7.1-FMEA-07 the staff finds the design satisfies the single failure criterion. In Revision 3 to the FMEA, the applicant incorporated the changes described in the RAI responses, which resolves this issue.

7.2.2.3.3 Quality

Clause 5.3 of IEEE Std. 603-1991 and 10 CFR Part 50, Appendix B, require safety-related I&C systems to be designed, manufactured, inspected, installed, and tested under an acceptable quality assurance program. NUREG-0800 Appendix 7.1-D, "Guidance for Evaluation of the Application of IEEE Std. 7-4.3.2"; Section 5.3; and BTP 7-14 specifically address the criteria for a quality software development process. Additionally, the staff evaluated the documentation in the SLC for the Common Q portion of the PMS against the guidance in the following documents:

- RG 1.168, “Verification, Validation, Reviews and Audits for Digital Computer Software Used in Safety Systems of Nuclear Power Plants,” which endorses IEEE Std. 1012-1998, “IEEE Standard for Software Verification and Validation,” and IEEE Std. 1028-1997, “IEEE Standard for Software Reviews and Audits”

- RG 1.169 “Configuration Management Plans for Digital Computer Software Used in Safety Systems of Nuclear Power Plants,” which endorses IEEE Std. 828-1990, “IEEE Standard for Software Configuration Management Plans”

- RG 1.170, “Software Test Documentation for Digital Computer Software Used in Safety Systems of Nuclear Power Plants,” which endorses IEEE Std. 829-1983, “IEEE Standard For Software Test Documentation”

- RG 1.171, “Software Unit Testing for Digital Computer Software Used in Safety Systems of Nuclear Power Plants,” which endorses IEEE Std. 1008-1987, “IEEE Standard for Software Unit Testing”

- RG 1.172, “Software Requirements Specifications for Digital Computer Software Used in Safety Systems of Nuclear Power Plants,” which endorses IEEE Std. 830-1993, “IEEE Recommended Practice for Software Requirements Specifications”

- RG 1.173, “Developing Software Life Cycle Processes for Digital Computer Software Used in Safety Systems of Nuclear Power Plants,” which endorses IEEE Std. 1074-1995, “IEEE Standard for Developing Software Lifecycles and Processes”

In Section 7.2.2.2, the staff discusses the approval of the Common Q platform topical report. However, additional requirements were placed on the SLC for the AP1000 safety system, beyond those described in the Software Program Manual (SPM), WCAP-16096-NP-A, “Software Program Manual for Common Q Systems,” Revision 1A, dated January 21, 2005. WCAP-15927, “Design Process for AP1000 Common Q Safety Systems,” Revision 0, placed additional requirements on the design and testing teams developing the PMS. The certified design (Revision 15) of the AP1000 DCD designated the SPM and WCAP-15927 as Tier 2* documents, requiring NRC approval before altering the applicant’s commitments. The staff recently received, reviewed, and approved the use of WCAP-15927, Revision 2. Section 7.2.5 provides further information concerning this matter.

In AP1000 DCD Tier 1, Table 2.5.2-8, Design Description 11, the applicant proposed the removal of design requirements and system definition phases of the PMS SLC ITAAC. The design requirements phase corresponds to the planning activities phase of the SLC in NUREG-0800 BTP 7-14, and the system definition phase corresponds to the requirements activities phase in the same NUREG-0800 BTP. The applicant made available for audit the software planning documents to support removal of the design requirements phase. The staff audited those software planning documents on several occasions, which are discussed below. The applicant describes its quality software development process for the AP1000 project in the Common Q SPM and WCAP-15927, Revision 2, documents. The staff reviewed the proprietary and nonproprietary documentation associated with the first two phases of the SLC as it relates to Common Q portion of PMS system development. Further information regarding lifecycle development and completion as it relates to the PMS is provided in Section 7.2.5.

The applicant originally provided 11 proprietary documents that comprise the design requirements phase of the AP1000 SLC. On April 9-11, 2008; October 9-16, 2008; January 22-30, 2009; and July 30, 2009, the staff conducted site visits at the Westinghouse Twinbrook location in Rockville, Maryland, to review the proprietary documents associated with the design requirements phase. In RAI-SRP7.1-ICE-03, the NRC asked the applicant to explain, in the Tier 2 information of the DCD, how it meets the requirements of the planning ITAAC. This includes a diagram of the planning process and sufficient planning documentation related to the lifecycle development plan for the Common Q and CIM system within the PMS, and the steps taken by the applicant to ensure the PMS is constructed in a SDOE and other project-specific documents. The lack of an adequately detailed CIM system programmable technology lifecycle was captured under Open Item OI-SRP7.2-ICE-05 and the discussion of how the applicant intends to ensure the PMS is constructed in a SDOE will be covered in Section 7.9. The issue of which documents delineate the design requirements or planning activities phases of the PMS developmental lifecycle and their relationship to one another was reconciled in Section 7.2.5 prior to the staff's acceptance of the design requirements phase of the PMS lifecycle development process as complete. As a result, the issue previously identified as Open Item OI-SRP7.2-ICE-02 is considered complete based upon the commitments made in the revised response to Open Item OI-SRP7.2-ICE-02 to include an adequately detailed discussion of the design requirements in Chapter 7 of the DCD. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

Several proprietary documents listed as proof of completion of the design requirements phase detail the relationship between two Westinghouse organizations: Repair, Replacement, and Automation Services (RRAS) and Nuclear Power Plants (NPP) (e.g., RRAS AP1000 NuStart I&C Program Project Plan (WNA-PN-00031-GEN[3]) and RRAS AP1000 NuStart I&C Program Project Quality Plan (WNA-PQ-00166-GEN[4])). The documents reveal how the subcontractor (Westinghouse RRAS) interfaces with the parent organization (Westinghouse NPP); however, they originally did not describe how Westinghouse NPP interfaces with, and holds accountable, Westinghouse RRAS, employees, and other subcontractors. The NRC requested this information in RAI-SRP7.1-ICE-04. The applicant provided a written RAI response stating that its RRAS organization will complete all work on safety systems (i.e., all work performed on the I&C safety systems for the AP1000 will be conducted by either RRAS or its subcontractors, who will be required to function under Revision 5 of the Westinghouse Quality Management System (QMS) Manual). The NRC accepted the applicant's use of Revision 5 of the QMS Manual to satisfy the requirements in Appendix B to 10 CFR Part 50. This satisfies RAI-SRP7.1-ICE-04. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

In July 2009, the staff conducted an audit of the recently developed proprietary PMS Test Plan, the SRNC and CIM Project Plan, and the CIM System Test Plan documents to ensure compliance with requirements and the applicant's commitments. Overall, the NRC finds the results of the audit to be acceptable. Originally requested under RAI-SRP7.1-ICE-05, the documents listed above satisfy the need for sufficient test plan information related to the planning phase of the Common Q SLC; therefore, the NRC staff considers RAI-SRP7.1-ICE-05 closed.

[3] Westinghouse altered the numbering format for this document. It is now numbered WNA-PN-00043-WAPP.
[4] Westinghouse altered the numbering format for this document. It is now numbered WNA-PQ-00201-WAPP.

Concerning the proprietary AP1000 NuStart Protection and Safety Monitoring System Software Project Plan (WNA-PJ-00071-GEN), the staff raised issues that included how the applicant could give a value of zero to the overall risk for software development when the risk in some specific areas was rated as high. Furthermore, Appendix A of the same report states that "Test/System Integration Phase Independent Verification and Validation [IV&V] is not within the scope of the AP1000 NuStart Project." The staff requested additional information in this area in RAI-SRP7.1-ICE-08, which discussed the revision to the table. At a meeting in January 2009, the applicant committed to revise notes in the Software Project Plan[5] document, WNA-PJ-00071-GEN, to inform the reader that "zero," in the case of risk, actually means minimal, not "no risk." During the staff visit to the Twinbrook facility on July 30, 2009, the staff confirmed that the applicant had incorporated this item into the proprietary software document. Therefore, this item adequately addresses the RAI, which is now considered closed.

The staff reviewed the proprietary document, WNA-PJ-00071-GEN, "AP1000 NuStart PMS Software Project Plan," and its descendent document, the AP1000/NuStart/DOE Design Finalization and Safety Monitoring System Software Development Plan, WNA-PN-00042-WAPP, as part of the design requirements phase review. Appendix A, Item 4, of WNA-PJ-00071-GEN states that the test/system integration phase IV&V is not within the scope of the AP1000 NuStart project. The software project will be frozen at the processor module software test for Division B software. The staff asked the applicant to clarify these statements; specifically, how the applicant would test Divisions A, C, and D software and the complete software of each division, beyond the processor module software tests. In a letter dated September 3, 2008, "AP1000 Response to Request for Additional Information (SRP7)," the applicant clarified the statements in WNA-PJ-00071-GEN regarding processor module software testing. The letter stated the following:

> The deliverable for the cited plan is a detailed design up to and including the software design. This includes a software demonstration system using a test bed configured for Division B. It was not intended to validate all software for all divisions. The demonstration software for Division B marks the conclusion of the plan's scope.
>
> Once the demonstration software for Division B is complete, a software development plan will be developed to complete the software development life cycle taking credit for work completed in first plan. This would include activities for unit testing, code review, channel integration test for all four divisions, and system integration test, as well as the life cycle V&V activities.
>
> The completed Division B software is a sufficient sample to close the DAC software open issue and the V&V issue, because the completed development of Division B software will demonstrate all of the representative software subroutines included in all of the divisions (i.e., the RPS, ESFAS and QDPS functions).

The staff understands the applicant's explanation that the portion of module testing to be combined and constructed into a test bed mimicking Division B of the PMS in its entirety will

[5] Westinghouse altered the numbering format for this document. It is now numbered WNA-PD-00042-WAPP. Westinghouse also retitled it, "AP1000 NuStart/DOE Design Finalization Protection and Safety Monitoring System Software Development Plan."

serve as a "proof of concept" test for PMS and QDPS software and hardware, rather than an interdivisional integration test of the PMS and QDPS, to which the applicant is committed, later in the SLC process. The staff accepts this approach and closes RAI-SRP7.1-ICE-09.

Section 7.2.5, "PMS Design Process Review," includes a detailed discussion of the level of quality the applicant requires to implement its SLC and programmable technology lifecycle for both the Common Q and CIM subsystem portions of the PMS, and provides the staff's findings as they relate to overall PMS quality.

7.2.2.3.4 Equipment Qualification

Clause 5.4, "Equipment Qualification," of IEEE Std. 603-1991 states, in part, that safety system equipment shall be qualified by type test, previous operating experience, or analyses, or any combination of these three methods, to substantiate that it will be capable of meeting, on a continuing basis, the performance requirements as specified in the design basis. The staff reviewed docketed and Westinghouse proprietary documents relating to the overall methodology and approach when dealing with equipment qualification. The Common Q topical report describes the generic equipment qualification of the Common Q equipment. Additionally, AP1000 DCD Tier 1, Table 2.5.2-8, Items 2, 3, and 4, identify ITAAC to address the seismic, electromagnetic/radio-frequency/electrostatic discharge, and temperature/humidity qualification of PMS equipment. To complete the ITAAC, a licensee incorporating the AP1000 certified design would need to verify that the generic equipment qualification for the Common Q as well as the CIM system portion of the PMS equipment includes the site-specific seismic, electromagnetic/radio-frequency/electrostatic discharge, and temperature/humidity profile. Based on the generic equipment qualification of the Common Q equipment and the ITAAC in Tier 1 of the AP1000 DCD, the staff finds the equipment qualification acceptable for the proposed DC amendment as it relates to the PMS.

7.2.2.3.5 System Integrity

Clause 5.5 of IEEE Std. 603-1991 states, in part, that safety systems shall be designed to accomplish their safety functions under the full range of applicable conditions enumerated in the design basis. The staff used the guidance in Appendix 7.1-C and Appendix 7.1-D of NUREG-0800 to review the PMS and its means of meeting the standard in Clause 5.5.

A special concern with any safety-related digital system is confirmation of its ability, in real time, to ensure completion of the protective actions within critical points of time identified in the design basis. Section 7.9 discusses real-time performance with respect to data communications. Items 6a, 6b, and 6c of AP1000 DCD Tier 1, Table 2.5.2-8, would, through their ITAAC, address the overall verification of the system response time. With regard to failure modes, the staff confirmed that the PMS design is such that reactor trip functions fail to the tripped state and ESF functions fail to the as-is state. Additionally, the Common Q equipment contains self-diagnostics to alarm failed conditions and place the system into a fail-safe state. However, the applicant does not propose to use self-diagnostic tests for technical specifications surveillance tests. Based on the ITAAC, FMEA, and self-testing features, the staff finds the PMS design acceptable from a system integrity standpoint.

7.2.2.3.6 Independence

Clause 5.6, "Independence," of IEEE Std. 603-1991 and GDC 22 and GDC 24 require, in part, that safety I&C systems be designed with physical, electrical, functional and communications independence among redundant divisions and between safety and nonsafety systems. The staff compared the independence requirements of the Common Q system to the guidance in NUREG-0800 Appendix 7.1-C and Appendix 7.1-D. Additionally, the staff compared the independence requirements of the PMS as they relate to ensuring the protection system was developed in a SDOE. The evaluation of the system being constructed and operated in a SDOE is discussed in Section 7.9.

Based upon information provided in the Common Q topical report and its appendices, the NRC approved the Common Q platform, which includes the BPLs, the LCLs, the interface and test processor (ITP), and the MTP. While the physical and electrical independence aspects of the Common Q have been demonstrated, several issues remained. One issue concerns the inter-and intra-divisional data communications independence requirements of the Common Q platform. Section 7.9 discusses this issue.

As previously stated, within the layout of the PMS, yet external to the previously approved Common Q platform, the NRC evaluated the RNC, the SRNC, and the CIM against the independence requirements for physical separation and electrical, functional and communications independence (covered in Section 7.9) in Clause 5.6 of IEEE Std. 603-1991. GDC 13, 20, 21, 22, 23, and 24 include other requirements affecting CIM independence.

IEEE Std. 603-1991, which the NRC endorsed in 10 CFR 50.55a(h), defines "associated circuits" as non-Class 1E circuits that are not physically separated or are not electrically isolated by acceptable separation distance, safety class structures, barriers, or isolation devices.

IEEE Std. 384-1981, "IEEE Standard Criteria for Independence of Class 1E Equipment and Circuits," defines the acceptance criteria for the associated circuits. The RNC, which serves as an interface between the nonsafety-related PLS Ovation® platform and the safety-related CIM, serve as part of the communications isolation function, according to Section 5.2.2 of WCAP-16674-P, Revision 4. This information also appears in Section 3.3.5 of WCAP-16675-P, Revision 5.

According to the description in the TRs, electrical and physical isolation between the RNC and the safety-related CIM is achieved by the use of fiber-optic cabling between the RNC and the remote input/output (I/O) bus, which connects to the PLS side of the RNC. The applicant committed to ensuring that the RNC will undergo qualification testing that meets or exceeds the guidance in IEEE Std. 384-1981. Thus, the device will undergo the qualification requirements placed on Class 1E circuits to ensure that the Class 1E circuits are not degraded below an acceptable level, even in the presence of a failure of the associated circuit. The NRC acknowledges that the RNC will be qualified as an associated circuit, since the fiber-optic cable providing electrical isolation is between the nonsafety-related PLS and the RNC.

The staff understands the subcomponent performing communications conversion is located physically on the CIM and that it creates the functional isolation between the RNC and CIM by performing the communications protocol or language conversion from the Emerson Ovation® programming language to discrete digital signals that will be provided to the priority logic, also located on the CIM. This type of arrangement also creates the functional isolation required to satisfy NRC requirements by ensuring that a failure, degradation, or corruption of the information being received by the CIM will not disable the ability of the PMS to execute or complete its function through the priority module, in accordance with IEEE Std. 603-1991, Clauses 5.2 and 5.6.1. Specifically, the priority logic of the CIM provides the PMS priority over the nonsafety-related control system if a safety-related plant component needs to actuate to its safe state in all cases. This issue was addressed adequately in the applicant's response to RAI-SRP7.0-ICE-03 providing additional information regarding how the PMS has priority over the PLS, even when failure conditions are present. These changes have been incorporated into WCAP-17179-P, Revision 2.

Section 7.9 includes the staff's full evaluation, covering nonsafety-related to safety-related data communications of the PMS, via the RNC and CIM, and other I&C systems.

7.2.2.3.7 Capability for Test and Calibration

The staff evaluated the Common Q system against the requirements of IEEE Std. 603-1991, Clause 5.7, "Capability for Test and Calibration," and the guidance in the following documents:

- NUREG-0800, BTP 7-17, "Guidance on Self-Test and Surveillance Test Provisions"
- NUREG-0800 Appendix 7.1-D, "Guidance for Evaluation of the Application of IEEE Std. 7-4.3.2"
- RG 1.22, "Periodic Testing of Protection System Actuation Functions," issued 1972
- RG 1.118, "Periodic Testing of Electric Power and Protection Systems," issued 1995, which endorses IEEE Std. 338-1987, "IEEE Standard Criteria for the Periodic Surveillance Testing of Nuclear Power Generating Station Safety Systems"

The staff found that the applicant meets the physical requirements that describe how testing and calibration will be performed administratively, through appropriate procedural guidance for both operational and maintenance personnel, as well as by the design of the Common Q platform and CIM subsystem, which provide various interlocks within the Common Q portion and CIM subsystem within the PMS. Based upon a review of all information in the DCD and referenced TRs, the applicant does not credit any self-testing features with the PMS as replacements for periodic technical specification surveillance tests. The staff finds the applicant's approach acceptable. The staff will continue to verify this finding through the ITAAC process in later development stages (implementation, integration, and factory acceptance testing) of the developmental lifecycles for the Common Q platform and CIM subsystem within the PMS as a whole to ensure the actual system meets the requirements described in the planning activities and requirements activities developmental stages.

The applicant stated that each individual RTCB would be opened during a trip actuation device operational test once per year. In current licensed plants, the maximum length of time between openings of RTCBs (or equivalent) is typically 92 days. This issue is discussed in Chapter 16 of NUREG-1793 and this report. This issue was determined to be adequately addressed in Revision 15 of the DCD and no changes were made to RTCB layout or design, including the periodicity of RTCB testing. Therefore, Open Item OI-SRP7.2-ICE-03 is considered resolved.

7.2.2.3.8 Information Displays

Clause 5.8 of IEEE Std. 603-1991 requires information displays for manually controlled actions, safety-system status, and indication of bypasses. Additionally, the information displays should be accessible to operators. The staff used the guidance in RG 1.47, “Bypassed and Inoperable Status Indication for Nuclear Power Plant Safety Systems,” issued 1973, during the review.

The information displays used by the PMS remain unchanged since they were found to be acceptable in the “Closeout of Category 1 Open Items for the Common Q Systems,” with the caveat that the flat panel display systems (FPDS) be qualified. Specifically, the NRC’s SER, “Safety Evaluation for the Closeout of Several of the Common Qualified Platform Category 1 Open Items Related to Reports CENPD-396-P, Revision 1, and CE-CES-195, Revision 1” (TAC Number MB0780), dated June 22, 2001, includes the following statement:

> PSAI 6.3 has been resolved generically and may be closed as a requirement in the SE. In connection with its resolution, the staff also found that the FPDS, subject to its successful performance during scheduled qualification testing, to be acceptable for use in Common Q designs as a Class 1E HMI device.

Therefore, a licensee incorporating by reference the AP1000 certified design would need to specifically address the equipment qualification of the FPDS when closing out ITAAC identified in AP1000 DCD Tier 1, Table 2.5.2-8, Design Commitments 2, 3, and 4. The staff finds the AP1000 information display design acceptable as it relates to Clause 5.8 of IEEE Std. 603-1991. Section 7.5 includes further discussion of information displays important to safety. Chapter 18, “Humans Factors Engineering,” evaluates the adequacy of display information presented to operators.

7.2.2.3.9 Control of Access

Clause 5.9, “Control of Access,” of IEEE 603-1991 requires control of access to the PMS. The staff judged the physical capability of the PMS to provide for access control to be acceptable with regard to its system design and administrative controls prior to the removal of the planning activities and requirements activities ITAAC. Section 7.9 includes the evaluation of the ability of the Common Q platform and CIM subsystem within the PMS to meet these requirements to ensure that the PMS is planned and constructed within a SDOE and a protected data communications standpoint. Additionally, Section 7.2.7 discusses the access controls to restrict the alteration of setpoints.

7.2.2.3.10 Repair

The staff compared the information the applicant presented in WCAP-16675-P regarding the capability of the PMS to undergo repair activities both online and offline to meet the requirements of IEEE Std. 603-1991; Clause 5.10, “Repair”; and adequately address the guidance in BTP 7-17. The staff finds that although online self-diagnostics may aid the operator, maintenance, or engineering team to diagnose a fault condition, they do not replace the need for surveillance testing as discussed in Section 7.2.2.3.7.

7.2.2.3.11 Automatic and Manual Control

Clauses 6.1 and 7.1 of IEEE Std. 603-1991 require provisions for automatic control of safety functions. Specifically, Clause 6.1 requires, in part, that means be provided to automatically initiate and control all protective actions except as justified in Clause 4.5. The safety-system design shall be such that the operator is not required to take any action before the time and plant conditions specified in Clause 4.5. Clause 7.1 requires the execute features to receive and act upon automatic controls.

Sections 1.1 and 1.2 of WCAP-16675-P identify the automatic reactor trip and ESF actuations. The applicant did not identify any manual controls for reactor trip or ESF actuations for the PMS in place of automatic controls. Additionally, the reactor trip breakers and ESF equipment are designed to accept and act upon automatic commands from the PMS. Therefore, the staff finds that the PMS design meets Clauses 6.1 and 7.1 of IEEE Std. 603-1991.

Clauses 6.2 and 7.2 of IEEE Std. 603-1991 require provisions for manual actuation of safety functions. Specifically, Clause 6.2 requires, in part, system-level manual actuation of safety functions that minimize the number of discrete operator manipulations and depend on the operation of a minimum amount of equipment, consistent with the constraints of Clause 5.6.1, “Independence Between Redundant Portions of the Safety System.” Position C.4 of RG 1.62, “Manual Initiation of Protective Actions,” issued October 1973, states that equipment common to both the automatic and manual initiation should be kept to a minimum. The action-sequencing logic may be common, as long as component-level control of safety equipment is provided in the control room. Figure 2-2 of WCAP-16675-P identifies the voting logic, as well as the action-sequencing logic, common to the automatic and manual ESF initiation paths. The staff finds that, while this departs from the guidance in RG 1.62, the design is acceptable for the following reason. In the event there is a failure that would disable common portions of the automatic and manual initiation paths in all divisions, a DAS is provided that is not common to the safety-related PMS. The point at which the system-level manual actuation is brought into PMS architecture minimizes the use of equipment and, therefore, reduces the complexity associated with implementing the system-level manual actuation. From a single-failure standpoint, both the automatic and manual initiation paths are designed for single-failure protection. For the RTS-level manual actuation, the switches in the MCR are hardwired to the reactor trip breakers. The staff finds the system-level manual actuation of the reactor trip and ESF to be acceptable.

Section 3.4.2 of WCAP-16675-P describes manual component-level control. The proposed design provides safety-related component-level control of components having onerous consequences, using the soft controls on the safety displays in the MCR and from the CIMs in the equipment rooms. Onerous consequences are defined as those that cause a breach of the RCS pressure boundary or cause a need to shut down the plant to cold conditions to effect repairs. Component-level control of equipment not having onerous consequences is provided through the nonsafety-related workstations in the MCR or the RSR in the event of a condition requiring evacuation of the MCR. The staff finds the proposal to be acceptable, since there is no regulatory requirement for component-level control as it relates to the AP1000 design. Specifically, the plant design does not credit component-level control of equipment to perform safety functions; all safety functions are performed at the system level. The applicant has defined the components having onerous consequences in Table A-1 of the FMEA of AP1000 PMS, WCAP-16438-P, Revision 3, and the staff finds this list acceptable. Although the applicant considers the information proprietary, it will make the component information available to operations, engineering, and maintenance personnel in a licensed power plant using the AP1000 design, thus making the information’s classification acceptable.

7.2.2.3.12 Operational and Maintenance Bypasses

Clauses 6.6, 6.7, 7.4, and 7.5 of IEEE Std. 603-1991 address the requirements as they relate to the operating and maintenance bypass of the sense and command and execute features of the safety I&C system. In part, the clauses require that operating bypasses automatically prevent the activation of an operating bypass or initiate the safety function if the applicable permissive conditions are not met. The capability of a safety system to accomplish its safety function shall be retained while equipment for sense and command and execute features is in maintenance bypass. Additionally, the guidance of RG 1.47 must be addressed to ensure the system responds appropriately in the presence of operational or maintenance bypasses.

The staff evaluated several sections of WCAP-16675-P regarding the PMS bypass capabilities. The four-division system has a high level of redundancy, which allows a division to be bypassed, placing the PMS logic function affecting a reactor trip or ESF actuation into a 2oo3 condition. Additionally, WCAP-16675-P, states that the design does not allow bypassing of two or more redundant channels or divisions. However, placing a given channel into a partial trip condition, if warranted, occurs automatically and does not require the “Function Enable” key switch on the MTP. The AP1000 DCD also commits to the prevention of the operating bypasses when permissive conditions are not met. This aspect of the design would be verified in the ITAAC described in AP1000 DCD Tier 1, Table 2.5.2-8, Design Commitments 9a–d and 11. Thus, based upon the information described above and that found in Section 7.5 of this report, the NRC finds the methodology described in WCAP-16675-P to bypass a given division of the PMS, for maintenance or operational conditions, to be acceptable.

7.2.2.3.13 Integrated Logic Processor Evaluation

The ILPs serve as the action-sequencing logic in the ESFAS portion of the PMS; they distribute the activate signal to the various CIMs, via their respective SRNCs. Based on the design information in WCAP-16675-P, the ILP acts as an intradivisional interface device between the comparative logic device (e.g., LCL) and the SRNC. The SRNC then forwards its output to the priority module (CIM). The ILP uses a design previously approved by the NRC (i.e., Common Q equipment). The staff identified this design information through examination of docketed material in Section 2.2.3.2.2 of WCAP-16775, which revealed the ILP uses an AC160 programmable logic controller to operate. As the AC160 is the processor within the Common Q platform, and the staff has previously approved its use, the staff finds the ILP design acceptable provided the remainder of its components function identically to that of a Common Q based module. The staff previously identified this issue as Open Item OI–SRP–7.2–ICE–04 and, based upon the review of the information in Section 2.2.3.2.2 of WCAP-16775, the staff finds the design of the ILP acceptable.

7.2.2.3.14 Component Interface Module Evaluation

The CIM serves as a transitional device that receives its safety-related input signals from the output of each of its respective SRNCs and delivers its output signal to the respective final actuation device of a given safety-related component. The CIM also serves as an interface device that receives input signals from the nonsafety-related PLS, in addition to the input signal it receives from the SRNC. The nonsafety-related communications (control) signal is applied to the CIM through the nonsafety-related RNC, which serves as a transitional device from the nonsafety-related to the safety-related systems.

The CIM system comprises the following major components:

Component Interface Module	(CIM)
Safety Remote Node Controller	(SRNC)
Double Wide Transition Panel	(DWTP)
Single Wide Transition Panel	(SWTP)
CIM Base Plates	
SRNC Base Plates	

The dual-redundant field programmable gate array (FPGA) based SRNCs receive their [ ] input from their respective ILP within the PMS via a high speed link (HSL). The SRNCs process the PMS signal [ ] prior to the safety-related PMS signal being presented to the CIM. Upon the completion of the signal conditioning being performed by the SRNC, the PMS signal is transmitted to the DWTP, which serves as a connection panel for various signals, and then to the CIM.

The DWTP connects the SRNC base plates and the incoming nonsafety-related Ovation® signal that is processed through the RNC to the input of the respective CIM. The DWTP also serves as the connection point for the 24 volts direct current (Vdc) power feeds that provide power to the SRNC and CIM base plates, the nonsafety-related RNC, and the SWTPs, if any are utilized. The SWTPs serves as extender modules that connect to the DWTP and allow additional CIMs to be connected to the given configuration of CIMs.

The SRNC and CIM base plates serve as physical mounting sockets to which a given SRNC or CIM can be attached.

The output signals from the DWTP or, if utilized, the SWTP, are presented to CIMs, namely the nonsafety-related Ovation® signal from the PLS and the dual redundant, safety-related PMS signal.

The CIM also utilizes FPGA programmable technology, which serves to evaluate and prioritize which of the two signals are present, and position the safety-related component accordingly.

IEEE Std. 603–1991 requires the CIM system satisfy all applicable criteria to ensure the device meets safety system requirements.

To address the single failure criterion in Clause 5.1 of IEEE Std. 603-1991, the applicant submitted WCAP-16438-P, Revision 3, and WCAP-16592-P, Revision 2. The AP1000 FMEA discusses the possibility of individual SRNCs and CIM failure modes and their effect upon the system. Sections 7.1.5, “I&C Architecture,” and 7.2.2.3.2, “Single-Failure Protection,” discuss the findings related to the PMS SHA and FMEA, respectively. The forthcoming FMEA for the CIM system will capture bounding failure types and the anticipated MTBF analysis for the components of the CIM system. Due to the forthcoming CIM system FMEA being bounded by the PMS FMEA (WCAP- 16438-P), the staff finds the approach of addressing the different failure modes of the CIM system adequate. Although both devices do not use software during their operational modes, the use of programming languages along with synthesizers, simulators and other testing tools being used during their lifecycles for both the SRNC and CIM require they be treated as software-based devices. Based upon the updated response to RAI-SRP-SHA-01, Revision 1, dated June 28, 2010, which discusses the CIM system within the SHA, the staff finds the CIM system satisfies the single failure criterion.

IEEE Std. 603–1991, Clause 5.2, requires the CIM system to be designed such that once the system has been actuated the executable features of the protective system continue to completion. Based upon the discussion in the AP1000 PMS FMEA (WCAP-16438-P), upon a failure of the SRNCs, such as through a loss of system power or overt module failure, the device will latch in its last command, such that if a failure occurs, the SRNC will continue to provide the actuate command. In the case of the CIM, should a single communication bus fail on the safety-related bus, the redundant bus will carry the signal through to completion. If a singular CIM fails outright, the system is designed with either a redundant CIM or another system design characteristic, such as a check valve in line with the valve actuator affected by the CIM failure to ensure the system is not adversely impacted by the component failure. These system design characteristics were verified during the April 20-22, 2009 audit conducted at the Westinghouse facility in Cranberry, Pennsylvania.

IEEE Std. 603–1991, Clause 5.3, along with 10 CFR Part 50, Appendix B, requires the CIM system to be designed with a sufficient measure of quality to ensure a high level of component and system reliability consistent with low failure rates. NUREG-0800 Appendix 7.1-D, "Guidance for Evaluation of the Application of IEEE Std. 7-4.3.2"; Section 5.3; and BTP 7-14 specifically address the criteria for a quality software development process. Additional regulatory guidance discussing acceptance criteria related to protective system quality are discussed in Section 7.2.2.3.3, "Quality." The staff found several areas of technical information to be lacking either a sufficient level of detail to satisfy BTP 7-14 or a proposed alternative method of providing adequate CIM system developmental detail in order for the staff to find the CIM development process of sufficient breadth and technical depth. As such, the final disposition of this issue related to CIM development, previously addressed as Open Item OI-SRP7.2-ICE-05, will be covered in Section 7.2.5.

IEEE Std. 603-1991 Clause 5.4, "Equipment Qualification," states, in part, that safety system equipment shall be qualified by type test, previous operating experience, or analysis, or any combination of these three methods, to substantiate that it will be capable of meeting, on a continuing basis, the performance requirements as specified in the design basis. Based upon a review of the ITAAC in Table 2.5.2-8, particularly Design Commitments 2, 3, 4, 5a and 5b, the listed commitments address the protective systems; therefore, the CIM system's ability to withstand the necessary seismic, electromagnetic/radio-frequency, and electrostatic discharge loads or transients. Additionally, the CIMs must be able to withstand additional environmental conditions, such as qualified temperature and humidity profiles. As a result of the requirements placed upon the protective system and, therefore, the CIM system, in the Tier 1 ITAAC of Section 2.5.2 of the AP1000 DCD, the staff finds that the CIM system meets the environmental qualifications as required by IEEE Std. 603-1991.

Safety systems must also be capable of accomplishing their safety functions under the full range of applicable conditions specified in the design basis in accordance with Clause 5.5, "System Integrity," of IEEE Std. 603-1991. Additionally, the staff used the guidance in Appendices 7.1-C and 7.1-D of NUREG-0800 to review the CIM system and the manner by which it meets the requirements of system integrity.

Of particular concern when dealing with computer-based or programmable technology-based systems is the system's ability to complete its function in an actual or real time period that would ensure that any design basis limits are not exceeded. The system must be left in a known state after an event condition has been resolved to satisfy Information Bulletin 80-06; "Engineered Safety Features (ESF) Reset Controls," thus ensuring that it is the operator, not the system that controls the repositioning of equipment during recovery from an event. Additionally, a digital system should be able to detect, alert the operator, and take appropriate action, perhaps by taking a component, channel or division to trip or bypass, once a failure is detected.

Based upon a review of WCAP-16674-P, WCAP-16675-P, and Section 2.3.1.2.8 of WCAP-17179-P, the staff determined the CIM subsystem portion of the PMS system functioned in a deterministically-based manner. This information is also captured in lower level proprietary Westinghouse documents, thus helping to ensure safety-system timing requirements are validated. Based upon Section 6.0, "Component Interface Module," of WCAP-16674-P, the applicant committed that, after the completion of an event scenario, the PMS components will remain in their actuated state until they can be repositioned by an operator. This commitment adequately addresses the guidance of Information Bulletin 80-06. In relation to the guidance of Appendix 7.1-C of NUREG-0800 detailing a protection system's response in the presence of a detected failure of a component, channel or division, the staff finds the information in Section 2.1 of WCAP-17179-P adequately addresses the system's self-identification and reporting of system faults. In addition, the FMEA for the PMS (WCAP-16438-P) discusses the overall system response in the presence of known component, channel or system faults in Section 4.4 ILC, "(Integrated Logic Cabinet) Process Station." Based upon a review of the docketed information presented by the applicant, related to system integrity, the staff concludes the CIM system operates in a manner consistent with Clause 5.5 of IEEE Std. 603-1991.

IEEE Std. 603-1991, Clause 5.6, "Independence," along with 10 CFR Part 50, Appendix A, GDCs 21, 22, and 24, require, in part, that safety-related protection systems be designed with sufficient physical, electrical, functional, and communications independence. The communications independence of the CIM will be discussed in Section 7.9. Electrical isolation of the CIM system is provided through the use of fiber optic connections from the PLS, through the RNC, to the DWTP within the ILC, in which the CIM system resides. Physical independence is provided by housing all CIM system safety-related components separately from the nonsafety-related PLS components, with one notable exception. The RNC is housed in the ILC with the CIM system. Although not classified as a Class 1E component, the applicant committed to qualify the RNC as an associated circuit in accordance with IEEE Std. 384-1981. Although the functionality of the RNC cannot be guaranteed during or after a design basis event, the applicant's commitment to qualify the RNC as an associated circuit prevents the loss of the CIM's safety function in the event of an RNC hardware failure. As such, the interaction of the PLS and PMS within the CIM also addresses functional isolation in that a loss of function within the RNC or another PLS-based component will not inhibit the CIM from carrying out its safety-related function in accordance with 10 CFR Part 50, Appendix A, GDC 24. For further information related to PMS independence, refer to Section 7.2.2.3.6, "Independence."

Based upon a review of the information in WCAP-16674-P, Revision 4; WCAP-16675-P, Revision 5; and WCAP-17179-P, Revision 2, the staff finds that the CIM system meets the criteria related to physical, electrical and functional independence requirements between the safety-related and nonsafety-related systems. A discussion related to the findings on communications independence of the CIM system is provided in Section 7.9.

IEEE Std. 603-1991, Clause 5.7, and 10 CFR Part 50, GDC 21, require the protection system be capable of testing and calibration during all anticipated modes of operation. In addition, the guidance in Appendix 7.1-D and BTP 7-17, of NUREG-0800, as well as RG 1.22, state how a system designed for high reliability will be able to be tested in various configurations while simultaneously ensuring the protection system stays in service. Based upon a review of all applicable information in Chapter 7 of the AP1000 DCD and associated TRs, the applicant credits no self tests that mitigate or replace the need to conduct periodic surveillance testing of the CIM or protection systems. After reviewing the CIM system TR, the system conducts periodic diagnostic self-tests and transmits the information via the CIM and SRNC to the ILP within the PMS, at which point the Common Q portion of the system alerts the operator to any condition outside of normal system operation. This topic is discussed further in Section 2.5 of the CIM TR. The staff finds that based upon a review of the information in WCAP-16674-P, Revision 4; WCAP-16675-P, Revision 5; and WCAP-17179-P, Revision 2; the CIM system satisfies Clause 5.7 of IEEE Std. 603-1991 and 10 CFR Part 50, Appendix A, GDC 21.

Clause 5.9, "Control of Access," in IEEE Std. 603-1991, stipulates appropriate levels of control be required to access the safety system. The PMS is typically accessed from either the PDSP in the MCR or via the division specific MTP. The CIM system components can be accessed when required, such as is the case when safety-related components with non-onerous consequences cannot be controlled via the PLS via the local controls on the CIM itself, but the cabinets in which the CIMs are housed are locked and administrative controls will be in place to prevent unwanted access of the CIM system. A more detailed analysis concerning the control of access to the CIM and PMS is provided in Section 7.9.5, which evaluates the applicant's requirements to ensure that the PMS is constructed in an SDOE.

Based upon a review of the material in WCAP-17179-P, Revision 2, in particular Section 2.12, "Human Factors and Maintenance Considerations," the staff finds that the CIM system adequately addresses Clause 5.10, "Repair," of IEEE Std. 603-1991.

In relation to the use of automatic and manual control, the CIM system is not designed for routine manual control. However, in the event of the failure of a safety-related component with non-onerous consequences that does not have individual safety-related controls on the safety-related PDSP in the MCR (as defined by the PMS FMEA in WCAP-16438-P, Revision 3), the CIM possesses local safety-related controls that can be utilized to position the safety-related component as the situation requires. It should be noted these non-onerous components are typically soft-controlled from the PLS; however, as the PLS is nonsafety-related, its actions are not credited in accordance with IEEE Std. 603-1991. Further discussion regarding how the PMS executes automatic and manual controls may be found in Section 7.2.2.3.11 of this report. Based upon its review of WCAP-17179-P, Revision 2, the staff finds that the CIM system meets the requirements of IEEE Std. 603-1991, Clauses 6.1 and 6.2, "Automatic," and "Manual Control," respectively.

IEEE Std. 603-1991, Clause 5.15, requires the protection system operate in a reliable manner. To facilitate this requirement as it relates to the CIM system, appropriate analyses shall be conducted to ensure that reliability goals have been achieved. The applicant has committed to present to the staff a formal CIM development process, in which it will demonstrate what quality measures, processes, policies, procedures and analyses will be completed in order to satisfy the requirements of IEEE Std. 603-1991, Clause 5.15. Additional discussion of the staff's understanding of the the applicant's commitments made related to CIM system reliability as a byproduct of the CIM development process, may be found in Section 7.2.5 of this report.

The staff conducted an engineering review with the applicant's technical personnel on October 15-16, 2008, and January 29-30, 2009, and conducted two audits, one on April 20-22, 2009, and the other on April 12-16, 2010, to discuss the PMS development process, of which the CIM is a critical part. Previously through the use of Open Item OI-SRP7.2-ICE-05, the staff raised the issue of an inadequate CIM development process and the staff restated this conclusion to the applicant after the April 12-16, 2010 audit and transmitted RAI-SRP7.0-ICE-11 to the applicant on May 17, 2010. After reviewing the updated response to the RAI in WCAP-17179, the staff found that the applicant did not provide sufficient planning or design information related to the CIM priority module. The following provides a topical breakdown of the required information:

- Section 5.1.5 of WCAP-16675-P describes the CIM as a non-software-based Class 1E device that is not considered to be susceptible to a software common-cause failure (CCF). However, the CIM is FPGA-based (programmable technology). The applicant did not provide sufficient information for the staff to determine that the CIM is not susceptible to a software common-cause failure (SWCCF). The applicant committed to updating all TRs by removing all text stating the CIM is not susceptible to a SWCCF.

- The applicant has not adequately described the programmable technology lifecycle development plans and processes for the CIM logic development, design, implementation, testing, and operation.

The applicant has not provided sufficient information on these topics, previously requested under RAI-SRP7.1-ICE-21, RAI-SRP7.1-ICE-22, and RAI-SRP7.1-ICE-23. Additionally, after conducting two audits, one in Scottsdale, Arizona (at the CIM and DAS supplier's facility) and the other in Warrendale, Pennsylvania (Westinghouse's location) and reviewing the information in WCAP-17179, the required information, in both depth and breadth, was determined not to be present for the CIM or its peer components in the AP1000 CIM TR. The staff previously identified this issue as Open Item OI-SRP7.2-ICE-05, and, based upon the applicant's commitment to develop an adequate CIM development process; this open item will be closed out as discussed in Section 7.2.5.

The additional detailed design information would otherwise have to be addressed through verification of implementation of the I&C DAC. Therefore, the changes to the DCD eliminate the need for I&C DAC and, thus, satisfy the finality criteria in 10 CFR 52.63(a)(1)(iv).

7.2.2.3.15 Safety-Related Remote Node Controller Evaluation

The staff conducted an audit that dealt with the review of the Phase 1 and Phase 2 proprietary documents for the AP1000 PMS SLC on April 20–22, 2009, in Cranberry, Pennsylvania. During the demonstration of a "test" system, the staff learned of a new device that the applicant would add to the PMS. The applicant demonstrated the use of an SRNC that would serve as the interface device from the ILP to the CIM. Under previous revisions of TRs, no intermediary device existed between the ILP and the CIM. Additionally, the staff reviewed WCAP-17179-P, the AP1000 CIM TR that discussed the use of the SRNC within the CIM system. Based upon the review of the report, questions regarding the use of and quality design process built into the SRNC device remain. Therefore, the issue was captured under the open item related to the CIM. The issue previously identified as Open Item OI-SRP7.2-ICE-06 pertaining to the quality development process of the SRNC will be captured by the response to Open Item OI-SRP7.2-ICE-05, which discusses quality development process of the CIM, of which the SRNC is a part. This open item is discussed in Section 7.2.5.

7.2.3 Common Qualified Platform Design and COL Action Items

In TR-42, the applicant stated its position on what current and future activities it will complete through the ITAAC process. In some cases, the closeout activities either point to more than one ITAAC for closure, or the applicant requested closure of a given PSAI when it had not met all the acceptance criteria for a PSAI. The information in TR-42 is not entirely consistent with the staff's position regarding the disposition of the GOIs and PSAIs.

To identify the applicant's position regarding currently open and previously closed PSAIs and GOIs through the ITAAC process, the NRC asked the applicant, in RAI-SRP7.1-ICE-01, to provide a detailed road map showing which I&C design items remain open and which have already been closed, as well as the method of closure through the ITAAC or DAC process.

On December 12, 2008, the NRC received the applicant's response to RAI-SRP7.1-ICE-01 in DCP/NRC2319. However, several of the applicant's conclusions were not consistent with the staff's findings, which are based on a review of the information in the following documents:

- "Safety Evaluation by the Office of Nuclear Regulation CE Nuclear Power Topical Report CENPD-396-P Common Qualified Platform Project 692," and its supporting future documents regarding the closeout of GOIs and PSAIs, also known as Category 1 and Category 2 Closeout Items

- APP-GW-GLR-017

- Response letter to RAI-SRP7.1-ICE-01, dated December 12, 2008

The staff determined that GOIs 7.1, 7.2, 7.3, 7.5, and 7.6 are closed, based on the findings in "Acceptance of the Changes to Topical Report CENPD-396-P, Revision 1, 'Common Qualified Platform,' and Closeout of Category 2 Open Items (TAC No. MB2553)." The NRC closed out GOIs 7.4 and 7.7 generically, as well as PSAI 6.3. The NRC closed GOI 7.9 and 7.10 in acceptance of "design concept only," based on findings in "Safety Evaluation for the Closeout of Several of the Common Qualified Platform Category 1 Open Items Related to Reports CENPD-396-P, Revision 1, and CE-CES-195, Revision 1 (TAC No. MB0780)."

The following provides the staff's position with regard to the remainder of the open GOIs and PSAIs:

- GOI 7.8

  The staff reviewed WCAP-16674, Revision 4. The staff determined the methodology used by the applicant that the staff understands to be a "safe state, system-based" approach, which typically used the nonsafety-related PLS to control a safety-related component, was acceptable, in that the system first attempts to activate the given safety-related component using the PLS and, failing that, the system then activates using the safety-related PMS. In the event of a SWCCF of the PMS, the AP1000 compensates by activating the DAS to meet the diversity requirements in BTP 7-19. Although other issues related to the development process of the priority device, known as the CIM system in the AP1000 design, still remain, the mechanism by which the safety-related component actuates, either by a nonsafety-related or safety-related system means, is deemed acceptable. Therefore, the staff considers GOI 7.8 closed.

However the issue of overall CIM system quality, planning and development processes continues to be a concern previously captured under Open Item OI-SRP7.2-ICE-05 and, based upon the applicant's commitment to adequately address a high quality CIM development process. This action is discussed in Section 7.2.5.

- GOI 7.9

  The applicant stated in TR-42 that the NRC can close GOI 7.9, regarding the specific use of the ITP and the Advant Fieldbus (AF) 100 buses to provide separation of safety and nonsafety signals, since the AP1000 I&C system differs in some details from the integrated solution described in Appendix 4, "Common Qualified Platform Integrated Solutions." Additionally, this TR provides other plant-specific implementations of safety-to-nonsafety communications.

  Thus, the staff considers GOI 7.9 closed. The staff evaluated the other plant-specific implementations of safety-to-nonsafety communications in Section 7.9.

- GOI 7.10

  The applicant committed to alter the characteristics of the AP1000 Common Q platform so that the AP1000 design no longer uses multichannel operator stations. Therefore, the NRC considers GOI 7.10 closed.

- PSAI 6.1

  The staff agrees with the applicant's conclusion in TR-42 that it uses its quality assurance program to determine the suitability of all I/O devices, by following the requirements of the Westinghouse QMS, which the NRC approved in August 2002. The NRC considers PSAI 6.1 closed.

- PSAI 6.2

  The staff agrees with the applicant's conclusion in TR-42 that, since the AP1000 does not use a hardware user interface, PSAI 6.2 is not valid in the AP1000 specific application. Therefore, the NRC considers PSAI 6.2 closed.

- PSAI 6.3

  The NRC closed out this issue (see above discussion).

- PSAI 6.4

  The staff agrees with the applicant's conclusion in the RAI response letter dated December 12, 2008 (see above), as well as the information in "Resolution of Common Q NRC Items for AP 1000," Revision 0, also referred to as TR-42, that this PSAI will not be closed until the completion of the testing phase for hardware and software for the PMS. This commitment to test the system's components to appropriate levels of environmental qualification appears in AP1000 DCD Tier 1, Chapter 2, Section 2.5.2, ITAAC Table 2.5.2-8, Design Commitment 4.

- PSAI 6.5

  The staff agrees with the applicant's conclusion in the RAI response letter dated December 12, 2008 (see above), that this PSAI will be addressed in the testing phase for PMS hardware and software. The commitment to verify the implementation of the SLC appears in AP1000 DCD Tier 1, Chapter 2, Section 2.5.2, ITAAC Table 2.5.2-8, Design Commitment 11.

- PSAI 6.6

  The staff agrees with the approach the applicant selected regarding the AP1000 setpoint methodology in WCAP-16361-P, Revision 1. AP1000 DCD Tier 1, Chapter 2, Section 2.5.2, ITAAC Table 2.5.2-8, Design Commitment 10, addresses the actual setpoint accuracy and response time of AP1000 safety systems. Since the DCD provides an acceptable setpoint methodology and ITAAC to verify setpoints and response time, the NRC considers PSAI 6.6 closed. Section 7.2.7 includes further discussion of setpoints.

- PSAI 6.7

  The staff agrees with the applicant's conclusion in the RAI response letter dated December 12, 2008 (see above), that this PSAI will be addressed during the human factors engineering (HFE) testing phase for the PMS. AP1000 DCD Tier 1, Chapter 3, ITAAC Table 3.2-1, includes the design commitments for verifying the HFE. Further information is provided in Chapter 18 of NUREG-1793.

- PSAI 6.8

  The staff agrees with the applicant's conclusion in the RAI response letter dated December 12, 2008 (see above), that this PSAI is applicable to existing NPPs, not new power plants incorporating new designs. Therefore, the NRC considers this PSAI closed.

- PSAI 6.9

  The staff agrees with the applicant that the plant procedures and/or technical specifications due to installation of the Common Q system will be dealt with at the plant-specific level. Chapter 16 of NUREG-1793 and this supplement address the technical specifications.

- PSAI 6.10

  Previously, the staff reviewed but had not approved the generic FMEA, and submitted several RAIs to the applicant to offer a more detailed technical response or to clarify several statements in the FMEA document that were unclear. Section 7.2.2.3, “Single-Failure Protection,” which discusses the technical information required of the applicant related to its FMEA. As a result, the NRC considered this PSAI open. Based upon the submission of Revision 3 of WCAP-16438-P, the PSAI is considered closed. For further information, regarding this topic, refer to Section 7.2.2.3.2, Single Failure Protection.

- PSAI 6.11

  PSAI 6.11 states that an applicant using the Common Q platform would need to address D3 to prevent an SWCCF. In Sections 7.1 and 7.7 of the AP1000 DCD, the applicant describes the functional requirements of the DAS. The DAC in Revision 19 of AP1000 DCD Tier 1, Table 2.5.1-4, Item 4, includes the design and analysis of the DAS. As described in Section 7.8, the applicant modified Item 4. The staff found that the applicant provided sufficient design information to justify the modifications. Therefore, this PSAI is closed.

- PSAI 6.12

  AP1000 DCD Tier 1, Chapter 2, Section 2.5.2, ITAAC Table 2.5.2-8, Design Commitment 10, defines the commitment to verify proper response times of circuits. Since the applicant has provided an acceptable ITAAC to address this action item, the NRC considers PSAI 6.12 closed. The time response of the CIM system is addressed in Section 7.2.2.3.14 of this report.

- PSAI 6.13

  The staff agrees that this PSAI will remain open until the completion of integration and preoperational testing. AP1000 DCD Tier 1, Chapter 2, Section 2.5.2, ITAAC Table 2.5.2-8, Design Commitment 11, includes the commitment to verify load capacity and sharing of communications resources for the PMS.

- PSAI 6.14

  PSAI 6.14 states implementation of the Common Q must not render invalid any previously accomplished Three-Mile Island (TMI) action items. In NUREG-1793, the staff found the AP1000 design addresses the TMI action items. The staff did not find any information in the proposed changes to the AP1000 DCD that would invalidate that conclusion. Since the AP1000 design meets the I&C-related TMI action items described in 10 CFR 50.34(f)(2), “Contents of applications; technical information,” the staff finds this PSAI closed.

Based upon the discussions above, the staff considers all GOIs closed. The open PSAIs listed above will continue to remain open until they are resolved.

7.2.5 Protection and Safety Monitoring System Design Process Review

In AP1000 DCD Tier 1, Section 2.5.2, the applicant describes its entire SLC process related to the development of the Common Q portion of the PMS, which it will implement during the planning, design, construction, testing, and operational phases for the AP1000 I&C safety systems. In AP1000 DCD Tier 1, Section 2.5.2, Design Commitment 11, the applicant deleted the design requirements phase and system definition phase. The applicant based this removal on the cumulative amount of both docketed and audited documentation made available to the staff as of this date.

The staff reviewed the information on the docket and conducted several site visits related to the review of the PMS design process at Westinghouse's Twinbrook facility, and in both Monroeville and Cranberry, Pennsylvania. The primary purpose of the Twinbrook visits (April 8–10, 2008, October 15–16, 2008, January 29–30, 2009, and July 30, 2009) was to conduct an engineering review of the documents for the design requirements and system definitions phases (described as the conceptual phase and system definition phase by the Common Q SPM and WCAP-15927, and the planning activities and requirements activities phases of NUREG-0800 BTP 7-14 SLC Process).

Additionally, the staff conducted three audits, the first was conducted on April 20-22, 2009, examining the Phase 1 and Phase 2 AP1000 PMS SLC proprietary material at the Westinghouse facility in Cranberry, Pennsylvania. The second audit was conducted on March 8–11, 2010, at CS Innovations, in Scottsdale, Arizona. CSI serves as the designer and supplier of the CIM subsystem (as well as the DAS – Section 7.8 provides further discussion of how adequate diversity is maintained between the two systems) within the PMS. The more recent audit was conducted in Warrendale, Pennsylvania at the Westinghouse Automation Services (formerly Repair, Replacement, and Automation Services) facilities on April 12-16, 2010. The more recent of the two audits was in order to determine whether an adequate demonstration of documentation had been presented to conclude that all requirements for the planning activities phase and requirements activities phases for both the PMS and the DAS would be considered complete. The October 3-5, 2006, trip report lists the design requirements phase documents associated with the staff's visit to the Monroeville, Pennsylvania, facility as of October 2006. The applicant based its conclusion that its design requirements and systems definition phases were complete on the proprietary information listed in the April 2009 audit report and the docketed information related to the AP1000 I&C safety systems design process. The applicant desired to close these two phases as part of its DAC closure process.

The staff finds that, once the requirements for each phase of the PMS (SLC) are met, "completion" rather than "elimination" of these and all phases described in the text of AP1000 DCD, Tier 1, Section 2.5.2, Item 11, is appropriate, provided the staff finds the information in those phases to be sufficient. When the staff arrives at that conclusion for each given design process phase, The applicant may remove the given SLC phase(s) in Tier 1, Table 2.5.2-8, Item 11. Those tables describe specific ITAAC activities that will be completed during the given facility's inspection process, rather than the process undertaken to ensure that the applicant has included sufficient quality in the overall design process for AP1000 I&C safety systems. However, the applicant may not remove the design process description from the text-based portion of the design process description in Tier 1, Section 2.5.2, Item 11. The applicant agreed to restore all AP1000 PMS design process phases to the text-based portion of Tier 1, Section 2.5.2, Design Commitment 11. On February 23, 2010, the applicant submitted a response to Open Item OI-SRP7.2-ICE-07 that dealt with the removal of the text based descriptions in Tier 1, Section 2.5.2. The applicant's commitment to reinsert the text-based portions of the PMS design process with the addition of the word "complete" to those given phases, once the staff finds a given developmental phase for the PMS to be adequately addressed, is an approach acceptable to the staff. However, although not specifically addressed by this open item, the staff's expectation would be that this process would be carried out in the Tier 1, Section 2.5.1 for the DAS in a similar fashion. The staff previously identified this as Open Item OI-SRP7.2-ICE-07. In a subsequent revision, the applicant incorporated this Tier 1 information in the AP1000 DCD. The staff concludes that these changes are acceptable.

Based on the review of all audited and docketed documentation provided to the NRC that relates to the design requirements, system definition, and remaining developmental phases of the SLC for the PMS, as well as the series of audits conducted and their conclusions, the staff has not concluded that the applicant adequately completed or addressed the system definition phase, both from a lack of technical adequacy and a lack of completeness of the given subject matter. After reviewing Section 7.1.2.14.1, "Design Process," of the AP1000 DCD, the staff was unable to locate additional information adequately describing all developmental phases of the Common Q SLC and the programmable technology lifecycle for the CIM system in Tier 2 of the AP1000 DCD. Additionally, based upon discussions held during the April 2009, March 2010, and April 2010, audits and conclusions drawn in the respective audit reports, the applicant stated they had "split" the system definition phase of development for the Common Q and CIM system portion of the PMS. However, based upon the documents made available for review, it appears the applicant has "split" the system definition phase of development in a discussion-based format only, as no alteration to the Common Q SPM, the Tier 2* document, WCAP-15927, or Tier 2 information has been made. The applicant did not provide sufficient technical information in the AP1000 DCD, its associated TRs, or its proprietary documentation (to be made available for audit or inspection) to demonstrate satisfactory completion or alteration of the system definition phase of Common Q development.

The applicant must provide adequate information regarding a programmable technology development plan for the CIM and SRNC, previously addressed by Open Items OI-SRP7.2-ICE-05 and OI-SRP7.2-ICE-06, respectively. The applicant must restore the listing of the system definition phase in AP1000 DCD Tier 1, Section 2.5.2, Design Description 11, and in ITAAC Table 2.5.2-8, Design Commitment 11, until the staff finds that the applicant has completed that group of activities. Once those activities had been completed, the staff required the applicant to comply with its commitment as delineated in its response to Open Item OI-SRP7.2-ICE-07, which dealt with the removal and restoration of the text-based descriptions in Tier 1, Section 2.5.2. Additionally, the staff required the applicant to restore information in Tier 1, provide additional, sufficient information in Tier 2, and Tier 2* documentation, especially WCAP-15927, that accurately describes all developmental phases and processes associated with the Common Q portion of the PMS. The staff previously identified this issue as Open Item OI-SRP7.2-ICE-08. Based upon the applicant's commitment to restore the system definition phase of the PMS SLC in a future revision of the AP1000 DCD and based upon the applicant's commitment to add ITAAC Design Description 14, in Tier 1, Section 2.5.2, and Design Commitment 14 in Table 2.5.2-8, in which the applicant describes how it will meet the requirements related to the development of the CIM subsystem within the PMS, the staff determined that Open Items OI-SRP7.2-ICE-05 and OI-SRP7.2-ICE-08 were closed. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

Since the applicant chose to add a more specific ITAAC related to the CIM development process (Tier 1, Section 2.5.2, Design Description 14 and Design Commitment 14 in

Table 2.5.2-8, ITAAC), and based upon the additional language added to the system integration and test phase acceptance criteria in Design Commitment 11, as discussed in Section 7.9.2.3.2 of this report, the staff finds the design requirements, or planning activities phase (in accordance with HICB BTP-14), of development for the PMS to be complete. However, the staff's expectation related to the forthcoming CIM development process is that it will sufficiently address and describe all phases of development for the CIM subsystem of the PMS, including the planning activities phase of development.

Furthermore, since the applicant submitted, and the staff approved, critical licensing documents in the system definition phase related to PMS development (such as the FMEA for the AP1000 PMS (WCAP-16438-P) and the SHA of the AP1000 PMS (WCAP-16592-P)), the staff does not consider the remaining development activities listed as part of the system definition phase of the PMS SLC to be DAC, as future development activities are not anticipated to impact licensing basis information, such as the AP1000 DCD Tier 2 or AP1000 TRs referenced in the DCD. However, if the design detail from future development activities impacts the licensing basis information, the staff expects that information to be incorporated into the licensing basis information.

In Revision 16 of the AP1000 DCD, the applicant asked to remove the reference to WCAP-15927, which the applicant submitted to the NRC in addition to the SPM, to resolve RAI 420.001 and RAI 420.023. The staff issued these RAIs during the certification of the original NUREG-1793 in 2002. The applicant had to demonstrate the measures it would take to ensure critical information in this report is not removed. In July 2009, the applicant decided not to remove the report and submitted Revision 2 of WCAP-15927, which explained which organization, in this case, the separate and independent IV&V organization, has the exclusive responsibility for IV&V activities, including testing activities. The staff considers the issue resolved, since WCAP-15927 elaborates on the organization that performs the software verification and validation (V&V) activities. Specifically, Section 3 of the document states that "…testing activities are defined as part of the V&V process." The statement indicates that the IV&V group is responsible for testing the PMS, as discussed in the Common Q SPM. Therefore, the staff finds that RAI-SRP7.1-ICE-10 is resolved.

The additional detailed design information would otherwise have to be addressed through verification of implementation of the I&C DAC. Therefore, the changes to the DCD eliminate the need for I&C DAC and satisfy the finality criteria in 10 CFR 52.63(a)(1)(iv).

7.2.7 Protection Systems Setpoint Methodology

On May 30, 2006, the applicant submitted WCAP-16361-P, Revision 0. The following regulatory requirements and guidance documents apply to the staff's review of WCAP-16361-P:

- GDC 13 and 20

- 10 CFR 50.36(c)(ii)(A), "Technical specifications," requires that the technical specifications include limiting safety-system settings

- RG 1.105, "Setpoint for Safety-Related Instrumentation," describes a method acceptable to the staff for complying with the NRC's regulations for ensuring that setpoints for safety-related instrumentation are initially within, and remain within, the safety limit

The Westinghouse setpoint methodology combines the AP1000 uncertainty components to determine the overall channel statistical allowance for the functions of the RTS/ESFAS. All appropriate and applicable uncertainties, as defined by a review of the AP1000 baseline design input documentation, have been considered for each RTS/ESFAS function. The methodology used to combine the uncertainty components for a channel is an appropriate combination of those groups that are statistically and functionally independent. Those uncertainties that are not independent are conservatively treated by arithmetic summation and then systematically combined with the independent terms. It includes instrument (sensor and process rack) uncertainties and non-instrument-related effects (process measurement accuracy). The methodology used the square-root-of-the-sum-of-the-squares technique, which the NRC has approved. Also, the American National Standards Institute (ANSI), the American Nuclear Society (ANS), and the International Society of Automation (ISA) approve the use of the same probabilistic and statistical techniques for the various standards that determine safety-related setpoints.

The staff reviewed WCAP-16361-P and found that the allowable values (AVs) are equal to the rack calibration accuracy, which is the acceptable "as-left" value. This methodology ensures that the purpose of the AV is satisfied by providing a large enough allowance to account for those uncertainties not measured during the surveillance tests to protect the safety limit. Also, the difference between the AV and the nominal trip setpoint is as large as the calibration tolerance, and the AVs, along with the nominal trip setpoint, are included in the plant technical specifications as the associated criteria, in accordance with 10 CFR 50.36. Therefore, the staff concludes that the proposed WCAP-16361-P, Revision 0, as it realtes to an overall setpoint methodology, is acceptable. However, due to proposed changes in the inputs to the OPΔT and OTΔT as discussed in Section 7.2.2.1.1 of this report, the applicant committed to revise the WCAP-16361-P report to address these changes. These changes were incorporated into Revision 1 to WCAP-16361-P, which the staff reviewed and found acceptable.

Section 7.1.6.1 of the AP1000 DCD states that all requested information on the subject of setpoint methodology and final setpoint calculations has been completely addressed and requires no further action by the COL applicant. This statement is not in agreement with WCAP-16361-P, in which the applicant concludes that it cannot determine the final setpoint calculations until it completes the final design of the power plant. The staff issued RAI-SRP7.2-ICE-08, requesting that the applicant demonstrate how it intends to meet the final calculation requirements, given that it has not completed the protection system design. The applicant submitted DCR/NRC2315 to the NRC on December 9, 2008, declaring that the COL applicant will determine the setpoint adequacy, in accordance with AP1000 DCD Tier 1, Table 2.5.2-8, Item #10. In its response to Open Item OI-SRP7.2-ICE-09, dated March 8, 2010, the applicant committed to restore the language in Section 7.1.6.1, stating that the COL applicant or licensee will be responsible for the final determination of setpoints, in accordance with AP1000 DCD Tier 1, Section 2.5.2, ITAAC Table 2.5.2-8, Design Commitment 10. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

Section 2.2.6 of WCAP-16675-P states that the applicant uses the MTP to alter setpoints and addressable constants. The MTP provides a dedicated display interface for each division and is used to bypass the channel before changes are made. The staff evaluated the access controls on the MTP to control the alteration of addressable constants, setpoints, parameters, and other settings to meet the requirements of IEEE Std. 603-1991, Clause 5.9. This clause required the design to provide administrative control of access to safety-system equipment. Section 1, Point 10, of the digital I&C ISG Document #4, "Highly-Integrated Control Rooms—

Communications Issues (ISG #4-HICRc)," Revision 1, clarifies this requirement by making the following statement:

> A workstation (e.g., engineer or programmer station) may alter addressable constants, setpoints, parameters, and other settings associated with a safety function only by way of the dual-processor/shared-memory scheme described in this guidance, or when the associated channel is inoperable. Such a workstation should be physically restricted from making changes in more than one division at a time. The restriction should be by means of physical cable disconnect, or by means of keylock switch that either physically opens the data transmission circuit or interrupts the connection by means of hardwired logic.

The staff finds the use of the MTP acceptable to bypass the channel in addressing the guidance in ISG No. 4-HICRc. Specifically, since the MTP serves as a dedicated display interface system for each division, the NRC does not require physical means to prevent the MTP from making changes to more than one division at a time.

7.2.8 Protection and Safety Monitoring System Evaluation Findings and Conclusions

The staff evaluated the revisions made to Chapter 7 of the AP1000 DCD, against the regulatory requirements stipulated in NUREG-0800 Table 7-1. Below is a summary of the staff's findings as they relate to the AP1000 PMS.

The staff finds that the proposed changes to the AP1000 DCD meets the requirements of 10 CFR 50.55a(a)(1). Specifically, the staff found that the applicant incorporated quality standards into the design of the AP1000 I&C systems.

Regulations in 10 CFR 50.55a(h) require compliance with IEEE Std. 603-1991 and the correction sheet dated January 30, 1995. The staff compared the PMS in the amendments to the AP1000 I&C systems design with the applicable clauses of IEEE Std. 603-1991 and has the following findings:

- The applicant satisfied Clause 5.1 of IEEE Std. 603-1991, as documented in Section 7.2.2.3.1.1. Specifically, the applicant has demonstrated how the PMS met the criteria presented in Clause 5.1 and GDC 21. The FMEA provided to the staff adequately demonstrates how the PMS will operate with a single failure under all postulated operating conditions, as discussed in Section 7.2.2.3.2 of this report.

- IEEE Std. 603-1991, Clause 5.3: The applicant satisfies the requirement of quality for the PMS, as documented in Section 7.2.2.3.3. Specifically, the applicant has not demonstrated how it meets the criteria in Clause 5.3 with regard to the design of the CIM and the SRNC, which would then provide reasonable assurance that it had developed a high-quality product for all components within the PMS. Sections 7.2.2.3.14 and 7.2.2.3.15 of this report discuss these issues. The staff previously identified these issues as Open Items OI-SRP7.2-ICE-05 and OI-SRP7.2-ICE-06, respectively. Based upon the applicant's commitment to add an ITAAC relating to the development of a programmable technology lifecycle for the CIM system, as demonstrated by the addition of Design Description 14 and Design Commitment 14 to Table 2.5.2-8 of the DCD, that is consistent with the requirements of IEEE Std. 603-1991 and the guidance of BTP 7-14 of NUREG-0800, the staff considers the open items closed.

10 CFR Part 52, “Licenses, certifications, and approvals for nuclear power plants,” Appendix D, “Design Certification Rule for the AP1000 Design,” Section II.D, defines Tier 1 information as that information explaining design descriptions, along with ITAAC information. Based upon the applicant’s commitment to restore all phases of the PMS SLC design process in the text-based portion of Item 11 in NUREG-0800 Section 2.5.2, “Protection and Safety Monitoring System,” the issue the staff previously identified as Open Item OI-SRP7.2-ICE-07 is closed.

- 10 CFR 52.47(b)(1) describes the ITAAC. The applicant provided sufficient information to satisfy the completion of the design requirements or conceptual phase of the PMS SLC, with the commitment to add the CIM Development Process ITAAC discussed above. Based upon its review of the documentation presented and based upon conclusions drawn in several audits, the staff will not approve the removal of the system definition phase of the PMS SLC until such time as the applicant provides satisfactory information to the staff for review and approval.

- IEEE Std. 603-1991, Clause 6.8: The staff found the proposed setpoint methodology acceptable. Additionally, the applicant commitment to restore the text in Section 7.1.6.1 of the AP1000 DCD stating that the COL applicant or licensee will be responsible for the final determination of setpoints was found acceptable to the staff. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

The staff finds that due to the addition of the ITACC related to the information that will be provided for the CIM development process, (design description and Design Commitment 14 in Tier 1, Chapter 2.5.2 and Table 2.5.2-8, respectively) the design requirements or planning activities phase of development for the PMS is considered complete.

The staff finds that the proposed changes to the AP1000 DCD did not affect the remaining requirements of IEEE Std. 603-1991. Therefore, the staff’s original conclusions in NUREG-1793 for these requirements are still valid.

The staff finds that proposed changes to the AP1000 DCD did not present changes that would invalidate the staff’s conclusions in NUREG-1793 regarding the requirements in 10 CFR 50.34(f)(2).

Appendix A to 10 CFR Part 50 provides specific criteria for the I&C systems. The staff found that the PMS design continues to comply with the specific GDC for the I&C systems in NUREG-0800 Table 7-1, as described in NUREG-1793.

Regulations in 10 CFR 52.47(a)(9), “Contents of applications; technical information,” require that applications for light-water-cooled NPPs evaluate the standard plant design against NUREG-0800 revision in effect 6 months before the docket date of the application. The evaluation required by this section shall include an identification and description of all differences in design features, analytical techniques, and procedural measures proposed for the design and those corresponding features, techniques, and measures given in NUREG-0800 acceptance criteria. NUREG-0800 Chapter 7 provides the design considerations for safety, including criteria for performance and reliability considerations. The staff evaluated the information presented for AP1000 safety systems in the AP1000 DCD against the guidance provided in NUREG-0800 Chapter 7. With the exception of the items listed above, the staff finds the PMS design descriptions to be acceptable.

The additional detailed design information for the I&C architecture and communications results in increased standardization of this aspect of the design. Therefore, the change meets the finality criterion for changes in 10 CFR 52.63(a)(1)(vii).

7.3 Engineered Safety Features Actuation Systems

7.3.1.4.1 Automatic Depressurization System Valve Block

The AP1000 design uses ADS valves in certain accident conditions to depressurize the RCS and allow passive safety systems to inject coolant to the reactor core. However, a potential CCF of the PMS could initiate the ADS and simultaneously cause the PMS to not appropriately respond to the condition. As a result, the plant would need to respond to the spurious actuation of the ADS valves using back-up systems, such as the DAS, nonsafety systems, and operator action. While the scenario is beyond design basis, the consequences of such a scenario would be similar to that of up to a large-break LOCA. In addition, the staff did not identify analyses demonstrating the capability of the plant to mitigate the scenario of a spurious actuation of the ADS valves.

To address the potential spurious actuation of ADS valves due to a CCF of the PMS, the applicant added an ADS valve block feature to prevent the spurious actuation of any of the ADS valve paths in each of the four stages of valve sets. The blocking feature prevents one valve in each of the two-valve valve sets from opening without deactivation of the block signal. For ADS Stages 1-3, the blocking feature is applied to the depressurization valve, and regarding ADS Stage 4, the blocking feature is applied to the squib valve. For ADS Stage 4, the applicant will determine whether the “arm” or “fire” signal within the squib valve will have the blocking feature applied. However, based upon the information provided, the staff determineds the use of either signal is acceptable.

Section 7.3.1.2.4.1 of the AP1000 DCD describes the need for a confirmatory process condition that is separate from the PMS actuation logic to serve as the input to the blocking signal circuit. The DCD describes the use of redundant CMT level switches, one in each CMT, to serve as the permissive that removes the block signal. Each of the respective level switches act to clear the block signal upon a lowering level in a given CMT once the tank level has reached or surpassed its setpoint. The DCD further states the blocking device will be a Class 1E module that will satisfy the requirements of safety-related I&C equipment. On a divisional basis, the interface between PMS and the blocking device will be the CIM for the each affected ADS valve in the division. The CIM resides in the PMS circuitry after the logic function has taken place. Additionally, the AP1000 DCD states that there are no interdivisional connections between the blocking devices nor will there be any coincidence voting between the blocking devices thus satisfying the independence requirements of IEEE Std. 603-1991. Section 7.3.1.2.4.1 of the AP1000 DCD also discusses the use of manual switches to enable the operator to manually clear the block signal as required. Since this action affects a component with onerous consequences the staff expects, that beyond the commitment in the AP1000 DCD for this switch to reside in the MCR, the given switches will be separate, hardwired switches in the primary dedicated safety panel or another safety-related panel in the MCR. In addition, the applicant updated Figure 7.2-1 noting that an ADS valve block signal is utilized via the CMT level switches’ signal.

Beyond the redundancy created through the use of two CMT level switches to prevent a single level switch from causing a blocking circuit failure as described in the AP1000 DCD, in accordance with the description in the FMEA for the AP1000 PMS, WCAP-16438-P, the text explains that should an ADS block signal within a division fail to remove the block signal, only a single division of PMS is affected. For Stages 1-3 ADS valves the other division's ADS valves will actuate and as Stage 4 ADS valves utilize signals from two divisions, the "other" PMS division's signal will actuate the given Stage 4 ADS valve.

Based upon a review of the information related to the ADS valve blocking circuit provided in the AP1000 DCD and the AP1000 FMEA for the PMS, the staff finds the addition of the ADS valve block circuit to be acceptable. In a subsequent revision to the AP1000 DCD and the FMEA, the applicant incorporated these changes, which resolves this issue.

7.3.4 ESFAS Evaluation Findings and Conclusions

The ESFAS is a portion of the PMS. AP1000 DCD, Section 7.2 discusses the additional design information associated with the PMS and the staff's evaluation. The staff identified no changes of substance in Section 7.3 of the AP1000 DCD other than those described below.

To prevent spurious actuation in of any of the valve paths for any and all of the stages of the ADS valves, the applicant chose to implement an ADS valve blocking circuit that prevents the given depressurization valve (for Stages 1-3 ADS valves) or the squib valve (for Stage 4 ADS valves) from opening unless system conditions warrant. Based upon a review of the information in AP1000 DCD, Section 7.3.1.2.4.1 and the FMEA for the AP1000 PMS, WCAP-16438-P, the staff finds the addition of the ADS valve block circuit to be acceptable These changes were incorporated in Revision 19 to the AP1000 DCD and WCAP-16438-P, Revision 3, which resolves this issue.

The additional detailed design information for the I&C architecture and communications results in increased standardization of this aspect of the design. Therefore, the change meets the finality criterion for changes in 10 CFR 52.63(a)(1)(vii).

7.4 Systems Required for Safe Shutdown

7.4.3 Evaluation Findings and Conclusions

The applicant changed the fifth bullet in Section 7.4.3.1.3 of the AP1000 DCD to clarify that the remote shutdown workstation is designed, not for a single failure, but with redundancy. However, when a random event other than fire causes an MCR evacuation, a coincident single failure in the safety systems controlled from the remote shutdown workstation is considered.

The staff finds the change acceptable, since RG 1.189, "Fire Protection for Operating Nuclear Power Plants," establishes the bases for safe shutdown with respect to fire protection. These limits do not require consideration of an additional, random, single failure in the evaluation of the capability to safely shut down because of fire. NUREG-0800 Section 9.5.1 addresses conformance to RG 1.189. Therefore, the application of the single-failure criterion to remote shutdown is applicable only to other events that could cause the control room to become uninhabitable. These events would not result in consequential damage or unavailability of systems required for safe shutdown. The AP1000 design does consider events other than fire, coincident with a single failure in the safety system, for the remote shutdown workstation.

7.5 Safety-Related Display Information

7.5.3 Network Gateway (Real Time to Protection and Safety Monitoring System)

The applicant removed the communications description from Revision 17 of AP1000 DCD Tier 2, Section 7.1.2.8, and added a reference to Section 3 of WCAP-16675-P, Revision 3. WCAP-16675-P, as supplemented by WCAP-16674-P, Revision 2 provides a comprehensive description of the communications within the safety system, between safety and nonsafety systems, and within the nonsafety systems. Section 7.9 documents the review of the modifications made to the AP1000 safety and nonsafety communications system, and provides additional information on the communications system.

7.5.5 Qualified Data Processing System

Revision 17 of the AP1000 DCD upgraded several variables in Table 7.5-1, "Post-Accident Monitoring System," to add seismic qualification to some instruments and to add a QDPS indication. The staff accepts this change, which increases safety with more highly qualified instruments and controls, as well as improved information to support MCR operations.

Revision 17 of the AP1000 DCD changed the information given for several variables in Table 7.5-1 and added Note 7 indicating, "This instrument is not required after 24 hours."

The staff finds the addition of Note 7 acceptable for these variables because AP1000 DCD, Section 7.5.4, includes the statement below:

> Class 1E position indication signals for valves and electrical breakers may be powered by an electrical division with 24-hour battery capacity. This is necessary to make full use of all four Class 1E electrical divisions to enhance fire separation criteria. The power associated with the actuation signal for each of these valves or electrical breakers is provided by an electrical division with 24-hour battery capacity, so there is no need to provide position indication beyond this period. The operator will verify that the valves or electrical breakers have achieved the proper position for long-term stable plant operation before position indication is lost. Once the position indication is lost, there is no need for further monitoring since the operator does not have any remote capability for changing the position of these components.

7.5.5.1 Combined License Information and Tables 7.5-1 and 7.5-8

Section 7.5.5 of the AP1000 DCD states: "This section has no requirement for information to be provided in support of the Combined License (COL) application." Section 7.5, Tables 7.5-1 and 7.5-8, indicate that the meteorological parameters and environs radiation and radioactivity variables are "site specific." The staff requested clarification of this inconsistency in RAI-SRP7.5-ICE-02. The applicant's response states: "The words 'site specific' for environs radiation and radioactivity parameters indicate that these variables are site-related and are to be addressed by the COL applicant in the site emergency response plan identified in DCD Tier 2, Chapter 13, Section 13.3.1. Therefore, each COL applicant is to provide information for monitoring the meteorological parameters and environs radiation and radioactivity as appropriate." In a letter dated May 26, 2010, the applicant provided a revised response to Open Item OI-SRP7.5-ICE-01 stating that the applicant commits to update Tier 2 Tables 1.8-1 and 1.8-2 in Revision 19 to the DCD. The applicant plans to modify Section 7.5.5 to indicate a

COL action item regarding meteorological parameters and environs radiation and radioactivity instrumentation is required by the COL applicant. The staff previously identified this as Open Item OI-SRP7.5-ICE-01 and, based upon the commitment in the applicant's response to the open item, the open item is considered resolved. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

7.5.6 Bypass and Inoperable Status Information

The applicant removed the description of the bypass and partial trip in AP1000 DCD Tier 2, Section 7.1.2.9, and provided a reference to Section 6 of WCAP-16675-P, Revision 5. Section 6.4 of WCAP-16675-P describes the design requirements for the bypass and partial trip conditions.

This section establishes the use of the Common Q network to provide bypass status indication in the MCR, in accordance with RG 1.47.

<u>Evaluation</u>

Regulations in 10 CFR 50.34(f)(2)(v) require the safety-system design to provide an automatic indication of the bypassed and inoperable status of safety systems. As applied to data communications systems, NUREG-0800 Section 7.9 states that the bypassed and inoperable status indications for data communications systems should be consistent with those of the systems of which they are part. The bypassed and inoperable status indication should conform to the guidelines of RG 1.47.

The staff finds the AP1000 DCD, as supplemented by WCAP-16675, sufficiently demonstrated how the PMS design provides bypass indications of protection channels used in the reactor trip and/or ESF actuation path to meet the requirements of 10 CFR 50.34(f)(2)(v). Specifically, the staff concludes the applicant provided adequate information that describes how the indications of bypassed channels or components on the MTP and MCR conform to RG 1.47, as specified in the guidance provided in NUREG-0800 Section 7.9. The staff previously identified this issue as Open Item OI-SRP-7.5-ICE-02, and based upon the information in Section 6.4, "Bypass and Partial Trip Condition," in WCAP-16675, the staff finds the design of the system's ability to inform the operators of bypassed and inoperable safety channels within the PMS to be acceptable.

7.5.7 In-Core Instrumentation System

7.5.7.1 In-Core Instrumentation Interaction with Core Exit Thermocouples

WCAP-17226, "Assessment of Potential Interaction between the Core Exit Thermocouple Signals and the Self-Powered Detector Signals in the AP1000™ In-core Instrumentation System," Revision 2, describes how the AP1000 IIS design satisfies the requirements of IEEE Std. 384-1981 such that any credible single fault in the non-Class 1E self-powered detector (SPD) signals will not reduce the number of valid Class 1E CET inputs to the PAMS below the required minimum number. The CET signal wires used by the Class 1E PAMS and the non-Class 1E SPD signal wires used by the on-line power distribution monitoring system (OPDMS) are in very close proximity, and do not satisfy the separation distances identified in IEEE Std. 384-1981. In addition, the required separation distance identified in IEEE Std. 384-1981 between safety and nonsafety signals is not met in the in-core instrument thimble assemblies (IITAs) and in the mineral insulated (MI) cable assembly hardware that route the

CET and SPD signals from the reactor vessel head (RVH) penetrations to the refueling disconnect panel (RDP). Furthermore, four of the AP1000 IITA contain non-Class 1E CET sensors that provide input to the non-Class 1E DAS.

Within the IITA, the active portions of the Class 1E CET elements and the non-Class 1E SPD elements are placed inside individual steel outer sheaths that share a common ground to provide electrical isolation between the CET and SPD elements. The presence of two commonly grounded metallic barriers within the IITA probe assembly and in the MI cables makes it incredible for an SPD emitter signal to short directly to the CET element signal leads.

From the Quickloc flanges on the RVH to the RDP, the CET signals and SPD signals share a common Class 1E design and post-accident environmentally qualified MI cable assemblies. The MI cable assemblies consist of individual flexible steel-sheathed cable sub-assemblies, which contain the separate CET and SPD signal lead MI cables, routed together in a flexible steel outer sheath that serve as conduits for individual CET and SPD cables in the cable assembly.

From the Class 1E connector panels on the RDP, the SPD signals are split and sent to two signal processing system (SPS) cabinets that are powered by non-Class 1E power supplies. The CET signals are also split at the RDP Class 1E connector panels, where most of the CET signals are sent to the PMS; the remaining 4 CET signals are sent to the DAS. The CET signals sent to the PMS are split into two corresponding trains and sent to the corresponding PMS divisions via separate qualified Class 1E MI cables. The CET signals sent to the DAS are routed through post-accident environmentally qualified MI cables.

An analysis was performed to determine whether the non-Class 1E power supplies that power the SPS cabinets can have an over-voltage or surge voltage that propagate backwards to the SPD inputs signals through the SPS circuitry without attenuation or shorting to ground. The analysis showed that it is credible that a sufficiently large over-voltage or a voltage surge at the SPS cabinet power supply inputs could cause at least a momentary loss of all Class 1E CET signals associated with the affected SPS cabinets via shorting between the SPD and CET wires in the backshell of the IITA or MI cable electrical connectors. If the over-voltage or transient surge condition were to occur on both SPS cabinets, then the result could be that all of the CET signals needed by the PAMS become inoperable.

To mitigate this concern, the applicant performed an analysis to determine the maximum sustained over-voltage value for low voltage circuits in Westinghouse NPP designs that run cable in accordance with nuclear industry standards. The staff requested the applicant describe how the maximum credible over-voltage generated by the SPS cabinets is established. In its response, the applicant proposed to modify WCAP-17226 with the following explanation:

> AP1000 requires that low voltage systems be installed in a separate raceway system from medium voltage systems. As such, the maximum credible sustained overvoltage condition which can occur in a low voltage power or control circuit routed in this (these) low voltage raceway system(s) can be determined conservatively by considering nominal system operating voltages and maximum preferred system voltage range as defined in ANSI C84.1-2006. The system voltage at the low voltage system will remain balanced when the medium voltage system is supplied from normal or reserved source of power during the normal plant operation. During the abnormal plant operation when the normal and reserve sources of power are not available, the low voltage system will

continue to function by receiving power from the standby diesel generators. The system voltage will also remain balanced even when the medium voltage continues to operate in the presence of a single line to ground fault indefinitely.

As the neutral of the load center transformers secondary windings are solidly (or effectively) grounded there will be no increase in the maximum credible sustained overvoltage of the low voltage system whether a ground fault is present at the medium voltage system or not. As such, the maximum credible sustained overvoltage numerical value, when the transformer is lightly loaded, can simply be derived from consideration of the nominal low voltage system of 480VAC plus a 10 percent multiplier (480VAC)(1.10) = 528 VAC for an maximum sustained system voltage during both normal full load and light load operation. The high voltage taps of the load center transformer is set such that the maximum allowable voltage at the terminals of the loads and the secondary winding of the load center transformers is not exceeded.

For purposes of defining a value for design of isolation devices a margin of 10 percent will be used yielding (528VAC)(1.10) = 580VAC. This value is developed specifically for use as a bounding design value for isolation devices and, as described above, is conservative beyond the actual design operating conditions of the plant.

This established maximum credible over-voltage value allows for the identification of operating characteristics of the IITA and MI cable hardware used in the IIS to be specified to withstand a peak over-voltage beyond the identified historical maximum over-voltage value. The design requirements for the MI cable and IITA electrical connector hardware require that manufacturing or proof testing be performed to demonstrate compliance with a 600 volts alternating current (VAC) peak voltage CET functional interaction exclusion requirements. This hardware testing requirement satisfies the requirements for testing or analysis of associated circuit interaction with Class 1E circuits in IEEE Std. 384-1981 for over-voltage conditions. To further mitigate the possibility of a transient surge voltage condition in the SPS cabinet's input power supply in excess of the identified maximum over-voltage value that may disable both divisions of the CET signals used by the PAMS, different divisions of safety power are supplied to the IIS SPS cabinets, with the power cables routed in separate shielded conduits.

The applicant also identified the DAS as another non-Class 1E system that can cause a surge or over-voltage faults to propagate to the IIS. The applicant’s analysis found that the maximum credible surge voltage output from the DAS to the DAS CET signal leads that could produce an interaction with the IIS is the same as the IIS IITA and CET cable. The identified maximum credible voltage output from the DAS to the CET signal leads are also equivalent to the electrical connector hardware voltage environmental electromagnetic interference qualification limit requirements in Tier 2, Appendix Section 3D.4.1.2 of the AP1000 DCD. The DCD hardware requirements specifically require that the IIS IITA and associated cables be qualified to meet RG 1.180, “Guidelines for Evaluating Electromagnetic and Radio-Frequency Interference for Safety-Related Instrumentation and Control Systems,” peak surge voltage pulse levels. This result ensures that if there is a voltage surge from DAS that propagates down through the DAS CET signal leads to the associated SPD cables, there will be no credible, systematic shorting of DAS CET signals to the associated SPD signal leads, which contain the CET signals that are sent to the PMS.

IEEE Std. 603-1991, Clause 5.6.3, requires that equipment in other systems that is in physical proximity to safety system equipment but that is neither an associated circuit nor another Class 1E circuit be physically separated from the safety system equipment to the degree necessary to retain the safety systems' capability to accomplish their safety functions in the event of the failure of nonsafety equipment. Physical separation may be achieved by physical barriers or acceptable separation distance. The separation of Class 1E equipment shall be in accordance with the requirements of IEEE Std. 384-1981.

The NRC issued RG 1.75, "Criteria for Independence of Electrical Safety Systems" to endorse IEEE Std. 603-384 with exceptions. RG 1.75 identifies the underlying separation criteria: (1) physical separation, and (2) electrical isolation are provided to maintain the independence of safety-related circuits and equipment so that the safety functions required during and following any design-basis event can be accomplished. Section 5.6(3) of IEEE Std. 384-1992 provides general criteria for independence between safety-related and nonsafety-related circuits. When minimum separation cannot be met, it allows an analysis of nonsafety-related circuits to demonstrate that the safety-related circuits are not degraded below an acceptable level. If the analysis is successful, the nonsafety-related circuits can remain as nonsafety-related circuits. RG 1.75 clarifies that: (1) nonsafety-related circuits that are not separated from safety-related circuits through the minimum separation or barriers must be treated as "associated circuits," and (2) the cables that are associated because they are powered from a safety-related source serving nonsafety-related loads or share the safety signal must also be treated as associated circuits. This regulatory guide defines "associated circuits" as "nonsafety-related circuits that are not physically separated or not electrically isolated from safety-related circuits by acceptable separation distance, safety class structures, barriers, or isolation devices."

Based on the staff's evaluation of the information presented in WCAP-17226, the staff finds that the associated circuit analysis performed and the ensuing design requirements adequately ensure that the Class 1E CET elements cannot be degraded below an acceptable level by over-voltage or surges from non-Class 1E SPD elements or other connected nonsafety systems. The specific evaluation of portions of this analysis is documented below:

- Within the IITA, the staff finds that placing the active portions of the Class 1E CET elements and the non-Class 1E SPD elements inside individual steel outer sheaths that share a common ground provides adequate electrical isolation between the CET and SPD elements. The staff finds that since the steel outer sheaths share a common ground, it can adequately protect the CET element from a potential overload of the SPD element.

- From the Quickloc flanges to the RDP, the staff finds the MI cable assembly adequately ensures the isolation of Class 1E CET elements from SPD elements through the use of separate individual flexible steel-sheathed cable subassemblies for the CET and SPD signal leads. The individual steel-sheathed cables provide adequate electrical isolation to prevent faults within the SPD signal leads from propagating to the CET signal leads.

  The staff finds adequate the analysis provided to evaluate the maximum credible over-voltage or surge voltage that can propagate backwards from the non-Class 1E power supplies in the SPS cabinets to the SPD input signals. Specifically, the staff finds that the applicant's analysis, which specifies that, for 3-wire low voltage AP1000 systems, the maximum sustained over-voltage will incorporate a 10 percent margin (which is above the 5 percent margin specified in ANSI C84.1-2006, "Electric Power Systems and Equipment - Voltage Ratings (60 Hz)") for a solidly grounded system is consistent with the criteria found in IEEE Std. 141-1993, "IEEE Recommended Practice for Electric Power Distribution for Industrial Plants." IEEE Std. 141-1993, Clause 7.2.5, states there are three levels of conductor insulation for medium-voltage cables that are permitted: 100, 133, and 173 percent. The solidly grounded system permits the use of 100 percent insulation level, which indicates that the maximum sustained over-voltage is at 100 percent of the line-to-ground voltage during a single line to ground fault. Thus, the 10 percent additional margin sufficiently bounds the anticipated maximum sustained over-voltage. Ultimately, the cable insulation selection for a nominal low voltage system of 480 VAC will be rated at a minimum of 600 volts (V), which encompasses the anticipated maximum sustained over-voltage value of 528 VAC. The derivation of the maximum credible over-voltage was incorporated in Revision 2 to WCAP-17226.

- The applicant proposed to specify design requirements for the MI cable and IITA electrical connector hardware to be tested to withstand the identified maximum credible voltage values. This approach is acceptable to the staff in that it meets the associated circuit requirements of IEEE Std. 384-1981 for over-voltage conditions. In addition, assigning each SPS cabinet and its corresponding PAMS division to a different Class 1E power bus, the staff finds this approach ensures any fault on the SPS cabinets' safety input power supplies will only occur on one SPS cabinet and can, therefore, only disable one division of the CET signals used by PAMS. The staff finds this acceptable.

- Furthermore, the staff finds adequate the identified maximum credible overvoltage that can be generated from the DAS that could produce an interaction with IIS. The staff finds that by qualifying the IIS IITA and associated cables in accordance with RG 1.180, the design characteristics ensure that a potential voltage surge from the DAS will not be able to cause systematic shortening of the DAS CET signal to SPD signal leads. Therefore, the staff finds that the PAMS CET coverage is adequately protected against failures of the DAS.

7.5.9 Evaluation Findings and Conclusions

Appendix D.II, "Definitions," to 10 CFR Part 52, defines COL action items (COL license information) as items that identify certain matters that applicants must address in the site-specific portion of the final safety analysis report (FSAR). The applicant selected the site-specific parameters required to meet 10 CFR 50.34(f)(2)(xvii), regarding accident monitoring instrumentation as a COL action item and updated Tier 2 Tables 1.8-1 and 1.8-2, accordingly. Therefore, the staff finds the above requirements have been satisfied via the commitment in the applicant's response dated May 26, 2010. In Revision 19 to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

Regulations in 10 CFR 50.34(f)(2)(v) require the applicant to provide for automatic indication of the bypassed and inoperable status of safety systems. The staff finds that the applicant has sufficiently addressed this requirement in the AP1000 DCD and the supporting TRs, as documented in Section 7.9.2.6. Specifically, the applicant has demonstrated how the indication of bypassed and operable status of safety systems in the MCR conforms to RG 1.47. The staff previously identified this issue as Open Item OI-SRP7.5-ICE-02, and based upon the discussion in Section 6.4 of WCAP-16675, the staff finds the issue has been satisfactorily resolved.

Based upon the staff's review of WCAP-17226-P, the interaction between the IIS and other safety-related systems is deemed acceptable provided the proposed change to WCAP-17226-P to include a discussion of how the maximum credible over-voltage value is derived is included in

Revision 2 of the document. These changes were incorporated in Revision 2 to WCAP-17226-P, which resolves this issue.

Additionally, the staff finds that the accident monitoring instrumentation meets the applicable requirements of GDC 13 and GDC 19, “Control Room.”

7.6 Interlock Systems Important to Safety

7.6.5 Evaluation Findings and Conclusions

Section 7.3.1.4.1 of this report describes the applicant’s commitment to add an ADS valve blocking circuit to prevent the spurious actuation of any of the valve paths in any of the stages for the ADS. As this circuit is described as a blocking circuit rather than an interlock (in which a block may be cleared or overridden but an interlock must not), the circuit’s operation is not captured in Section 7.6 of this report. As such, the changes in Section 7.6 of the AP1000 DCD did not affect any conclusions regarding regulatory compliance in NUREG-1793. Therefore, the staff finds the applicant continues to meet the requirements identified in NUREG-1793 for Section 7.6.

7.7 Control and Instrumentation Systems

7.7.1 System Description

7.7.1.1 Reactor Power Control System

The applicant revised the second paragraph of Section 7.7.1.1.1, “Power Control,” to remove the term “lead/lag compensated.” The applicant revised the AP1000 design to apply the lead/lag compensation after the high auctioneer, versus before it. The applicant claims that this design does not require compensation to be factored into signal quality check acceptance criteria in the auctioneer. The applicant described this justification in APP-GW-GLR-080, Revision 0, “Mark-up of AP1000 Design Control Document Chapter 7.” The staff’s review confirms that this design change does not affect any staff conclusions in NUREG-1793.

The applicant also revised the description of the T_{ave} reactor control band for the various plant modes of control (i.e., load follow, load regulation, base load). The applicant claims that there is no advantage to increasing the deadband during load follow operations. The applicant further states that doing so would erode margins to reactor trip setpoints. The applicant also stated this justification in APP-GW-GLR-080, Revision 0. The staff’s review confirms that this change does not affect any staff conclusions in NUREG-1793.

The applicant removed the “time weighted average” or “smoothing” compensation to the nuclear flux and the axial offset signals while the plant is in a load regulation mode of control. The applicant states that this current transient specification does not require complex “time weighted average” nuclear flux and axial offset signal compensation on the inputs to the axial offset control band calculation and that simple lag compensation is adequate. The applicant also stated this justification in APP-GW-GLR-080, Revision 0. The staff’s review confirms that this change does not affect any staff conclusions in NUREG-1793.

7.7.1.2 Rod Control System

The applicant revised the interlock and “low” and “low-low” alarms associated with control rod insertion limits. The revision will move the automatic activation of the rod insertion interlock from the “low” rod insertion alarm setpoint to the “low-low” rod insertion alarm setpoint. In moving the activation of the rod insertion interlock from the “low” to the “low-low” rod insertion alarm, rod insertion will be prevented, at the “low” alarm setpoint, by following appropriate plant operating procedures and will be prevented at the “low-low” setpoint by automatically actuating the rod insertion interlock and terminating automatic AO bank insertion (or withdrawal to prevent further M bank insertion).

By moving the rod insertion interlock to the “low-low” alarm setpoint, continued rod insertion (and thus, a continued reduction in control rod shutdown margin) is automatically terminated by plant controls versus “appropriate plant operating procedures.”

Furthermore, removing the interlock from the “low” alarm setpoint does not reduce any plant protection function or increase the risk of reducing protection against a reduction in control rod shutdown margin caused by the margin built into the difference between the “low” and the “low-low” rod insertion setpoints. Therefore, the staff’s review confirms that this design change does not affect any staff conclusions in NUREG-1793, including Supplement 1.

7.7.1.3 Pressurizer Pressure Control

The applicant changed the description of the pressurizer variable heating control by stating that it is not sensitive to the rate of change in pressure and that it will respond in the same manner to small, fast, or slow small changes in pressure. The staff’s review confirms this change does not affect any staff conclusions in NUREG-1793.

7.7.1.5 Feedwater Control

In Section 7.7.8.1 of the AP1000 DCD, the low-range feedwater flow measurement is no longer used in the low-power mode, and it is not used in the integration (reset) action of the low-power mode feedwater flow controller. This means that only feedwater temperature (low-power mode) and steam flow (high-power mode) are used to tune the integrator setpoints.

In both Sections 7.7.8.1 and 7.7.8.2, the control of the lift on the main and startup feedwater control valves is no longer determined by the ΔP available across the feedwater control valve, and the flow coefficient (C_v) characteristic of the valve. Therefore, in high-power control mode, the feedwater flow is regulated in response to changes in steam flow and proportional plus integral (PI)-compensated steam generator narrow-range water level deviation from setpoint. In the low-power control mode, the feedwater flow is regulated in response to changes in steam generator wide-range water level and PI-compensated steam generator narrow-range water level deviation from setpoint.

The startup feedwater control subsystem regulates the flow of feedwater in a manner similar to the way the (main) feedwater is controlled in the low-power control mode. Feedwater flow is regulated in response to changes in the steam generator wide-range water level and PI-compensated steam generator narrow-range water level deviation from setpoint. The staff’s review confirms that this design change does not affect any staff conclusions in NUREG-1793.

7.7.2 Diverse Actuation System

Section 7.8 includes a detailed evaluation regarding the DAS design changes.

7.7.3 Signal Selector Algorithms

The applicant has not demonstrated what specific actions are taken by the signal selector algorithms (SSAs) in the event that one of the multidivisional or multichannel inputs is deemed faulty or of "bad" quality. The staff requires all outputs of the device, whether they are in the form of control, alarm, interlock, or indications, to be identified and addressed. The staff issued this request to the applicant as RAI-SRP7.7-ICE-01. The applicant responded to the RAI in a letter, dated July 7, 2008. However, the staff found the response inadequate. The applicant submitted Revision 1 to address this issue on May 6, 2009, and subsequently the applicant submitted Revision 2 of RAI-SRP7.7-ICE01. In the Revision 2 response, submitted on January 27, 2010, the applicant states it will update the forthcoming revision of the AP1000 DCD so that it is clear that the SSAs are executed in the PLS and additionally that PMS and DAS performance are independent of the SSA. The staff previously identified this as Open Item OI-SRP7.7-ICE-01. Revision 2 of RAI-SRP7.7-ICE-01 adequately addresses this issue. In a subsequent revision to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

7.7.4 Evaluation Findings and Conclusions

The staff finds the conclusions described in NUREG-1793 still valid, based on the staff's review of the changes proposed in the AP1000 DCD. Specifically, the staff required additional information on how the SSAs would affect the PMS and the DAS. Information on such impacts could affect the degree of independence between the control system and the protection system, as required in GDC 24. Also, such impacts could affect the degree of diversity and quality of the DAS as required in GDC 22. The response discussed in Section 7.7.3 above, adequately addressed the issue. The staff previously identified this as Open Item OI-SRP7.7-ICE-01.

Section 7.8 includes further evaluation of the DAS.

7.8 Diverse Instrumentation and Control Systems

7.8.1 System Description

The I&C systems reviewed in this section include the diverse I&C systems and equipment that provide a diverse backup to the safety-related PMS and the defense against postulated CCFs in the PMS and the nonsafety-related PLS concurrent with postulated transients.

The review ensured that the applicant designed and installed the anticipated transient without scram mitigation systems and equipment in accordance with the requirements of 10 CFR 50.62, "Requirements for Reduction of Risk from Anticipated Transients without Scram (ATWS) Events for Light-Water-Cooled Nuclear Power Plants," and 10 CFR Part 50, Appendix A, GDC 22.

The DAS in the AP1000 DCD is a nonsafety related I&C system and provides a diverse and independent method for tripping the reactor and performing several ESFs in order to meet the requirements of 10 CFR 50.62 and 10 CFR Part 50, Appendix A, GDC 22. In addition, a set of dedicated and independent displays of selected plant indications and manual controls is provided in the MCR to address the criteria in BTP 7-19, "Guidance for Evaluation of Diversity and Defense-in-Depth in Digital Computer-Based Instrumentation and Control Systems."

The scope of the safety evaluation in the following section is limited to the changes that have been made to the approved DAS system since the AP1000 DCD, Revision 15, was certified.

7.8.2 Diverse Actuation System Assessment

The findings in NUREG-1793, Supplement 0, related to DAS functionality are based upon WCAP-15775, "AP1000 Instrumentation and Control Defense-in-Depth and Diversity Report," (APP-GW-J1R-004), Revision 0, issued April 2002. The applicant submitted Revision 2 of its D3 assessment on April 3, 2003. The applicant revised its D3 assessment based on the response to the NRC's RAI 420.013, Revision 1, in a letter dated February 21, 2003. The applicant referred to the Revision 2 of the D3 assessment in the certified AP1000 DCD, Revision 15. In the certified AP1000 design the hardware of the DAS is microprocessor based and its operating systems or programming languages are different from those used in the PMS.

In the original NUREG-1793, Section 7.1.6, the staff concluded that "the proposed design satisfies the Commission's position on I&C system diversity." The NRC based its conclusion on the proposed DAS design, as stated in Revision 15 of the applicant's DCD, which included the ITAAC listed in AP1000 DCD Tier 1, Section 2.5.1.

In the second paragraph of Section 7.7.2 of NUREG-1793, the staff concluded that based on the design commitments of Revision 15 of the AP1000 DCD:

> The DAS automatic actuation is accomplished by a microprocessor-based system. Diversity from the PMS is achieved by using a different architecture, different hardware implementation, and different software. Software diversity is achieved by running different operating systems and programming in a different language.

The applicant submitted TR-97, Revision 1, in which it changed the DAS design commitments and DAS ITAAC in Revision 15 of the AP1000 DCD to allow non-microprocessor-based implementations, added the DAS instrumentation cabinet, added an electrical penetration to the containment, and relocated a portion of the DAS to another area of the plant.

The following evaluation focuses on the modification to allow non-microprocessor-based implementations of the DAS and the addition of the DAS instrumentation cabinet. The relocation of DAS equipment within the plant has no impact upon the I&C review. Additionally, the installation of another electrical penetration to the containment is beyond the scope of the Chapter 7 review.

For the purposes of the Chapter 7 I&C review, the following areas of the DCD are affected:

Tier 1
Section 2.5.1
Table 2.5.1-4
Table 2.5.1-5
Table 3.7-1
Tier 2
Section 7.7.1.11
Figure 7.2-1
Section 9A.3.1.3.1.1
Table 14.3-3
Table 14.3-6
Table 17.4-1
Table 19.59-18

The applicant discussed the change to the I&C technology utilized for the DAS throughout Tier 1 and Tier 2 in Revision 16 of the AP1000 DCD by substituting language, as appropriate, where it used the terms “microprocessor” and “software” to describe DAS technology. The applicant replaced the term “microprocessor” with “microprocessor or special purpose logic processor,” and the term “software” with “any software.” The addition of the DAS instrument cabinet, DAS-JD-004 will contain the 4-20 mAdc loop transmitters and power supplies necessary to complete the DAS instrumentation requirements. The DAS-JD-004 cabinet mounts next to the DAS squib valve control cabinet, DAS-JD-003. This is acceptable. The applicant revised Section 7.7.1.11 of the AP1000 DCD Tier 2, Revision 16, by replacing the terms “microprocessor-based” and “microprocessor” with “logic”, “software” with “any software” from several design change descriptions in APP-GW-GLR-080, Revision 0, which describes all changes to the AP1000 I&C systems in the certified AP1000 DCD.

This proposed change to use non-microprocessor-based technology is intended to increase reliability and was found to be acceptable. However, a discussion concerning the diversity between the PMS and the DAS is provided later in this section.

In Revision 17 of the AP1000 DCD, the applicant removed DAS DAC from Tier 1, Section 2.5.1, “Diverse Actuation System (DAS) Design Description,” Items 4a and 4b, as well as from Tier 1, Table 2.5.1-4, ITAAC Items 4a and 4b. Items 4a and 4b are the design requirements and system definition phases of the DAS hardware and software design process. The applicant removed portions of the DAC, and also provided the corresponding design information in WCAP-17184-P, Revision 2, which addresses those two phases. However, the applicant failed to provide a description in Chapter 7 of the AP1000 DCD, Tier 2, regarding completion of those two phases found in the AP1000 DCD Tier 1. 10 CFR 52.47(a)(2) requires standard DC applications to provide a level of design information sufficient to enable the Commission to reach a final conclusion on all safety issues associated with the design before the certification is granted. In the proposed amendment to the AP1000 DCD, Tier 1, ITAAC Items 4a and 4b are removed based on design work accomplished. In Chapter 7 of the AP1000 DCD, Tier 2, the applicant should provide a summary and justification for why the ITAAC found in Items 4a and 4b of AP1000 DCD, Tier 1, Table 2.5.1-4, can be removed. The staff issued RAI-SRP7.8-DAS-12, requesting the applicant describe the completeness of the above two phases in Chapter 7 of the AP1000 DCD, Tier 2. In response to this RAI, the applicant provided a detailed description about the two completed life cycle phases as a markup for AP1000 DCD Tier 2, Section 7.7.1.11, which is found acceptable. In addition, the applicant added an ITAAC item to Table 2.5.1-4 of the AP1000 DCD Tier 1 to address the ITAAC for DAS manual actuations. The staff finds the above changes to the AP1000 DCD Tier 1 and Tier 2 acceptable and finds the response to RAI-SRP7.8-DAS-12 acceptable. In Revision 19 to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

In the initial submittal of WCAP-17184-P, Revision 0, the staff found that the applicant failed to address the DAS setpoint methodology. GDC 13 requires, among other things, that appropriate controls be provided to maintain variables and systems within prescribed operating ranges. The guidance in BTP 7-19, Section B, Item 3, Positions 1 and 2, acceptance criteria address confirmation that an anticipated operational occurrence (AOO) and postulated accidents are mitigated in the presence of CCF.

In WCAP-17184-P, Revision 0, the applicant did not identify how the DAS actuation setpoints and timing delays would be established. DAS must be able to perform its functions to ensure the potential release of radioactive material for postulated accidents and AOOs fall within acceptable limits in the event of a software CCF of the safety-related protection system. The staff issued RAI-SRP7.8-DAS-02, requesting that the applicant describe the DAS setpoint methodology. To address this RAI, the applicant provided WCAP-17184-P, Revision 1, to add the DAS setpoint methodology description as a new appendix to this TR. After reviewing the DAS setpoint methodology description, the staff found that the DAS allowances for automatic actuation signals, “Containment Temperature High” and “Pressurizer Water Level Low” are outside of the typical ratio of 1.15σ/2σ. The staff issued RAI-SRP7.8-DAS-10, requesting that the applicant provide the design basis to support the deviation. In response to this RAI, the applicant proposed a revision to WCAP-17184-P in which it described why the DAS channel statistical allowances for “Containment Temperature High” and “Pressurizer Water Level Low” do not conform to the typical ratio of 1.15σ/2σ when comparing a 75 percent probability/75 percent confidence level to 95 percent probability/95 percent confidence level for determination of the random and independent terms of the square-root-sum-of-the-squares calculation. Additionally, the applicant also provided a justification for the use of a 75 percent probability/75 percent confidence level. After reviewing the revised report, the staff found that the applicant adequately addressed the DAS setpoint methodology and found it acceptable. Therefore, the staff finds the responses to RAI-SRP7.8-DAS-02 and RAI-SRP7.8-DAS-10 acceptable. These changes were incorporated into Revision 2 to WCAP-17184-P.

In the proposed changes to the AP1000 DCD, the applicant changed the microprocessor-based implementation of the DAS to be a special purpose logic processor-based system. This special purpose logic processor-based DAS is further described as an FPGA digital platform-based system in WCAP-17184-P. The applicant also made changes to use the FPGA technology for the CIM in the safety-related PMS in WCAP-17179-P and WCAP-16675-P. According to the above reports, the CIM and DAS systems will be designed and manufactured by the same company at a common design and manufacturing facility. 10 CFR Part 50, Appendix A, GDC 22, requires, among other things, that design techniques such as functional diversity or diversity in component design and principles of operation shall be used to the extent practical to prevent loss of the protection function. BTP 7-19 provides guidance for evaluating an applicant’s D3 assessment to ensure conformance with the NRC position on D3 for digital I&C systems. NUREG/CR-6303, “Method for Performing Diversity and Defense-in-Depth Analyses of Reactor Protection Systems” provides diversity analysis methods and strategies to demonstrate that adequate and sufficient diversity should be included within the design. The staff found that the applicant had not provided design descriptions capable of demonstrating adequate and sufficient diversity between the DAS and CIM systems in accordance with the guidance listed above. Hence, the staff issued RAI-SRP7.8-DAS-04, requesting that the applicant describe in detail how the DAS equipment (i.e., hardware, software) would be diverse from the safety-related CIM in PMS. The staff also issued another RAI-SRP7.8-DAS-05 requiring the applicant to identify the criteria, practices, and processes that will ensure adequate diversity in the development of the CIM and the DAS at the common design and manufacturing facility, including the diversity with respect to human, software, and equipment diversity.

In response to the above RAIs, the applicant states, in part, that diversity is a principle in instrumentation of sensing different variables, using different technology, using different logic or algorithm, or using different actuation means to provide different ways of responding to postulated plant conditions. The applicant also revised WCAP-15775 to Revision 4 to address the specific requirement of diversity between CIM and DAS. The applicant demonstrated in Section 2.11 of WCAP-17179-P, Revision 2, and Section 9 of WCAP-17184-P, Revision 2, how the requirements of diversity are met between CIM and DAS. For example, for the human diversity, the applicant states in the two TRs that different designers are used for the CIM and DAS designs. In addition, the different design teams and different test teams will be used to test the CIM and DAS designs. In order to achieve the software diversity between the DAS and PMS (i.e., CIM), the applicant will use different algorithms, logic, program architecture, executable operating system and executable software/logic. The staff concludes that the applicant has provided sufficient information demonstrating conformance with regulatory policies and criteria concerning diversity. The AP1000 DCD Tier 1 and Tier 2 will also be updated accordingly to address the software diversity. Therefore, the staff finds the responses to RAI-SRP7.8-DAS-04 and RAI-SRP7.8-DAS-05 acceptable.

The staff found inconsistencies between Chapter 7 of the AP1000 DCD, Tier 2, Revision 17 and WCAP-17184-P, Revision 1, regarding DAS manual actuations. 10 CFR 52.47(a)(2) requires that an application must include a sufficient description and analysis of the structures, systems, and components (SSCs) of the facility, with emphasis upon performance requirements, the bases, with technical justificationupon which these requirements have been established, and the evaluations required to show that safety functions will be accomplished. The description shall be sufficient to permit understanding of the system designs and their relationship to the safety evaluation. The design information provided for the design basis items, taken alone and in combination, should have one and only one interpretation. Therefore, the staff issued RAI-SRP7.8-DAS-06 to request the applicant provide correct and unambiguous design descriptions for the list of DAS manual actuations. The applicant clarified that the list in the AP1000 DCD is all-inclusive of any manual actuation performed by DAS. The tripping of the RCPs is only done in conjunction with the CMT actuation and, therefore, not separately listed in the DCD. The list in Section 2.3 of WCAP-17184-P, Revision 1, is the list of manual actuations that are cited in the probabilistic risk assessment (PRA) for enabling AP1000 to meet its large release frequency (LRF) goal for beyond design basis events. Therefore, this list would be different from the list in the DCD because not all of the DAS manual actuations are needed to meet the LRF goal for beyond design basis events. Table B-1 in WCAP-17184-P is also not intended to be a complete list of all of the manual actuations. This table is modified to only include those manual actuations that do not have automatic DAS actuations. To incorporate the above clarification, the applicant proposed a revision to WCAP-17184-P, which the staff found acceptable. Therefore, the staff finds the response to RAI-SRP7.8-DAS-06 acceptable. These changes were incorporated into Revision 2 to WCAP-17184-P, which resolves this issue.

The staff found Appendix B, Table B-1, in WCAP-17184-P, Revision 2, includes the manual actuation of the hydrogen control system or igniters, but it is not credited in Section 2.3 of WCAP-17184-P for the DAS manual operator action and/or a DAS automatic function. The applicant did not provide a technical basis for this non-credited DAS manual operator action. BTP 7-19 states where operator action is cited as the diverse means for response to an event, the applicant should demonstrate that adequate information (indication) and sufficient time is available for operator action. The staff's review of Section 10.2.1.1 in WCAP-17184-P, Revision 2, determined that the stated design descriptions do not provide an explanation of how the manual action is used in the DAS design beyond listing the manual actions. From the PRA evaluation the staff found that there is a 19-minute window for accomplishing this action. The applicant failed to provide a clear technical basis that will permit sufficient understanding of credited DAS manual actuations and their conformance with the applicable regulatory requirements. The staff issued RAI-SRP7.8-DAS-07 to request the applicant provide the technical basis for the hydrogen igniter manual action as a non-credited DAS function.

In response, the applicant states, in part, that for this manual actuation of the hydrogen control system or igniters, PRA analysis techniques show acceptable results even if the act of manually actuating the hydrogen igniters is not accomplished (operator fails to act with 100 percent certainty). For this reason, manual actuation of the hydrogen igniters is not a credited manual operator action nor is it required (or credited) for hydrogen igniters to operate automatically. The 19-minute window as described in the PRA analysis is for a beyond design basis event. The PRA analysis was used to provide insights into this particular scenario. Hydrogen igniters were added to the AP1000 design even though they are not credited in the design basis. In response to this RAI, the applicant revised WCAP-17184-P to provide the reasoning behind installation of hydrogen igniters. After evaluating the response, the staff found the applicant's response to this RAI acceptable. Therefore, the staff finds the response to RAI-SRP7.8-DAS-07 acceptable. These changes were incorporated into Revision 2 to WCAP-17184P, which resolves this issue.

In Appendix B, Table B-1, in WCAP-17184-P, Revision 1, the staff found that there is a 20-minute window for accomplishing the manual actuation of the ADS. However, after reviewing the above TR, the staff found that the stated design descriptions do not provide an explanation of how the ADS manual actions are used in the DAS design beyond listing them. According to BTP 7-19, the applicant should demonstrate that adequate information (indication) and sufficient time is available for manual operator actions. The staff issued RAI-SRP7.8-DAS-08 to request the applicant provide a clear technical basis description in the TR that permits sufficient understanding of ADS manual operator action as credited DAS manual actuations and the basis for why the 20-minute window is sufficient for completing the ADS manual actuation. In response to this RAI, the applicant revised WCAP-17184-P to provide clarification for this manual actuation of ADS.

The DAS credits manual actions to depressurize the RCS during AOOs or postulated accidents following a software CCF in the protection system. BTP HICB-19, "Guidance for Evaluation of Defense-in-Depth and Diversity in Digital Computer-Based Instrumentation and Control Systems," Revision 4, states that where operator action is cited as the diverse means for response to an event, the applicant should demonstrate that adequate information (indication) and sufficient time is available for operator action. The staff reviews acceptability of these manual actions using guidance in DI&C-ISG-05, "Highly-integrated Control Rooms – Human Factors Issues" (ISG-5).

Manual actions that can be initiated from DAS are listed in the following places:

- AP1000 DCD, Revision 19, Tier 2, Section 7.7.1.11
- WCAP-17184-P, Revision 1, Section 2.3
- WCAP-17184-P, Revision 1, Appendix B, Table B-1

The manual actions listed in WCAP-17184-P, Section 2.3, were not consistent with the other two lists. The staff initiated RAI-SRP7.8-DAS-06 to resolve the differences. In its response of June 22, 2010, the applicant explained that the DC described all manual actions that can be performed by DAS. WCAP-17184-P, Section 2.3, described the manual actions that are cited in the PRA for enabling AP1000 to meet its LRF goal for beyond design basis events. The lists are different because not all of the DAS manual actions are needed to meet the LRF goal for beyond design basis events. Appendix B, Table B-1, provided a list matching the DCD. The applicant will modify Table B-1 to include only those manual actions that do not have corresponding automatic DAS actuations. For these manual actions, the applicant provided specific information describing whether the manual action is credited as part of the DAS response to a CCF or whether the manual action is part of the defense-in-depth strategy for severe accident management, thus providing a clearer communication of why the manual actions are included in the DAS design. These changes were provided in Revision 2 of WCAP-17184-P. The staff found the changes acceptable. These changes were incorporated in a Revision 2 to WCAP-17184-P, which resolves this issue.

Appendix B of WCAP-17184-P now lists the following 4 manual actions:

Manual Action 1: Manual Initiation of IRWST Recirculation/IRWST Drain for In Vessel Retention Support

The DAS provides this capability as part of the defense-in-depth strategy for severe accident management. It is an action needed to address AOOs or postulated accidents following CCFs in the protection systems. Therefore, the regulatory guidance in BTP 7-19 and ISG-05 apply.

Manual Action 2: Manual Initiation of the Hydrogen Control System

The DAS cabinet presents a convenient and reliable location for the manual hydrogen control system switches because it is in the MCR and has a diverse battery-backed power supply. It is not an action needed to address AOOs or postulated accidents following CCFs in the protection systems. Therefore, the regulatory guidance in BTP 7-19 and ISG-05 does not apply.

Manual Action 3: Manual Depressurization of the RCS

This action is credited in the DAS response to a CCF. In summary, ISG-05 states that an analysis must be completed that demonstrates:

- The time available to perform the required manual actions is greater than the time required for the operator(s) to perform the actions.

- The operator(s) can perform the actions correctly and reliably in the time available

No information was provided to the staff to explain how this guidance was addressed. The staff initiated RAI-SRP7.8-DAS-8 requesting this information. In its response, dated June 22, 2010, the applicant committed to include a new ITAAC in Tier 1 Chapter 2, Section 2.5.1, “Diverse Actuation System,” Table 2.5.1-4. This commitment was provided in the response to RAI-SRP7.8-DAS-12 and reads as follows:

Table 2.5.1-4. Inspections, Tests, Analyses, and Acceptance Criteria

Design Commitment	Inspections, Tests, Analyses	Acceptance Criteria
5. The DAS manual actuation of ADS, IRWST injection, and containment recirculation can be executed correctly and reliably.	An evaluation to confirm that the operator actions can be performed within the specified times.	b) A report exists and concludes that DAS manual operator action verification was conducted.

The staff finds the proposed ITAAC to be an acceptable way to develop the information needed to address the regulatory guidance in ISG-05, provided the commitment is also included as a separate “Design Description” in the text-based portion of Section 2.5.1. In a subsequent revision of the AP1000 DCD, the applicant added Design Description 5 and Design Commitment 5 to Tier 1 Section 2.5.1 and Table 2.5.1-4 respectively, which resolves this issue.

The staff notes that APP-GW-GL-011, “AP1000 Identification of Critical Human Actions and Risk Important Tasks,” Revision 0, Tables 3-1 and 3-2 identify risk-important human actions. Table 3-2, Basic Event ID: AND-MAN01 identifies failure to actuate the ADS for RCS depressurization as recovery from failure of automatic actuation or for manual ADS actuation as a risk-important human action. As such this manual action is already included in the HFE program described in Chapter 18 of this report. In summary, that program includes all risk important human actions as priority items in the task analysis, the human-system interface (HSI) design, the HFE design V&V, and human performance monitoring elements. By being included in the HFE program the regulatory guidance provided in ISG-05 is either met or exceeded.

Manual Action 4: Manual Initiation of IRWST Gravity Injection.

The DAS provides this capability as part of the defense-in-depth strategy for severe accident management. It is an action needed to address AOOs or postulated accidents following CCFs in the protection systems. Therefore, the regulatory guidance in BTP 7-19 and ISG-05 applies.

Operator manual actions credited within the DAS design have not yet been evaluated to verify they are viable. The applicant provided an acceptable DAS ITAAC in Section 2.5.1 of Tier 1, Chapter 2 information that will track completion of this evaluation. A similar evaluation is required within the HFE program described in DCD Chapter 18. Together or independently these commitments will ensure the regulatory guidance in BTP 7-19 and ISG-05 is implemented. This, in turn, will provide reasonable assurance that the operator manual actions to depressurize the RCS are an effective element of the DAS design for coping with AOOs or postulated accidents following CCFs in the protection systems.

Additionally, by the applicant adding a new ITAAC item to Table 2.5.1-4 of the AP1000 DCD Tier 1 to address the design commitment and ITAAC for DAS manual actuations, the staff found the applicant’s response to this RAI acceptable. Therefore, the staff considers RAI-SRP7.8-DAS-08 closed. In Revision 19 to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

The staff found in Appendix B, Table B-1, in WCAP-17184-P, Revision 1 that the applicant includes IRWST gravity injection as an DAS manual actuation. From the PRA evaluation in the table, there is a 20-minute window for accomplishing this manual action. However, the applicant failed to provide the technical basis for the sufficiency of this manual operator action. The applicant should demonstrate that adequate information and sufficient time is available for manual operator actions based on the guidance in BTP 7-19. Therefore, the staff issued RAI-SRP7.8-DAS-09 to request the applicant identify a clear technical basis description that permits sufficient understanding of this credited DAS manual actuation and its basis for why the 20-minute window is sufficient for this DAS manual action. In response to this RAI, the applicant states, in part, that for this particular scenario, PRA analysis techniques show acceptable results even if the act of manually actuating IRWST gravity injection is not accomplished (operator fails to act with 100 percent certainty). For this reason, manual actuation of IRWST gravity injection is not a credited manual operator action nor is it required (or credited) for automatic operation. The 20-minute window as described in the PRA analysis is for a beyond design basis event. The PRA analysis was used to provide insights into this particular scenario. The capability to manually actuate IRWST gravity injection from DAS was added to the AP1000 design out of caution, even though it is not credited in the design basis. The applicant proposed to revise WCAP-17184-P to Revision 2 to provide further clarification of the reasoning behind the manual initiation of IRWST gravity injection. The applicant committed to add a new ITAAC item to Table 2.5.1-4 of AP1000 DCD Tier 1 to address the design commitment and ITAAC for DAS manual actuations, which include the manual actuation of the IRWST gravity injection. The staff found that the applicant’s response and changes related to this RAI are acceptable. The staff finds the response to RAI-SRP7.8-DAS-09 acceptable. These changes were incorporated into Revision 2 of WCAP-17184-P, which resolves this issue.

In WCAP-17184-P, Revision 1, which the applicant submitted to justify the removal of ITAAC Items 4a and 4b from AP1000 DCD Tier 1, Table 2.5.1-4, the staff found that the applicant addressed the requirements of cyber security. The requirements of cyber security were also addressed in WCAP-17184-P, Revision 1. However, the staff’s position related to cyber security issues is that cyber security is addressed by 10 CFR 73.54, “Protection of digital computer and communication systems and networks,” and is not a 10 CFR Part 50 review item. As such, the reference to cyber security in the above TRs should be modified and/or replaced with a docketed TR describing the SDOE in which the applicant chooses to develop its software-based and programmable technology based DAS and CIM, paying particular attention to IEEE Std. 603-1991, Clauses 5.3, 5.6.3, and 5.9. The staff issued RAI-SRP7.8-DAS-11, which requested that the applicant remove the discussion of cyber security from the two TRs. In response to this RAI, the applicant deleted the mention of cyber security requirements in the revised WCAP-17184-P and WCAP-17179-P. The applicant also made corresponding changes to AP1000 DCD Tier 2, Table 1.6-1 and Section 7.1 to address the requirements of this RAI. The staff finds the response to RAI-SRP7.8-DAS-11 acceptable. In addition, the applicant submitted APP-GW-J0R-012, Revision 1, to address the secure development and operational environment for the AP1000 PMS. Section 7.9 provides the evaluation of this new TR.

The staff found that the following issues in WCAP-17184-P, Revision 1, need to be addressed by the applicant:

- Section 6.1.2.2 references the Wolf Creek license amendment request regarding self-test features of the DAS. However, the Wolf Creek license amendment request is not part of the AP1000 DCD licensing basis. Therefore, self-test features should be identified in the TR for the AP1000 DAS.

- The statement in Section 8.1 currently states that the “two-out-of-two logic … lends itself to reliability.” However, this configuration is less reliable than a single train configuration, although the PRA-based DAS design and two-out-of-two (2oo2) actuation logic were approved in the certified AP1000 DCD, Revision 15, and the applicant has not made changes to the DAS logic in the applicant’s DC application. Hence, the above statement is not accurate and should be modified to reflect the approved DAS design feature.

- Section 8.1 states that “The use of FPGAs results in a hardware-based design that is not subject to software CCFs. The only software involved in the process is that used to burn-in the required logic design into the FPGA.” These two statements are inaccurate and should be removed because the FPGA-based systems are developed with software tools and can have programming errors similar to microprocessor-based digital systems, although FPGA-based systems do not run any system or application software during operation. Therefore, evaluation for CCFs in the FPGA development process and software programming shall be conducted. A high quality and well documented life-cycle design process should be provided according to BTP 7-14, “Guidance on Software Reviews for Digital Computer-Based Instrumentation and Control Systems.”

During the review of WCAP-17184-P, Revision 1, the staff identified the above issues and issued RAI-SRP7.8-DAS-13 to request that the applicant correct those statements for technical and regulatory accuracy. In response to this RAI, the applicant proposed to modify WCAP-17184-P, Revision 2, to make the necessary corrections. After reviewing the draft revised TR, the staff found the applicant’s response acceptable. The staff finds the response to RAI-SRP7.8-DAS-13 acceptable. These changes were incorporated into Revision 2 of WCAP-17184-P.

The staff finds the DAS is properly credited for providing a diverse backup to the safety-related protection system; however, the ATWS mitigation systems actuation circuitry (AMSAC) system should not have been credited with providing diverse protection upon a postulated CCF of the safety-related PMS. During the evaluation of the changes made to the certified AP1000 DCD, Revision 15 for the DAS, the staff found that the applicant provided ambiguous descriptions for the DAS circuitry and the AMSAC. 10 CFR 52.47(a)(2) requires, in part, a description of the SSCs to be of sufficient detail to permit understanding of the systems designs. Section 15.8 of the AP1000 DCD, states that the DAS provides AMSAC functions. It also states that for Westinghouse plants the ATWS rule (10 CFR 50.62) requires the installation of AMSAC, which consists of circuitry separate from the reactor protection system to trip the turbine and initiate decay heat removal. The applicant failed to provide a description of the AMSAC or the relation between the DAS and the AMSAC system in Section 7.7 of the AP1000 DCD Tier 2. The applicant also failed to clearly describe if the DAS circuitry and the AMSAC system circuitry are the same system or if they are separate systems. The staff issued RAI-SRP7.8-DAS-01 to request the applicant clarify the design descriptions for DAS and AMSAC. In response, the applicant states that for Westinghouse plants the ATWS rule requires the installation of equipment that is diverse from the reactor protection system to automatically trip the turbine and initiate decay heat removal. This equipment must be designed to perform its function in a reliable manner and be independent from sensor output to final actuation device from the existing reactor protection system. The AP1000 is designed with a DAS, which provides the functions required by the ATWS rule. In response to this RAI, the applicant also provided a markup for Section 15.8 of the AP1000 DCD to clarify the description of DAS and AMSAC. The staff found the response to RAI-SRP7.8-DAS-01 acceptable. In Revision 19 to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

When evaluating the changes to the certified AP1000 DCD, Revision 15, the staff issued RAI-SRP-7.8-DAS-03 requesting the applicant identify design descriptions that demonstrate how the 2oo2 DAS actuation logic would meet the applicable regulatory criteria. 10 CFR 50.62 requires ATWS mitigation equipment to perform its functions in a reliable manner. The guidance of BTP 7-19, Point 3, on D3 states that the diverse or different function may be performed by a nonsafety system if the system is of sufficient quality to perform the necessary function under the associated event conditions. The applicant stated in Revision 17 of AP1000 DCD, Tier 2, Section 16.3-2 that "when a required channel is unavailable, the automatic DAS function is unavailable."

In its response, the applicant explained that there are two actuation logic modes, automatic and manual. The automatic actuation logic mode functions to logically combine the automatic signals from the two redundant automatic subsystems in a 2oo2 basis. The combined signal operates a power switch with an output drive capability that is compatible, in voltage and current capacity, with the requirements of the final actuation devices. The 2oo2 logic is implemented by connecting the outputs in series. The manual actuation mode operates in parallel to independently actuate the final devices. Actuation signals are output to the loads in the form of normally de-energized, energize-to-actuate signals. The normally de-energized output state, along with the dual, 2oo2 redundancy reduces the probability of inadvertent actuation. The staff found the applicant's response to RAI-SRP-7.8-DAS-03 acceptable.

The 2oo2 DAS actuation logic was included in the approved DAS design in the certified AP1000 DCD, Revision 15. Specifically, 10 CFR 50.62 requires that ATWS mitigation equipment be designed to perform its function in a reliable manner. As described in Section 15.8.3 of the AP1000 DCD, the AP1000 is equipped with a DAS, which provides the functions required by the ATWS rule (10 CFR 50.62). The ATWS core damage frequency for the AP1000 is below the SECY-83-293, "Amendments to 10 CFR 50 Related to Anticipated Transients Without Scram (ATWS) Events," goal of 10^{-5} per reactor year. In NUREG-1793, the staff reviewed and approved the AP1000's basis for meeting the ATWS core damage frequency goal.

Reliability of digital systems can be achieved through various means including redundancy, fault detection and management, quality of design, and use of reliable components. Reliability can be defined as the likelihood that a given component or system will be properly functioning when needed, as measured over a given period of time. Reliability, in itself, does not account for any repair actions that may take place. Availability can be defined as the percentage of time that a given system will be functioning as required. In other words, availability is the probability that a system is not failed or undergoing a repair action when it needs to be used.

The AP1000 DAS design addresses reliability from a design/component approach and by fault detection and management. From a design/component reliability approach, Section 8.1 of WCAP-17184-P states that a FMEA, mean-time-between-failure analysis, and a reliability block diagram analysis will be performed on the DAS at the component level. Since the DAS detailed design is not complete at the DC stage, nor required to be complete in accordance with 10 CFR 52.47, those analyses were not part of the staff's review. However, sufficient criteria in the AP1000 DCD are available to guide the detailed design analysis, such as the use of MIL-HDBK-217F for component failures and hardware reliability analysis. From a fault detection/management approach, Section 6.1.2.2.1 of WCAP-17184-P states that the DAS will include self-diagnostic features to identify failures of the processor and supporting circuitry. The self-diagnostic features provide real-time indication to operators of a DAS failure, limiting the fault exposure time and improving DAS availability.

As part of the determination for meeting the ATWS core damage frequency goal, the AP1000 PRA assumed an availability goal for DAS, as described in Section 8.2 of WCAP-17184-P. As committed in WCAP-17184-P, the detailed reliability analysis performed on the DAS would be consistent with the availability goal. Specifically, the reliability analysis will determine an expected failure rate based on hardware failures. Both the failure rate and expected repair time will be calculated and compared to the availability goal for consistency. By utilizing self-diagnostic features, the operators are given real-time indication of a DAS failure, which allows maintenance to be performed in a timely manner. By using the self-diagnostic features, the fault exposure time is reduced on the DAS, thus improving DAS availability as it relates to latent, undetected faults.

Given the commitments in WCAP-17814-P regarding the reliability analysis and self-diagnostics, the staff finds that the DAS will operate reliably. DAS may be taken out of service for maintenance, or be subjected to a failure, but would meet the committed availability target, which is part of the overall basis for meeting the ATWS core damage frequency goal. NRC regulations such as 10 CFR 50.65, “Requirements for monitoring the effectiveness of maintenance at nuclear power plants,” would provide verification that the availability goal is being achieved while the plant is in operation.

As part of the AP1000 design changes, the applicant proposed the addition of a new DAS high hot leg temperature reactor and turbine trip. The reason for the design change is that in the original DAS design, which is modeled in PRA, a reactor trip and turbine trip should occur for ATWS sequences with main feedwater available. Because feedwater is still available, the DAS low steam generator water level signal will not initiate the reactor or turbine trip. The DAS high hot leg temperature signal is needed to perform this function.

The staff evaluated ATWS for the AP1000 as documented in NUREG-1793. For that evaluation, the applicant analyzed a number of cases that included scenarios with and without normal feedwater operating. The most limiting case was confirmed to be the loss of normal feedwater event with turbine bypass operable, resulting in the highest RCS pressure. Addition of the hot leg temperature DAS trip would not alter that conclusion. The additional trip provides additional margin for the limiting case, and hence, is a conservative change that is acceptable for ATWS response. With respect to DAS reliability, quality, qualification, and independence from the primary protection system, the staff finds that the addition of a new function would not impact any of these design characteristics. Specifically, the function can be added into the current DAS architecture without changes to the DAS architecture described in the certified AP1000 design. Therefore, the staff finds the new DAS high hot leg temperature reactor and turbine trip meets the requirements of 10 CFR 50.62.

The additional detailed design information for the I&C architecture and communications results in increased standardization of this aspect of the design. Therefore, the change meets the finality criterion for changes in 10 CFR 52.63(a)(1)(vii).

7.8.3 Evaluation Findings and Conclusions

After reviewing WCAP-17184-P, Revision 2; TR-97, Revision 1; WCAP-15775, Revision 4; changes to the AP1000 DCD, Tier 1 and Tier 2; and responses to related RAIs, the staff concludes that the applicant provides sufficient information to support the changes made to the DAS in Revision 19 of the AP1000 DCD.

The staff concludes that the proposed changes to the AP1000 DCD meet the requirements of 10 CFR 50.62 and 10 CFR Part 50, Appendix A, GDC 22. The proposed changes to the AP1000 DCD did not affect the design commitments regarding an ATWS. The staff also found that the applicant provided sufficient information to support the removal of the two completed lifecycle phases and other changes for DAS. Therefore, the staff concludes the changes the applicant made to the DAS design meet regulatory requirements and criteria.

7.9 Data Communication Systems

7.9.1 System Description

The AP1000 I&C systems consist of the PMS safety system, which contains four independent divisions, four nonsafety systems, the PLS, data display and processing system (DDS), main turbine control and diagnostic system, and special monitoring system (SMS)), and two systems that perform both safety and nonsafety functions (IIS and operations and control centers system (OCS)). AP1000 DCD, Section 7.1.2.8, references WCAP-16675, Revision 5, for AP1000 data communications systems design. This TR provides an overview of the design of data communications within the PMS and communications between the PMS and nonsafety systems. Section 3 of WCAP-16675 references WCAP-16674, Revision 4, for a more detailed description of data communications in the AP1000 I&C systems design.

WCAP-16675, as supplemented by WCAP-16674, describes the use of the Common Q platform for data communications within the internal PMS safety functions (nuclear instrumentation system (NIS), QDPS, RTS, ESFAS, and the component logic system) and the safety portions of the IIS and OCS. This TR also describes the use of the Emerson Ovation® Network for data communications within the nonsafety systems, the nonsafety portions of IIS and OCS, and outputs from the safety system data (via the Advant-Ovation® Interface (AOI) gateways).

7.9.2 Communication within Safety Systems

7.9.2.1 Common Q Communications Subsystems

The NRC evaluated WCAP-16097, "Common Qualified Platform Topical Report," and issued safety evaluations approving the Common Q platform on August 11, 2000; June 22, 2001; and April 2, 2003. WCAP-16097 described the communications subsystems of the Common Q system. The SER for the Common Q platform provided an evaluation of the following three types of communications subsystems:

(1) AF100 bus communication for intrachannel communications and a separate AF100 bus for interchannel communications in the DDS

(2) HSL serial communications for interchannel communications

(3) external communications for communications between the Common Q platform and external computer systems

The Common Q platform topical report SER concluded that these three types of communications subsystems met the requirements of IEEE Std. 603-1991, as supplemented by IEEE Std. 7-4.3.2-1993. The staff's review of these communications subsystems supplements the conclusions made in the SER of the Common Q platform topical report. Specifically, the staff evaluated the application of these communications subsystems for data communications within the AP1000 I&C systems. Sections 7.9.2.2, 7.9.2.3, and 7.9.3 document the evaluation of the application of these communications subsystems to the PMS design.

The additional detailed design information would otherwise have to be addressed through verification of implementation of the I&C DAC. Therefore, the changes to the DCD eliminate the need for I&C DAC and satisfy the finality criteria in 10 CFR 52.63(a)(1)(iv).

7.9.2.2 Intradivisional Communication via the AF100 Bus

7.9.2.2.1 Functional Description of the AF100 Bus

Section 3 of WCAP-16775 describes the use of the AF100 bus for intradivisional communications between the AC160 controllers and the safety and QDPS display systems within the same division. This section states that, within each PMS division, the internal functions and the safety portions of both IIS and the OCS are integrated using an intradivisional AF100 bus.

Specifically, the AF100 bus is used to allow the various AC160 controllers and FPDS within a division to exchange information for maintenance, test, diagnostic, communication (to the nonsafety system), display, and manual control. The majority of the dataflow is from the AC160 controllers to the FPDS (for display and for communication to the nonsafety system). Therefore, the AF100 bus is used to integrate information exchange among the AC160 controllers performing the ESFAS and reactor trip functions and the FPDS. The AF100 is not in the sensor-to-reactor trip path or sensor-to-ESFAS-actuation path. The ESFAS and reactor trip functions do not require information from each other to perform their safety functions.

The AF100 bus is a deterministic communication bus with a transmission rate of 1.5 megabit (Mbit)/second or faster. Section 4.1.2 of WCAP-16674 describes the two types of data communication that occur within the AF100 bus. The real-time data distribution communication provides a scheduled periodic broadcast of real-time data (process data transfer) pertaining to the plant processes. The general purpose communication provides a periodic exchange of data (message transfer) for other purposes, such as system operation, diagnostics, and maintenance. As described in Section 3.1 of WCAP-16675, message transfer does not influence process data transfer in any way. This is accomplished by reserving bandwidth for process data transfer and using the remaining bandwidth for message transfers. In addition, Section 3.1.1 of WCAP-16675 describes how the application program configuration tool is used to limit the maximum number of process data transfer packets that can be transferred over the AF100 bus to prevent overloading it. Process data packets are transferred with fixed packet size and cycle time to ensure deterministic communications.

Section 2.2.6.2 of WCAP-16675 states that software changes can be accomplished in the AC160 in two ways. One way is to program the AC160 over the AF100 bus. Even though this network and the only programming source (the MTP) are totally contained within a division of the PMS, this mode of programming is prevented. This is accomplished by using the AC160 Function Chart Builder tool to configure the equipment to not accept AF100 bus programming. The other way to load software into the AC160 is by a serial connection between the division's MTP and the AC160. Within a division, a separate cable is permanently routed from the maintenance and test cabinet (MTC) to each cabinet containing an AC160 processor module. This configuration allows for software loading to any processor module within a division from the MTP. The software loading cable is normally disconnected on each end. To perform a software update, the cable (coming from the cabinet containing the target processor module) in the MTC is connected to the MTP. The opposite end of the software loading cable is connected to the target AC160 processor module and the software update is performed from the MTP.

Section 3.1 of WCAP-16675 states that an AF100 bus is totally contained within each division of the safety system. The physical extent of each AF100 bus is limited to its corresponding I&C equipment room, the MCR, and the raceways between the two. Onsite access is not provided in any other location. Offsite access to the four PMS intradivisional Common Q networks is not available. This section also states that, within the PMS, security is maintained, since the ability to remotely program the AC160 controllers and safety and QDPS display systems over the AF100 bus has been disabled in the PMS. Access to the PMS intradivisional Common Q network is only available from the MCR. Access is not available in any of the other operation and control centers.

7.9.2.2.2 Evaluation of the AF100 Bus

The staff finds the use of the Common Q AF100 bus acceptable for intradivisional communication within each PMS division. The AF100 bus only serves one division in each PMS division, with no direct connections to other divisions or nonsafety systems. Data from other divisions and nonsafety systems can only reside on the AF100 bus via the other components within the same division (e.g., integrated communications processor (ICP) through HSLs). In such cases, electrical and communications isolation is provided by the fiber-optic connection between the given component and other divisions, and the communications processor of that particular component, respectively. IEEE Std. 603-1991, Clause 5.6.1, requires independence between redundant portions of safety systems to the degree necessary to retain the capability to accomplish the safety function during and following any design-basis event requiring that safety function. In addition, IEEE Std. 603-1991, Clause 5.6.3, “Independence Between Safety Systems and Other Systems,” requires independence between safety and nonsafety systems, such that credible failures in, and consequential actions by, nonsafety systems shall not prevent the safety system from accomplishing its intended safety function. Based on the communications and electrical isolation present in the Common Q AF100 bus, the staff finds the independence requirements of IEEE Std. 603-1991, Clauses 5.6.1 and 5.6.3, are met.

The staff evaluated the access controls to the AF100 bus against the requirements of IEEE Std. 603-1991, Clause 5.9, as clarified by the guidance provided in DI&C ISG #4-HICRc. IEEE Std. 603-1991, Clause 5.9, requires the design to permit the administrative control of access to safety-system equipment. DI&C ISG #4-HICRc, Section 1, Point 10, states that safety division software should be protected from alteration while the safety division is in operation. Hardwired interlocks or physical disconnection of maintenance and monitoring equipment should prevent online changes to safety-system software. The staff has evaluated the access controls described in Section 3.1 of WCAP-16675, as discussed in the above section.

The staff finds the use of the AC160 Function Chart Builder tool to configure the equipment so that it does not accept programming over the AF100 bus to be acceptable in meeting the requirements of IEEE Std. 603-1991, Clause 5.9, by addressing Section 1, Point 10, of DI&C ISG #4-HICRc regarding restrictions to the online programmability of safety equipment. In addition, the staff finds that the access control provided for programming the AC160 controller over the serial software loading cable to the equipment provides additional assurance that unauthorized software modifications to the AC160 controller and to the safety and QDPS displays are prevented. Specifically, the staff finds the physical disconnection of the software load cable between scheduled software updates meets Section 1, Point 10, of DI&C ISG #4-HICRc.

The staff evaluated how the design of the AF100 bus addressed the system integrity requirements of IEEE Std. 603-1991, Clause 5.5, which requires in part that safety systems be designed to accomplish their safety functions under the full range of applicable conditions enumerated in the design basis. BTP 7-21, "Guidance on Digital Computer Real-Time Performance," states that risky design practices such as non-deterministic data communications, non-deterministic computation, use of interrupts, multitasking, dynamic scheduling, and event-driven design should be avoided. Based on the deterministic nature of the process data transfer on the AF100 bus, as described in Section 3.1 of WCAP-16675, and the limitations on maximum allowed process data transfer packets, the staff finds that the design of the AF100 bus adequately addresses the deterministic communications criteria provided in BTP 7-21 to meet IEEE Std. 603-1991, Clause 5.5.

7.9.2.3 Interdivisional and Intradivisional Communication via the High-Speed Link

7.9.2.3.1 Functional Description of the High-Speed Link

Section 3 of WCAP-16775 describes the use of the HSL for interdivisional and intradivisional communication within the PMS. This section states that the PMS uses HSLs, which are point-to-point, to communicate certain data within and across PMS divisions. The HSL is a serial RS 422 link using high-level datalink control protocol with a 3.1 Mbits/second transfer rate. The HSL is used for planned data exchanges of predefined data packets between two Common Q processor modules in the sensor-to-reactor trip path or sensor-to-ESFAS actuation path.

As stated in Section 6.2.1 of the SER to WCAP-16097, the PM646 function processor is divided into two sections, the process section and the communications section. The communications section in the PM646A processor module is used for HSL communications. Each processor module has one independent transmit link (output to two ports) and two independent receive links. The receivers of each HSL are independent and can receive different data independently, in accordance with the guidance of DI&C ISG #4-HICRc. As specified in Section 5.1 of the SER to WCAP-16097, these ports are used with fiber-optic cables for interchannel communications. Section 6.4 of this TR states that the integrity of data transmitted is monitored by using a CRC. The receiving processor module calculates the CRC of the received data and compares it with CRC bits received with the data. If the CRC comparison fails three consecutive times, the processor module declares the link has failed and reports the failure to the application software, which takes appropriate action. The processing section and the communication section of each PM646A processor module communicate with each other, in accordance with DI&C ISG #4-HICR, such that the communication and function processors operate asynchronously, sharing information only by means of dual-ported memory or some other shared memory resource that is dedicated exclusively to this exchange of information. This allows the two sections to share data between them while preventing either from affecting the operation of the other. The specific implementation, as described in Section 6.2.1 of the SER to WCAP-16097, is proprietary.

Based upon the specification listed in Section 4.1.1.4 of WCAP-16097, to ensure deterministic behavior of the Common Q platform, the measured load of the application programs on a single PM646 processor has to be less than 70 percent. To verify that safety systems meet the response time requirement, WCAP-16097 states that the applicant committed to perform a throughput analysis and a response time analysis. This topical report stated that, during the testing phase of the Common Q application, the applicant will perform response time tests to validate the design's compliance with both the system response and the display response requirements. In the SER for the WCAP-16097, the staff concluded that the design features, the operation of the AC160 PLC system, and CENP's commitments to perform timing analyses and tests provide sufficient confidence that the AC160 will operate deterministically to meet the recommendations in BTP HICB-21 and is, therefore, acceptable in that regard. However, the staff issued PSAI 6.6 to ensure that timing analysis and validation tests for applications of Common Qualified platform system verify that the design satisfies the plant-specific requirements for accuracy and response time presented in the accident analysis in Chapter 15 of the safety analysis report. The resolution of PSAI 6.6 is documented in NUREG-1793 for the certified AP1000 design, which states: "The accuracy and response time of the AP1000 safety systems will be commensurate with the Chapter 15 safety analysis. The COL applicant is responsible for the setpoint analysis. The setpoint analysis shall be performed by the COL applicant, as defined in DCD Tier 1, Section 2.5.2, Item 10, and DCD Tier 2, Section 7.1.6. This is COL Action Item 7.2.7-1."

Section 3.2 of WCAP-16675 describes the functional use of the HSL for interdivisional and intradivisional communication within the PMS. Below is a summary of how the HSL is used for data communications between equipment within the PMS.

Bistable Processor Logic to Local Coincidence Logic Communication

The PMS uses the Common Q HSLs to transmit certain data for partial trip, partial actuation, and related status information calculated in the BPL controllers to the LCL controllers. In addition, these serial links are used to transmit voting information between divisions. Fiber-optic cables provide electrical isolation and the communications processor in the PM646 module provides communications isolation.

Local Coincidence Logic to Integrated Logic Processor Communication

The PMS uses Common Q HSLs to transfer ESF system-level actuation and related status information calculated in the LCL controllers to ILPs that distribute the signals to the safety components via the CIM sub-system of the PMS. These links are only used locally within a division.

Integrated Logic Processor Communication to Integrated Communication Processor Communication

The PMS uses Common Q HSLs to transfer data to support the QDPS function and data to support cross-division diagnostics between divisions. Cross-division diagnostics are completed outside the PMS, using outputs from the ICP to the PLS. For communications across divisions of the PMS, fiber-optic media converters and fiber-optic cables provide electrical isolation and the communications processor within each PM646 module provides communications isolation. Section 3.3 of WCAP-16775 states that qualified isolation devices maintain electrical isolation and communications independence between the ICP and the PLS.

Integrated Test Processor

The PMS uses Common Q HSLs to transfer data to the ITP to support testing and monitoring the PMS system. The ITP compares information from within the division via the AF100 bus to information received via HSLs from the other divisions for fault detection. Fiber-optic media converters and fiber-optic cables provide electrical isolation and the communications processor within each PM646 module provides communications isolation.

7.9.2.3.2 Evaluation of the High-Speed Link and PM646 Deterministic Performance

Clause 5.5 of IEEE Std. 603-1998 requires safety systems be designed to accomplish their safety functions under the full range of applicable conditions enumerated in the design basis. In addition, Clause 4.10 of IEEE Std. 603-1998 requires, as a part of the design basis, identification of the critical points in time or the plant conditions, after the onset of a design basis event.

To meet IEEE Std. 603-1991, Clause 5.5 and Clause 4.10, data communications systems in support of the protection system should demonstrate real-time performance in accordance with NUREG-0800 BTP 7-21. NUREG-0800 BTP 7-21 stipulates that:

1. Time delays within the data communications systems and measurement inaccuracies introduced by the data communications systems should be considered when reviewing setpoints.

2. Data rates and data bandwidths should be reviewed including impact by environmental extremes.

3. Sufficient excess capacity margins should be available to accommodate future increases.

In addition, limiting response times should be consistent with safety requirements. Digital computer timing should be consistent with the limiting response times and characteristics of the computer hardware, software, and data communications systems.

As stated above, in the SER for the Common Q topical report and NUREG-1793, the staff concluded that the HSL communications and the PM646 processor design is adequate to address the deterministic performance criteria in HICB BTP 7-21 in the Common Q topical report, and the resolution of PSAI 6.6 in NUREG-1793. The applicant included ITAAC acceptance criteria to verify the PMS response time under maximum central processing unit (CPU) loading meets Chapter 15 response time limits. Specifically, the applicant committed to modify the acceptance criteria in Item 11d) the system integration and test phase of ITAAC Table 2.5.2-8 in Tier 1, Chapter 2, Section 2.5.2 of the AP1000 DCD to state "Performance of system tests and the documentation of system test results, including a response time test will be performed under maximum CPU loading to demonstrate the PMS can fulfill its response time criteria." The staff finds this proposed update to Item 11d) of ITAAC Table 2.5.2-8 acceptable. In Revision 19 to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

IEEE Std. 603-1991, Clause 5.6.1, requires independence between redundant portions of safety systems to the degree necessary to retain the capability to accomplish the safety function during and following any design-basis event requiring that safety function. NUREG-0800 BTP 7-11, "Guidance on Application and Qualification of Isolation Devices," states that fiber-optic cables are acceptable isolation devices. Based on the guidelines in BTP 7-11, the staff finds that optical media converters with optical fiber cabling in the HSL provide adequate electrical isolation. In addition, DI&C ISG #4-HICRc clarifies existing guidance on acceptable methods to meet the communications independence requirements of IEEE Std. 603-1991, Clause 5.6. Section 1 of this ISG specifies that communications between redundant divisions of safety systems should adhere to the points presented in that section. Table 7.9-1 documents the staff's evaluation of interdivisional communications using the HSLs against each criterion in DI&C ISG #4-HICRc.

Based on the staff's evaluation of the HSL design against the 20 criteria presented in Section 1 of DI&C ISG #4-HICRc, the staff finds that this design has addressed all criteria in Section 1 of DI&C ISG #4-HICRc, as shown in Table 7.9-1. Thus, the staff finds that the PMS design meets the independence requirements of IEEE Std. 603-1991, Clause 5.6.1.

IEEE Std. 603-1991, Clause 5.6.3, requires independence between safety and nonsafety systems, such that credible failures in, and consequential actions by, nonsafety systems shall not prevent the safety systems from accomplishing their intended safety function. Section 7.9.3 discusses communications independence between the ICP and the PLS to meet the requirements of IEEE Std. 603-1991, Clause 5.6.3.

The staff has evaluated the access controls to HSLs against requirements of IEEE Std. 603-1991, Clause 5.9. Clause 5.9 required the design to provide administrative control of access to safety-system equipment. Since the HSLs are point-to-point dedicated serial links that are only used within safety systems of the PMS, access control is maintained by the physical security controls in the MCR. The staff finds that access controls to the HSLs meet the requirements of IEEE Std. 603-1991, Clause 5.9.

7.9.2.4 CIM Communication

WCAP-17179, Revision 2, provides a description of the data communications for the CIM. Section 2.1 of this technical report states that the CIM is designed to interface a field component to the PMS and the PLS. Communication with the PMS is accomplished with the SRNC assembly. The SRNC module accepts a HSL connection. The SRNC communicates with each CIM through a safety bus known as the X bus. The X-bus is an independent, bidirectional link between the CIM and the SRNC. The PMS communication link is known as the X port. The CIMs communicate with the PLS through an Ovation® RNC. The Ovation® RNC bus is known as the Y bus.

Section 2.3.1.2.8 of WCAP-17179 states that the CIM has design features to provide for deterministic operation of the CIM. Communication between the PMS to the SRNC via the HSL is designed to be deterministic as described in Section 2.4.1.1 of this TR. Furthermore, the communication between the SRNC and the CIM via the X bus is designed for deterministic communications as described in Section 2.4.1.2 of this TR. Messages received from the PLS via the Y bus is translated to discrete digital signals prior to input into the CIM.

Evaluation of the CIM Communications

The staff evaluated how the CIM communications design addressed the system integrity requirements of IEEE Std. 603-1991, Clause 5.5, which requires in part that safety systems be designed to accomplish their safety functions under the full range of applicable conditions enumerated in the design basis. BTP 7-21 states that risky design practices such as non-deterministic data communications, non-deterministic computation, use of interrupts, multitasking, dynamic scheduling, and event-driven design should be avoided. Based on the design commitments for deterministic operation and communications for the CIM, as stated in WCAP-17179 and summarized above, the staff finds that the applicant has adequately addressed the deterministic communications criteria provided in BTP 7-21 to meet IEEE Std. 603-1991, Clause 5.5.

Table 7.9-1. Evaluation of the PMS Interdivisional Communication via HSL

Point	Acceptability	Basis
1	The staff finds Point 1 of DI&C ISG #4 has been satisfied.	Aside from voting purposes, the components within the PMS do not receive any information from outside their division that will be used for accomplishing any safety functions.
2	The staff finds Point 2 of DI&C ISG #4-HICRc has been satisfied.	Except for voting purposes, the information received from other divisions is not used for initiating a protective function. Information received from other divisions for display and signal comparison purposes is validated through CRC checks. A communications fault in which the information is delayed, incorrect, or missing will be handled by the communications processor of each PM646 module.
3	For Point 3 of DI&C ISG #4, the applicant provided an alternative method to the guidance. The staff finds the alternative method is acceptable.	Aside from voting purposes, the information shared across divisions of the PMS does not meet DI&C ISG #4-HICRc interdivisional communication Point 3. In the PMS design, information received from other divisions for display and cross-divisional diagnostic purposes does not enhance the safety function. However, since: (1) the received information is not used for reactor trip and ESF actuation function, (2) it is communicated on a separate communication medium (AF100 bus), and (3) failure of such communication would not affect the safety functions, the staff finds the proposed alternative method acceptable.
4	The staff finds Point 4 of DI&C ISG #4 has been satisfied.	Within the PM646 module, the communications processor is separate from the function processor, and data transmission between the two processors can only be accomplished using dual port-RAM. As such, any communications errors will not propagate from the communications processor to the function processor within each PM646 module.
5	The staff finds Point 5 of DI&C ISG #4 has been satisfied.	As stated above, in the SER for the Common Q Topical Report and NUREG-1793, the staff concluded that the HSL communications and the PM646 processor design is adequate to address the deterministic performance criteria in HICB BTP 7-21 in the Common Q Topical Report, and the resolution of PSAI 6.6 in NUREG-1793. The PMS is designed to meet the Chapter 15 overall response requirements. The proposed response time testing in ITAAC Item 11d of Table 2.5.2-8 in the AP1000 DCD will verify that the as-built PMS fulfills the response time criteria under maximum CPU loading.
6	The staff finds Point 6 of DI&C ISG #4 has been satisfied.	The safety processor operates asynchronously to the communications processor within the PM646 module, and the operation does not perform any communication handshaking or accept interrupts from other divisions.

Table 7.9-1. Evaluation of the PMS Interdivisional Communication via HSL

Point	Acceptability	Basis
7	The staff finds Point 7 of DI&C ISG #4 has been satisfied.	The communication section of PM646 module only accepts predefined data sets and uses a CRC check to ensure the integrity of the data.
8	The staff finds Point 8 of DI&C ISG #4 has been satisfied.	The received information from other divisions is only used for display, diagnostic, and voting purposes. The use of predefined data sets and CRC checks ensures that the integrity of the data prevents any communications errors from affecting the safety functions.
9	The staff finds Point 9 of DI&C ISG #4 has been satisfied.	Section 2.1 of WCAP-17201 describes how the incoming messages are pre-allocated memory in static locations in the communications portion of the AC160 controller. Additional features are implemented to ensure that any software faults in the application data will be detected. Based on the storage of incoming messages in pre-allocated memory space and the use of error detection features to identify any software faults, the staff finds that Point 9 has been satisfied.
10	The staff finds Point 10 of DI&C ISG #4 has been satisfied.	As stated in Section 7.9.2.2.2 of this report, there only two methods to load software to the AC160 controllers. One is via the AF100 bus, which has been disabled during the software programming. The other way to load software into the AC160 is by a serial connection between the division's MTP and the AC160. This loading cable is normally disconnected on each end to prevent inadvertent programming during operations. As such, the staff finds Point 10 has been satisfied.
11	The staff finds Point 11 of DI&C ISG #4 has been satisfied.	The information received from other divisions is only used for display, diagnostic, and voting purposes. The design does include using the information for any other functions, including functions that allow the safety function to receive software instructions. The implementation of the design will be evaluated in the review of the specific design specifications.
12	The staff finds Point 12 of DI&C ISG #4 has been satisfied.	WCAP-17201, Section 2.2, discusses how messages will be checked to ensure validity of the message (e.g., repeated messages or messages out of sequence.) The specific features implemented to ensure the validity of the messages are proprietary. However, based on the information presented in technical report WCAP-17201, Section 2.2, the staff finds that Point 12 of ISG-04 has been satisfied.

Table 7.9-1. Evaluation of the PMS Interdivisional Communication via HSL

Point	Acceptability	Basis
13	The staff finds Point 13 of DI&C ISG #4 has been satisfied.	As described in Section 2.3 of WCAP-17201, the HSL protocol does not support error detection; only error detection is implemented to detect data communication failures. Once a message is detected as bad, it is flagged, and the application software will respond accordingly. The staff finds the use of error detection for HSL data communications acceptable to ensure received messages are correct and correctly understood. Therefore, the staff finds that point 13 has been satisfied.
14	The staff finds Point 14 of DI&C ISG #4 has been satisfied.	The HSL is a point-to-point serial link; thus, Point 14 of DI&C ISG #4 is satisfied.
15	The staff finds Point 15 of DI&C ISG #4 has been satisfied.	Although the Common Q topical report states that the communication section of the PM646 is event driven, and does not communicate a fixed set of data at regular intervals, the processing section of PM646 is cyclic. As such, as discussed in Section 2.4 of WCAP-17201, at the end of every execution cycle, the application program store data from the processing section into the dual-ported memory for the communication section to transmit. Since the communication section transmits the data whenever there is a message in dual-ported memory, this communication is thus linked to the cyclic operation of the process section. Therefore, although the communication section is event driven, the communications are really cyclic and deterministic, and thus the staff finds that Point 15 has been satisfied.
16	The staff finds Point 16 of DI&C ISG #4 has been satisfied.	The watchdog timer feature of the PM646 module ensures message and link liveliness.
17	The staff finds Point 17 of DI&C ISG #4 has been satisfied.	The AP1000 DCD and the supporting TRs, along with the Common Q topical report, and Tier 1 ITAAC have committed to completing equipment qualification.
18	The staff finds Point 18 of DI&C ISG #4 has been satisfied.	The AP1000 DCD and the supporting TRs, along with the Common Q topical report, have committed to providing the FMEA and the SHA.

Table 7.9-1. Evaluation of the PMS Interdivisional Communication via HSL

Point	Acceptability	Basis
19	The staff finds Point 19 of DI&C ISG #4 has been satisfied.	As stated above, in the SER for the Common Q Topical Report and NUREG-1793, the staff concluded that the HSL communications and the PM646 processor design is adequate to address the deterministic performance criteria in HICB BTP 7-21 in the Common Q Topical Report, and the resolution of PSAI 6.6 in NUREG-1793. The PMS is designed to meet the Chapter 15 overall response requirements. The proposed response time testing in ITAAC Item 11d of Table 2.5.2-8 in the AP1000 DCD will verify that the as-built PMS fulfills the response time criteria under maximum CPU loading.
20	The staff finds Point 20 of DI&C ISG #4 has been satisfied.	As stated above, in the SER for the Common Q Topical Report and NUREG-1793, the staff concluded that the HSL communications and the PM646 processor design is adequate to address the deterministic performance criteria in HICB BTP 7-21 in the Common Q Topical Report, and the resolution of PSAI 6.6 in NUREG-1793. The PMS is designed to meet the Chapter 15 overall response requirements. The proposed response time testing in ITAAC Item 11d of Table 2.5.2-8 in the AP1000 DCD will verify that the as-built PMS fulfills the response time criteria under maximum CPU loading.

The evaluation of the interface between the CIM and the PLS with respect to communications independence requirements, as stipulated in IEEE Std. 603-1991, Clause 5.6.3, is provided in Section 7.9.3 of this report.

7.9.2.5 Main Control Room Multiplexers

Section 7.1.2.6 of the AP1000 DCD removed the use of multiplexers in the protection and safety monitoring system to provide a signal path between the protection system equipment and the MCR. This section states that each division's safety and QDPS display will communicate with the protection system equipment via the dedicated AF100 communications network within each division. In addition, Section 3.4.1 of WCAP-16675 states that the MCR system-level actuation switches are cabled directly from the switches in the MCR to the LCL located in the bistable coincidence cabinets in each instrument room.

Since the switches in the MCR are directly connected to the LCL, the staff finds the justification for removal of the multiplexers in the MCR acceptable.

7.9.2.6 Testing of Communications Modules

The applicant removed the description of the fault tolerances, maintenance, test, and bypass from the DCD, and replaced it with references to WCAP-16675. Section 6.1 of WCAP-16675 describes the test features of communications modules within the PMS.

Sections 6.1.2 of WCAP-16675 states the AF100 bus communication modules provide communications between subsystems (e.g., BPL, LCL, ILP, MTP, and ITP). These communications include transferring data in support of system diagnostics. The AF100 bus supports two types of communications: process data and message transfer. Process data are dynamic data used to monitor and control the process, while message transfer is used for program loading and system diagnostics.

The AF100 bus communications modules are individually supervised by their own internal diagnostics and additional run-time diagnostic. In addition, the processor module performs continuous background diagnostics of the communications modules and automatically detects errors during operation. The process module contains the error messages in the error buffer for system troubleshooting.

Evaluation for Testing of Communications Modules

IEEE Std. 603-1991, Clause 5.7, requires the design to provide the capability to test and calibrate safety-system equipment, while retaining the capability of the safety systems to accomplish their safety functions. As applied to data communications systems, NUREG-0800 Section 7.9 states that data communications systems should be designed to support self-testing and surveillance testing. The design of automatic self-test features should maintain channel independence. The staff finds that the self-testing of the AF100 bus communications modules, including the internal diagnostics and additional runtime diagnostics, demonstrate conformance with the self-testing criteria in Section 7.9 of NUREG-0800 and, thus, meets the requirements of IEEE Std. 603-1991, Clause 5.7. However, the staff notes that these self-test features are not to replace the requirements for surveillance testing. In addition, since self-testing of the AF100 bus does not traverse multiple divisions or go outside the safety system, these testing features meet the independence requirements of IEEE Std. 603-1991, Clause 5.6.

7.9.3 Communication between Safety and Non-safety Systems

Section 5 of WCAP-16674 describes the data communications between the safety system and nonsafety system within the AP1000 design. This TR also describes the changes made to the certified AP1000 design regarding data communications between the safety and nonsafety systems. This TR states that the certified AP1000 design had the following data flow between the safety and nonsafety systems:

(1) data flow from PMS to PLS for control purposes
(2) data flow from PMS to DDS for information system purposes
(3) data flow from DDS to PMS for safety-system actuation purposes (via Remote Shutdown Panel when activated)
(4) data flow from PLS to PMS for component control purposes

In addition, the certified design establishes the following ITAAC in AP1000 DCD Tier 1, Section 2.5.2, regarding the implementation of these data flows:

7.a The PMS provides process signals to the PLS through isolation devices.

7.b The PMS provides process signals to the DDS through isolation devices.

7.c Data communications between safety and nonsafety systems does not inhibit the performance of the safety function.

7.d The PMS ensures that the automatic safety function and the Class 1E manual controls both have priority over the non-Class 1E soft controls.

In the certified design, the data flow between safety and nonsafety systems is primarily implemented using divisionalized bidirectional gateways. Section 5 of WCAP-16674 states that the data communications between the PMS and the nonsafety system have been modified in the PMS design. These modifications have the following effects:

- Reduce the dependence on the gateways.
- Make the gateways [ ].
- Create segmentation and network independence of the nuclear steam supply system (NSSS) control functions within the PLS.
- Make a clear delineation of the points of electrical, communication, and functional isolation.

In the modified design, the PMS implements data flows between safety and nonsafety equipment using divisionalized, [ ] gateways and individual analog and digital signals. Five cases of safety-system-to-nonsafety-system communication are identified within the AP1000 design. WCAP-16674 provides an analysis of the ITAAC in AP1000 DCD Tier 1, Section 2.5.2 for compliance for each of the cases, including the following requirements:

- There are isolation devices between the PMS and PLS, and between the PMS and the DDS.
- Data communications between safety and nonsafety systems do not inhibit the performance of the safety function.
- PMS ensures that the automatic safety function and the Class 1E manual controls both have priority over the non-Class 1E soft controls.

The additional detailed design information would otherwise have to be addressed through verification of implementation of the I&C DAC. Therefore, the changes to the DCD eliminate the need for I&C DAC to satisfy the finality criteria in 10 CFR 52.63(a)(1)(iv).

7.9.3.1 Description of the Five Cases of Communication between Safety and Nonsafety Systems

Below is a summary of the five cases of safety-system-to-nonsafety-system communication.

Case A and Case B

Section 5 of WCAP-16674 states that Case A and Case B communications allow the PMS to communicate with the nonsafety control system (PLS) via qualified isolation devices. Case A involves transferring safety-related input signals that are isolated in the PMS cabinets and sent to the PLS as individual hardwired analog signals. This is identical to the type of interface in existing plants. Case B allows the PMS to transfer analog and discrete digital signals calculated within the PMS to the PLS using qualified isolation devices. Section 5 of WCAP-16674 states that the qualified isolation devices used in both Case A and Case B communications provide electrical isolation between the systems as required by IEEE Standard 603-1991. They also provide functional isolation by preventing the nonsafety system from adversely affecting the safety function.

Case C

Case C communications allow various process-related signals (analog input signals, analog signals calculated within the PMS, and digital signals calculated within the PMS) to be sent to the DDS for information system (plant computer) purposes. Non-process signals, such as cabinet entry status, cabinet temperature, and direct current power supply, are also provided to the DDS for information system purposes. As described in Section 5.1.2 of WCAP-16674, the AOI Gateway in each PMS division connects that division's internal network to the nonsafety real-time data network. The sole purpose of the AOI Gateway is to provide data from the safety system to the nonsafety system for nonsafety applications. The AOI Gateway has no protection function in the PMS. The reliability of the PMS to perform its safety function is not dependent on the AOI Gateway's being functional.

The gateway has two subsystems: one is the safety subsystem that interfaces with the AF100 bus, and the other is the nonsafety subsystem that interfaces with the nonsafety Emerson Ovation® network. The AOI safety subsystem is implemented within the PMS to gain access to the desired data. This functionality is included in the PMS MTP, a Common Q FPDS. The PMS portion of the AOI function is implemented using the hardware and software dedication and qualification methodologies accepted by the NRC as part of the Common Q topical report SER process. A fiber-optic link provides communication between the safety subsystem and the nonsafety subsystem. Communication isolation is achieved through the use of [ ] transmission of data from the optical transmitter on the safety subsystem to the optical receiver on the nonsafety subsystem.

For sequence of events (SOE) signals, such as partial trip signals, reactor trip signals, and ESFAS, each division provides the signals to the SOE system or interface via a [ ] fiber-optic link. The flow of information is strictly from the safety subsystem to the nonsafety SOE system or interface. The [ ] nature of the link is assured by the use of a single [ ] fiber. The safety end of the fiber is connected to an optical transmitter. The nonsafety end of the fiber is connected to a fiber-optic receiver. This arrangement also provides electrical isolation between the safety and nonsafety portions of the system.

<u>Case D</u>

Case D communications allows the nonsafety system to communicate with the safety system using discrete digital signals. These signals are used to implement nonsafety manual control of system-level safety functions (actuations, manual blocks, and resets, manual reactor trip) and a nonsafety interlock of certain PMS test functions.

Case D communications allows nonsafety manual controls of system-level safety functions that originate from dedicated switches in the RSR. Section 5.2.1 of WCAP-16674 states that in the RSR, the nonsafety manual controls of system-level safety functions (actuations, manual blocks and resets, manual reactor trip) originate from dedicated switches. The individual discrete digital signals are classified as nonsafety-related and are, therefore, isolated in the PMS cabinets before being used. At the RSR, a fiber-optic transmitter encodes the switch contact state to send over the fiber-optic cable. In the PMS, the fiber-optic receiver decodes the data and recreates the switch contact state on its discrete output signal to the AC160 rack in the safety system. Electrical isolation is provided via the fiber-optic connection. There is no metallic path to conduct an electrical fault into the PMS. Functional isolation is provided by logic within the PMS to prevent the nonsafety data flow from inhibiting the safety function. The functionality associated with these controls is disabled until operation is transferred from the MCR to the RSR. This transfer is accomplished by the divisionalized Class 1E transfer switches, which are connected directly to the LCL controllers in each division. Additionally, when the controls are enabled, their functionality is limited to that defined in the PMS functional design, because the information transferred is only in the form of discrete digital signals (i.e., there is no computer software-based communication). Specifically, the PMS design only permits the RSR manual system-level ESF actuations and the manual reactor trip inputs to initiate safety functions, not inhibit them. The manual system-level resets only remove the system-level actuation signals; they do not cause any components to change state. An additional signal is required to cause a component to change state. To reduce the chance of the spurious actuation of a function, switch contacts and communication paths are arranged in complementary pairs. Two simultaneous failures in opposite directions would be required to cause a spurious actuation.

In addition for some PMS test functions that are subject to interlocks, Case D communications also allows for transfer of discrete individual hardwired digital signals for interlocks from nonsafety equipment to the PMS. Section 5.1.2 of WCAP-16674 states that, for certain PMS test functions that are subject to interlocks from nonsafety equipment, individual hardwired digital signals from nonsafety systems are isolated in the PMS cabinets before being used. Qualified isolation devices are used. These devices provide electrical isolation between the systems, as required by IEEE Std. 603-1991.

Case E

Case E communications allows the nonsafety system to communicate with the safety system using discrete digital signals. These signals are used to implement nonsafety manual component-level controls of safety components.

As described in Section 5.2.2 of WCAP-16674, Case E communications allows manual component soft controls originating in the PLS to actuate safety components. The use of a remote I/O node, consisting of one or more Class 1E CIMs, will congregate the signals from the nonsafety manual soft controls to provide one signal digital output to a non-processor-based priority logic also contained in the CIM. The remote I/O node from the nonsafety system is physically located within each division of the safety system. The remote I/O node is electrically isolated from the nonsafety system by the fiber-optic remote I/O bus. The node is powered by the safety system, and the portions of the node not performing a safety function are qualified as an associated circuit, in accordance with IEEE Std. 384-1981. Specifically, the safety-system qualification program will demonstrate that, when it is subject to environmental, electromagnetic, and seismic stressors, it does not degrade the Class 1E circuits below an acceptable level. The environmental, electromagnetic, and seismic stressors used for these tests are the same as those used to qualify the Class 1E equipment in the same cabinet.

Within the CIM, demands from the nonsafety system are evaluated against Class 1E automatic actuation signals and Class 1E manual actuation signals from the PMS subsystem. If conflicting demands are present, the safe state of the component takes priority. The CIM uses non-processor-based priority logic hardware to implement this priority function. The CIM module also provides status updates of the safety component to the PLS. The remote I/O bus that connects the remote I/O node to the PLS uses fiber-optic cables to provide electrical isolation. As depicted in Figure 6-3 of WCAP-16674, the remote I/O bus uses bidirectional communications between the PLS and the remote I/O node. However, the communications interface of the CIM translates this data into simple discrete signals for input into the Class 1E priority logic to ensure communications independence.

PMS Interfaces to Standalone Systems

In addition to the five cases of communications between the PMS and nonsafety systems, Section 4.2.1 of WCAP-16674 states that the PMS interfaces to the standalone radiation monitoring system (RMS). RMS has two parts, one for safety functions and the other for nonsafety functions. There is no interface between the two parts. The safety portion of the RMS interfaces with the PMS using simple analog and/or discrete digital signals; this interface does not use network or datalink connections. Communication isolation does not apply to discrete hardwired signals. Electrical isolation between the RMS and the PMS is not required since the safety portion of the RMS is Class 1E. There is no interface between the nonsafety portion of the RMS and the PMS.

The CETs used by the QDPS function of the PMS are physically housed within IIS. There is no electrical interface between the CETs and the incore instrumentation electronics of the IIS. The CETs interface to the PMS using simple analog signals; these interfaces do not use network or datalink connections. Communication isolation does not apply to discrete hardwired signals. Electrical isolation between the CETs and the PMS is not required since the CETs are Class 1E.

7.9.3.2 Evaluation of Safety to Nonsafety Data Communication

IEEE Std. 603-1991, Clause 5.6.3, requires independence between safety and nonsafety systems, such that credible failures in and consequential actions by nonsafety systems shall not prevent the safety system from accomplishing its intended safety function. In addition, GDC 24 requires the protection system to be separated from control systems to the extent that failure of any single control system component or channel, or failure or removal from service of any single protection system component or channel, which is common to the control and protection systems, leaves intact a system satisfying all reliability, redundancy, and independence requirements for the protection system. NUREG-0800 Section 7.9 provides acceptance criteria for independence between safety and nonsafety systems to meet the requirements of IEEE Std. 603-1991, Clause 5.6.3, and GDC 24. NUREG-0800 Section 7.9 states that physical, electrical, logical, or software malfunction in one portion cannot adversely affect the safety functions of the connected system. In addition, NUREG-0800 BTP 7-11 provides acceptable methods for ensuring electrical isolation between safety and nonsafety systems. The staff evaluated each of the five cases of communication between the components within the PMS and nonsafety systems, and the PMS interface to nonsafety standalone systems, against the requirements of IEEE Std. 603-1991, Clause 5.6.3, and GDC 24. DI&C ISG #4-HICRc clarifies existing guidance on acceptable methods to meet the communications independence requirements of IEEE Std. 603-1991, Clause 5.6. Section 1 of this ISG specifies that communications between safety and nonsafety systems should adhere to the points presented in that section. The staff evaluated the safety-to-nonsafety communications scheme for each of the five cases against the criteria presented in DI&C ISG #4-HICRc. The staff's evaluation is documented below.

<u>Case A and Case B</u>

Based on the staff's evaluation of WCAP-16675 and WCAP-16674, the staff finds that the design of hardwired interfaces used to send analog and digital signals from the PMS to the PLS meets the electrical isolation and communications independence requirements of IEEE Std. 603-1991, Clause 5.6.3, and GDC 24. Specifically, the staff finds that since the signal transmission between the PMS and PLS is limited to analog and discrete digital signals, communications independence do not apply. Section 5 of WCAP-16674 qualified isolation devices are used in Case A and Case B communications to provide electrical isolation between the PMS and the PLS. As stated in Section 7.1.2.10 of the AP1000 DCD, isolation devices are used to maintain the electrical independence of divisions, and to prevent interaction between nonsafety-related systems and the safety-related system. Isolation devices are incorporated into selected interconnections to maintain division independence. Isolation devices serve to prevent credible faults (such as open circuits, short circuits, or applied credible voltages) in one circuit from propagating to another circuit. The staff finds these design criteria are consistent with the guidance of NUREG-0800 BTP 7-11. Since these design criteria have not changed from the certified Revision 15 of the AP1000 DCD to the current revision, the staff finds the use of qualified isolation devices acceptable to ensure adequate electrical isolation between the PMS and nonsafety systems. Therefore, the staff finds that the applicant has satisfied the requirements of IEEE Std. 603-1991, Clause 5.6.3, and GDC 24. In addition, in Tier 1, Chapter 2, Table 2.5.2-8 of the AP1000 DCD, the staff identified ITAAC for isolation devices from the PMS to the PLS and from the PMS to the DDS to ensure electrical isolation. Since these ITAAC were approved in Revision 15 of the AP1000 DCD, and no modifications were made in subsequent revisions, the staff finds that these ITAAC adequately verify electrical isolation between the PMS and the PLS and DDS to meet the electrical isolation requirements in IEEE Std. 603-1991, Clause 5.6.3, GDC 24.

<u>Case C</u>

The staff evaluated the description of the safety-to-nonsafety system communications in Case C against the electrical isolation requirements, and the communications and functional independence requirements, of IEEE Std. 603-1991 and GDC 24. Based on the information presented in Section 5.1.2 of WCAP-16674, the staff finds the use of one-way fiber-optical communication between the MTP and the AOI Gateway, and between the PMS and the SOE system and interface in Case C, provides adequate electrical isolation and communications independence between the PMS and the nonsafety, Ovation® network to meet the requirements of IEEE Std. 603-1991, Clause 5.6.3, and GDC 24. Specifically, the staff finds that the use of fiber-optic cable for electrical isolation is in accordance with BTP 7-11. The staff finds that communications independence is achieved in the design, since the design does not include an optical receiver on the MTP for data to traverse from the nonsafety network to the PMS. Since the communication is physically [ ] from the safety system to the nonsafety system, a failure within the nonsafety system cannot propagate to the safety system. The staff finds that the safety-to-nonsafety system communications in Case C meet the communication and functional independence requirements of IEEE Std. 603-1991, Clause 5.6.3, and GDC 24.

<u>Case D</u>

The staff evaluated the description of interconnections between the RSR and the PMS in support of nonsafety manual controls of system-level safety functions in Case D communications based on the electrical isolation and functional independence requirements of IEEE Std. 603-1991, Clause 5.6, and GDC 24. Based on the information provided in Section 5.2.1 of WCAP-16674, the staff finds that the design provides adequate electrical isolation, and communications and functional independence for manual system-level ESF actuation and manual reactor trip inputs from the RSR to the PMS to meet the requirements of IEEE Std. 603-1991, Clause 5.6.3, and GDC 24. Specifically, the staff makes the following findings:

- The use of fiber-optic cables provides adequate electrical isolation, as specified in NUREG-0800 BTP 7-11.

- Since the data flow from the RSR to the PMS is in the form of discrete digital signals (e.g., no communications protocol or handshaking), the guidance in DI&C ISG #4-HICR does not apply. The use of discrete digital signals for initiating system-level ESF actuation and reactor trip from the RSR using point-to-point fiber cabling provides adequate communications independence between the PMS and the RSR.

- The software within the PMS, which allows the discrete signals to only initiate safety functions, specifically, initiation of system-level ESF actuation and reactor trip, provides adequate functional isolation.

The staff evaluated the description of data communications between nonsafety equipment and the PMS in support of certain PMS test functions that require interlocks in Case D communications based on the electrical isolation and communications and functional independence requirements of IEEE Std. 603-1991, Clause 5.6, and GDC 24. The staff finds that the information presented in Section 5.2.1 of WCAP-16674 provides an adequate description of how electrical isolation, communications and functional independence are achieved for the inputs from nonsafety equipment to the PMS to meet the requirements in IEEE Std. 603-1991, Clause 5.6.3, and GDC 24. Specifically, the staff makes the following findings:

- Electrical isolation is provided between the PMS and nonsafety equipment through the use of an isolation device. As stated above in the evaluation of Case A and Case B communications, the isolation device serve to prevent credible faults (such as open circuits, short circuits, or applied credible voltages) in one circuit from propagating to another circuit, which is consistent with the guidance of NUREG-0800 BTP 7-11.

- Since the data flow from the nonsafety equipment to the PMS is in the form of discrete digital signals (e.g., no communications protocol or handshaking), the guidance of DI&C ISG #4-HICR does not apply. The use of discrete digital signals for activating interlocks for certain PMS tests provides adequate communications independence between the PMS and the nonsafety equipment.

- The software in the PMS allows the discrete signals to only affect the ability to perform tests. The interlocks do not affect automatic or manual safety functions.

In Tier 1, Chapter 2, Section 2.5.2, Table 2.5.2-8 of the AP1000 DCD, the staff identified ITAAC for isolation devices between the PMS and the PLS and between the PMS and the DDS to ensure electrical isolation. However, the staff did not identify any ITAAC for verifying electrical isolation between the PMS and the nonsafety equipment that will be used to activate interlocks for these PMS tests. The staff requested the applicant to provide additional information to demonstrate how the qualified isolation devices provide electrical isolation between the nonsafety equipment and the PMS. Specifically, the staff requested the applicant to provide an additional ITAAC to verify electrical isolation between the PMS and the nonsafety equipment to activate these interlocks. In its response letter, dated February 8, 2010, the applicant proposed to include an additional ITAAC in Tier 1, Chapter 2, Section 2.5.2, Table 2.5.2-8 of the AP1000 DCD. The proposed ITAAC states:

> The PMS receives signals from non-safety equipment that provide interlocks for PMS test functions through isolation devices.

The proposed acceptance criterion state:

> A report exists and concludes that the isolation devices prevent credible faults from propagating into the PMS.

The staff finds the proposed ITAAC acceptable in verifying that adequate electrical isolation exists to prevent credible faults from nonsafety equipment from impacting the PMS, and thus satisfies the requirements of IEEE Std. 603-1991, Clause 5.6.3, and GDC 24. In Revision 19 to the AP1000 DCD, the applicant added Design Commitment 7e to Table 2.5.2-8, which resolves this issue.

<u>Case E</u>

The staff evaluated the description of data communications between the CIM and the PLS in Case E, based on the electrical isolation and communications and functional independence requirements of IEEE Std. 603-1991, Clause 5.6, and GDC 24. The staff finds that the information presented in Section 5.2.2 of WCAP-16674 provides an adequate description of how the applicant achieves electrical isolation and communications and functional independence for nonsafety manual component-level control of safety components for Case E, to meet the requirements of IEEE Std. 603-1991, Clause 5.6.3, and GDC 24. Specifically, the staff makes the following findings:

- The use of fiber-optic cables between the remote I/O bus that connects the remote I/O node to the PLS provides adequate electrical isolation, as specified in NUREG-0800 BTP 7-11.

- Although the remote I/O bus uses bidirectional communications between the PLS and the remote I/O node, the communications interface of the CIM translates these data into simple discrete signals for input into the Class 1E priority logic. Since the data flow into the Class 1E priority logic is in the form of discrete digital signals (e.g., no communications protocol or handshaking), the guidance in DI&C ISG #4-HICR does not apply. The use of discrete digital signals for initiating nonsafety manual component-level control of safety components provides adequate communications independence between the CIM and the PLS.

The priority logic within the CIM provides functional isolation by ensuring that the PMS has priority to actuate the safety component, such that the nonsafety signal cannot prevent the PMS from actuating the component. If the nonsafety system initiates an actuation command without the PMS initiating an actuation command, then the safe state of the component takes priority.

IEEE Std. 603-1991 defines associated circuits as non-Class 1E circuits that are not physically separated or are not electrically isolated from Class 1E circuits by acceptable separation distance, safety class structures, barriers, or isolation devices. IEEE Std. 384-1992, Clause 5.5, includes the classification and qualification of associated circuits. IEEE Std. 384-1992, Clause 5.5.3, states that associated circuits, including their isolation devices or the connected loads without the isolation devices, shall be subject to the qualification requirements placed on Class 1E circuits to ensure that the Class 1E circuits are not degraded below an acceptable level. Associated circuits need not be qualified for performance of function, since the function is non-Class 1E. The staff finds that Section 5.2.2 of WCAP-16674 adequately demonstrates how the RNC is qualified as an associated circuit to meet the requirements of IEEE Std. 603-1991, Clause 5.6, and IEEE Std. 384-1992. Specifically, the staff finds that the commitment, as part of the overall safety-system qualification program, to demonstrate that, when the RNC is subject to environmental, electromagnetic, and seismic stressors, it does not degrade the Class 1E circuits below an acceptable level, meets the associated circuit qualification requirements in IEEE Std. 384-1992, Clause 5.5.3.

PMS Interfaces to Standalone Systems

Section 4.2.1 of WCAP-16675 provides a description of the PMS interfaces to standalone safety systems. This section states that the PMS interfaces to the standalone RMS. However, there is no interface between the safety portion of the RMS and the nonsafety portion.

In addition, the CETs used by the QDPS function of the PMS are physically housed within the IIS. There is no electrical interface between the CETs and the incore instrumentation electronics of the IIS. The CETs interface to the PMS using simple analog signals; these interfaces do not use network or datalink connections.

Based on the information provided in Section 4.2.1 of WCAP-16675 regarding PMS interfaces with standalone systems, such as the RMS, the staff finds the design adequately demonstrates compliance with the communications and functional independence requirements of IEEE Std. 603-1991, Clause 5.6.3, and GDC 24. Specifically, for the RMS, since there is no interface between the safety portion of the RMS and the nonsafety portion, communications independence does not apply. In addition, functional independence is achieved through the isolation of safety functions to only the safety portion of the RMS, and does not require interaction with the nonsafety portion to perform the intended safety functions. For the CETS used by the QDPS function of the PMS, the staff finds that since the CETS interface to the PMS using simple analog signals and these signals are Class 1E, communication independence does not apply. Since the CETS are Class 1E, the staff finds that electrical isolation between the CETS and the PMS is not required.

7.9.4 Nonsafety Communications

7.9.4.1 Description of the Nonsafety Communication Network

Nonsafety communications consist primarily of the nonsafety communication network and the nonsafety data link interface. The nonsafety communication network is implemented using the Ovation® network. This network uses unaltered Ethernet protocols, high-speed Ethernet switches, and full duplex cabling (fiber or copper shield twisted pair).

Section 3 of WCAP-16674 provides a detailed description of the AP1000 nonsafety communications system. The nonsafety communications network provides real-time data distribution and general purpose communications. Real-time data distribution is defined as the scheduled periodic broadcast of real-time data pertaining to the plant processes. The term "general purpose communications" is defined as the aperiodic exchange of data for other purposes, such as system operation, diagnostics, and maintenance.

The Ovation® network supports network standard communications protocols, such as Transmission Control Protocol/Internet Protocol and User Datagram Protocol/Internet Protocol for general purpose communications. Within the Ovation® system, general purpose communications based on standard protocols are used for aperiodic data, including file-type data transferred from the historian and plant databases to be presented at the HSI, plant informational data messages, alarm messages, and SOE messages to the plant historian for long-term historical storage. This communication occurs on the same physical media as the real-time periodic data, but it is implemented in such a way as to preserve the design philosophy of guaranteeing the real-time periodic data transmission without loss, degradation, or delay, even during plant upsets.

With respect to periodic data, the network is designed to support up to 200,000 point values per second, using a nominal percentage of the overall network bandwidth. The network load associated with periodic data origination is constant; it does not change during plant upset conditions. The Ovation® vendor has tested the network at the limit of 200,000 point values per second. A design goal is to limit the number of point values per second, to the extent possible. This will provide additional spare capacity and will result in a lower base load on the network. As the design is finalized, a firm number of point values per second will be determined. This will be used to calculate the base network load and, therefore, the network bandwidth available for aperiodic data communications. With respect to aperiodic data, the network load is variable but managed. The aperiodic data levels can be managed through careful system configuration. Alarm message data will be minimized, to the extent possible, by limiting the number of points subject to alarm checking and by carefully selecting alarm limits to minimize nuisance alarms. Network impacts associated with station staff in the main control area are somewhat limited by the number of operators and operator stations and by the number of engineers and engineering stations. In general, the network load from aperiodic data traffic is expected to be very small in relation to the overall bandwidth of the system. Analytical justification of network capacities will be reviewed for correctness. Based on the current evaluation of expected network traffic, the single network design will meet or exceed all system capacity and network loading requirements.

Storm control is configured on the Ovation® network to ensure that highway availability requirements are satisfied, given the possibility that a software or hardware malfunction, or a malicious network attack, would introduce a packet storm on the control system highway. Storm control is implemented with configuration settings provided by the switch operating system. In general, each port subject to storm control is configured with traffic ingress block and restoration settings. These values are typically a percentage of the total available bandwidth that can be used by the broadcast or multicast traffic. When traffic entering a port exceeds the predefined block value, packet forwarding on the port is blocked. Packet forwarding resumes when the traffic falls below the predefined "restore forwarding" setting. Storm control is put in place to protect the network from data storms produced as a result of atypical conditions, including hardware malfunctions, and errors introduced by humans. The thresholds are set on a per-port basis, so that native Ovation® traffic (e.g., periodic process point data, aperiodic alarm message traffic) will not activate the storm control function. In addition to the system storm control configuration installed on the network switches, the Ovation® controller has been hardened against excessive network traffic through the use of a software modification that prioritizes critical control functionality over network communications.

7.9.4.2 Evaluation of the Non-safety Communication Network

The staff evaluated the adequacy of the nonsafety Ovation® network to perform the required control functions specified in the AP1000 DCD and the supporting TRs, as well as WCAP-16675 and WCAP-16674, including how the applicant met the requirements of 10 CFR 52.47(a)(9). Regulations in 10 CFR 52.47(a)(9) require applications for light-water-cooled NPPs to evaluate the standard plant design against the NUREG-0800 revision in effect 6 months before the docket date of the application. The evaluation required by this section shall include an identification and description of all differences in design features, analytical techniques, and procedural measures proposed for the design and those corresponding features, techniques, and measures given in the NUREG-0800 acceptance criteria. NUREG-0800 Section 7.9 provides performance criteria for data communication systems; specifically, for system capacity, data rates, and bandwidth requirements. The staff finds that the description provided for system capacity, data rates, and bandwidth requirements, and the analysis on expected network traffic, presented in Section 3 of WCAP-16674, adequately address the performance criteria for data communications systems specified in NUREG-0800 Section 7.9. Specifically, the staff finds that the evaluation of expected network traffic demonstrates that the network design is bounded by the Ovation® system capacity and network loading requirements.

Specifically, the staff evaluated the nonsafety Ovation® network design features to determine how the applicant has addressed operating experience with data storm, as described in NRC Information Notice 2007-15, "Effects of Ethernet-Based, Non-Safety Related Controls on the Safe and Continued Operation of Nuclear Power Stations," dated April 17, 2007. The staff finds that the storm control features within the Ovation® network design adequately demonstrate how data storms are precluded in the Ovation® network. Specifically, the staff finds that the use of storm control configuration settings provided by the switch operating system, and the software feature that prioritizes critical control functionality over network communications, ensure that the

Ovation® controller can continue to control critical plant operations during a network storm or a complete loss-of-network event.

7.9.4.3 Description of the Non-safety Data Link Interfaces

Section 3.2 of WCAP-16674 describes the nonsafety data link interfaces in the AP1000 I&C design. Each system is summarized below.

Standalone Systems

The Ovation® system supports standard and custom data links, both at the controller and workstation level. Controller-level interfaces include standard interfaces to Allen-Bradley programmable logic controllers and GE Mark V/VI, Toshiba, and MHI turbine control systems, as well as a standard MODBUS interface and OSI PI historian interface. At the controller level, the data link interface can be accomplished via a standard I/O module (the R-line Link Controller), or via fast Ethernet communications interfaces at the controller processor level.

Remote I/O

The Ovation® system supports the use of remote I/O, so that I/O modules can be clustered close to field devices, minimizing field cabling costs and also accommodating harsher environments. Remote I/O is in contrast to local I/O, which is housed in the same cabinet as the controller or next to it in an extended cabinet. For local I/O, all I/O modules reside in up to four cabinets, which are placed side by side. All field wiring leads to these cabinets.

Non-safety Smart I/O Field Buses

The Ovation® system supports HART I/O, FOUNDATION™ Fieldbus, Prefabs DP, and DeviceNet™ smart I/O interfaces. The Ovation® fieldbus solution is modular, and a single controller can simultaneously interface to fieldbus devices, HART I/O modules, conventional I/O modules, and third-party I/O.

HART I/O

The Ovation® controller supports native HART I/O modules. HART is technology that provides a digital information signal superimposed on a 4-20 milliampere traditional sensor loop. The digitized signal provides up to four HART multivariables, which provide additional information from HART-enabled devices, eliminating additional cabling required to provide the same information using traditional sensors and control output devices.

The Ovation® HART input module has eight inputs, with each input having an individual HART modem (supporting up to four HART multivariables), and individual channel-to-channel isolation. The Ovation® HART output module has four channels, also with individual HART modems per channel, and individual channel-to-channel isolation.

Foundation Fieldbus

FOUNDATION™ Fieldbus H1 is typically used for analog devices, such as sensors and modulating control valves. A large assortment of “smart” devices is available with the interface. The Ovation® FOUNDATION™ Fieldbus solution is modular and scalable. The interface between the FOUNDATION™ Fieldbus instrumentation and the Ovation® controller is via dedicated, redundant Fieldbus Ethernet switches, and Ovation® FOUNDATION™ Fieldbus Gateways. There are up to 16 FOUNDATION™ Fieldbus gateways per controller, with up to four H1 segments per gateway and up to 16 devices per segment.

Profibus DP

Profibus DP is typically used for digital on/off devices. In addition to being supported by the appropriate devices, it is suitable for long distances while remaining less sensitive to power, grounding, polarity, and resistance concerns.

The Ovation® Profibus Interface uses a standard Ethernet switch, attached to the Ovation® controller via the controller's standard MODBUS/TCP third-party I/O capability.

DeviceNet

DeviceNet™ is an interface for discrete actuators and sensors. The Ovation® DeviceNet™ interface has the same fundamental design as the Profibus DP interface, using a standard Ethernet switch, attached to the Ovation® controller via the controller standard MODBUS/TCP third-party I/O capability.

Asset Management

Another important component of the intelligent field interface solution is the Asset Management Solutions (AMS) suite of software. AMS software and the associated SNAP-ON applications is a suite of software solutions for streamlining all maintenance activities related to instrumentation and valves in a process plant. This package can be integrated into the Ovation® workstation and Ovation® controller to give the user direct access to all intelligent devices connected to the Ovation® I/O. With AMS integrated into Ovation®, digitized HART or FOUNDATION™, Fieldbus parameters such as valve position can be mapped to Ovation® process points that can be used anywhere they are required in the Ovation® distributed control system. AMS provides direct visibility from the Ovation® workstation to each “smart” device in the plant that is connected to Ovation®.

7.9.4.4 Evaluation of the Nonsafety Data Link Interfaces

The staff evaluated the nonsafety data link interfaces within the AP1000 I&C design. IEEE Std. 603 1991, Clause 5.6.3, requires independence between safety and nonsafety systems so that credible failures in, and consequential actions by, nonsafety systems shall not prevent the safety system from accomplishing its intended safety function. In addition, GDC 24 requires the protection system to be separated from control systems to the extent that failure of any single control system component or channel, or failure or removal from service of any single protection system component or channel that is common to the control and protection systems, leaves intact a system satisfying all reliability, redundancy, and independence requirements of the protection system. These nonsafety data link interfaces do not communicate with any of the safety systems beyond the five cases of safety-to-nonsafety system data communications specified in WCAP-16674. As such, the staff finds that the electrical isolation, communications and functional independence requirements of IEEE Std. 603-1991, Clause 5.6.3, and GDC 24 do not apply.

7.9.5 Secure Development and Operational Environment

10 CFR Part 50, Appendix A, GDC 21 requires, in part, that protection systems (or safety systems) must be designed for high functional reliability commensurate with the safety functions to be performed. Criterion III of Appendix B to 10 CFR Part 50 requires, in part, that quality standards must be specified and design control measures must be provided for verifying or checking the adequacy of design.

10 CFR 50.55a(h) requires that safety systems for NPPs must meet the requirements stated in IEEE Std. 603-1991. Clause 5.6.3 of IEEE Std. 603-1991 requires safety systems to be designed, such that credible failures in and consequential actions by other systems will not prevent safety systems from performing their intended safety functions. In addition, Clause 5.9 of IEEE Std. 603-1991 requires the design to permit the administrative control of access to safety system equipment. These administrative controls shall be supported by provisions within the safety systems, by provision in the generating station design, or by a combination thereof.

RG 1.152, "Criteria for Digital Computers in Safety Systems of Nuclear Power Plants," Revision 2, provides a method that the NRC finds acceptable for complying with the Commission's regulations (i.e., 10 CFR Part 50, Appendix A, GDC 21, Criterion III of Appendix B to 10 CFR Part 50, and IEEE Std. 603-1991, Clauses 5.6.3 and 5.9) for promoting high functional reliability, design quality, and security for use of digital computers in safety systems of NPPs. Security in this context refers to the establishment of an SDOE for digital safety systems by: (i) measures and controls taken to establish a secure environment for development of the digital safety system against undocumented, unneeded and unwanted modifications; and (ii) protective actions taken against a predictable set of undesirable acts (e.g., inadvertent operator actions or the undesirable behavior of connected systems) that could challenge the integrity, reliability, or functionality of a digital safety system during operations. RG 1.152, Revision 2, utilizes the waterfall life cycle phases to provide a framework for establishing digital safety system security guidance, as well as criteria for acceptability, in the development of high quality safety systems.

As proposed in the response to Open Item OI-SRP7.1-ICE-01, Section 7.1.2.14.1 of the AP1000 DCD will be revised to reference, APP-GW-J0R-012, hereinafter referred to as the "PMS Computer Security Plan," to demonstrate how computer security is incorporated into the design and development of AP1000 safety systems. This plan provides a description of the planning phase for the AP1000 PMS. This plan summarizes the quality standards and design control measures implemented to provide computer security and ensure that the PMS and CIM are designed for high functional reliability commensurate with the safety functions to be performed throughout the development phases of digital safety system lifecycle. These commitments include the design and development of security features and development controls for the PMS and CIM. Although the PMS Computer Security Plan does not officially commit to conformance to RG 1.152, Revision 2, this TR addresses the system security aspects of the Common Q platform, PMS application, and CIM from the concepts phase through the test phase to protect against non-malicious events that is consistent with the criteria provided by RG 1.152, Revision 2.

The safety evaluation for AP1000 I&C secure development and operational environment, provides a separate assessment of the PMS Computer Security Plan and includes official use only information. This separate safety evaluation forms the basis for the following conclusions.

- The identified vulnerabilities in the PMS design for the conceptual phase of the development life cycle, and the security capabilities that mitigate these vulnerabilities adequately address Regulatory Position C.2.1 in RG 1.152, Revision 2.

- The performance of additional V&V activities for the Common Q platform satisfies the criteria for identifying and mitigating vulnerabilities as specified in Regulatory Position C.2.1 of RG 1.152, Revision 2.

- Although the vulnerabilities of the PMS and CIM development process are general, these vulnerabilities were only based on the conceptual phase assessment, and these vulnerabilities encompass more detailed vulnerabilities that may be identified in later portions of the development process. Thus, the identified vulnerabilities are acceptable in specifying particular portions of the development process that are susceptible to unintended or inadvertent modification to the PMS or CIM while under development or to the development tools. As such, the applicant has adequately addressed the criteria in Regulatory Position C.2.1 of RG 1.152, Revision 2, for the PMS application and the CIM. In addition, the quality assurance program for both the development of the PMS and the CIM, and the V&V process are adequate to mitigate the identified vulnerabilities by identifying and preventing inadvertent changes to the PMS and CIM design during development.

- By precluding capabilities for remote access to the PMS during operations in the design and by ensuring one way data flow from the PMS to nonsafety systems (except for use of discrete digital or analog signal), the applicant has satisfied Regulatory Position C.2.1 in RG 1.152, Revision 2. In addition, the commitment to ensure that the isolated development infrastructure (IDI) is created to preclude remote access is sufficient to satisfy Regulatory Position C.2.1 in RG 1.152, Revision 2.

- Based on the PMS access control functional requirements, the safety to nonsafety interfaces requirements, and the commitment to ensure that proper human factors are considered during the development of the PMS design, these requirements adequately provide sufficient measures to protect the PMS from inadvertent operator actions or unpredictable behavior of connected systems during operations to address the criterion in Regulatory Position C.2.2.1 of RG 1.152, Revision 2, to define the security functional performance requirements.

- The Common Q Platform has adequately addressed the criteria in Regulatory Position C.2.2.1 of RG 1.152, Revision 2. Specifically, the Common Q platform software V&V, as described in Section 5.5.3 of the Common Q Software Program Manual, was reviewed and accepted by the NRC in the SER for the Common Q platform SPM. This includes the approval of the V&V process for use of pre-developed software within the Common Q platform. The V&V activities that were performed on the Common Q platform are adequate to ensure the integrity, reliability, and functionality of this platform for use in the AP1000 PMS application.

- By incorporating the security requirements into the overall system requirements, the PMS V&V process in accordance with the Common Q SPM is adequate to ensure the correctness, completeness, accuracy, testability, and consistency of the system security requirements. Thus, the applicant has met the criteria in Regulatory Position C.2.2.1 of RG 1.152, Revision 2.

- Based on the described security measures provided in the IDI, the commitment to assess and mitigate vulnerabilities in the IDI, and the quality assurance and V&V process described in the PMS Computer Security Plan, the applicant has adequately ensured that undocumented code or functions are precluded in the design to meet Regulatory Position C.2.2.2 of RG 1.152, Revision 2.

- By incorporating the security features as part of the overall system design, the design process described in Section 2.3 of the PMS Computer Security Plan is adequate to ensure that the system security requirements is accurately translated into specific design configuration items to meet Regulatory Position C.2.3.1 of RG 1.152, Revision 2. In addition, the additional security assessment completed during the design phase is adequate to ensure that any vulnerability that has not been identified during earlier phases of the development life cycle is captured and that the security features chosen in the conceptual phase are adequate.

- Based on the quality assurance and V&V process described in the PMS Computer Security Plan, the staff finds that the applicant has adequately ensured that undocumented code or functions are precluded in the PMS and CIM design to meet Regulatory Positions C.2.3.2 of RG 1.152, Revision 2. This is based on control of the design document revision process, storage of design process in an accessed controlled manner, and requirements traceability to ensure that all design features are traceable to requirements specifications.

- By incorporating the security features as part of the overall system implementation, the implementation process described in Section 2.4 of the PMS Computer Security Plan is adequate to ensure that the system design is accurately transformed into code, database structures, and related machine executable representations to meet Regulatory Position C.2.3.1 of RG 1.152, Revision 2. In addition, the additional security assessment completed during the implementation phase is adequate to ensure that the security controls chosen are adequate.

- Based on the commitment to secure the IDI, to perform testing and scanning to identify undocumented code and functions, and to follow the quality assurance and V&V process described in Section 2.1.2.2 of APP-GW-J0R-012, Revision 1, the applicant has adequately ensured that undocumented code or functions are precluded in the PMS and CIM implementation to meet Regulatory Positions C.2.4.2 of RG 1.152, Revision 2.

- Based on the commitment to perform integration, system, and acceptance tests where practical and necessary on the PMS security features, including testing of the system configuration, and the performance of additional vulnerability assessments to ensure that no new vulnerabilities are identified in the PMS, the applicant has adequately addressed Regulatory Position 2.5 of RG 1.152, Revision 2.

- Based on the commitment to secure the testing environment and to test the hardware architecture, external communication devices, and configurations for unauthorized pathways that affect system integrity, the applicant has adequately addressed Regulatory Position C.2.5.2 of RG 1.152, Revision 2.

Based on the staff's conclusions on the PMS Computer Security Plan, as discussed above, the staff finds that the applicant has sufficiently addressed the criteria in Regulatory Positions C.2.1 through C.2.5 of RG 1.152, Revision 2, to meet the requirements of 10 CFR Part 50, Appendix A, GDC 21; Criterion III of Appendix B to 10 CFR Part 50; and IEEE Std. 603-1991, Clauses 5.6.3 and 5.9; as it relates to security and reliability of the PMS application and CIM. In Revision 19 to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

7.9.6 Evaluation, Findings, and Conclusions

The staff reviewed the revisions to Section 7.1 and the associated TRs of the AP1000 DCD against the regulatory requirements of a data communications system as stipulated in the guidance of NUREG-0800 Section 7.9. Below is a summary of the staff's findings.

Regulations in 10 CFR 50.55a(h) require compliance with IEEE Std. 603-1991 and the correction sheet, dated January 30, 1995. The minimum requirements that are applicable to all data communications systems are in IEEE Std. 603-1991, Clause 5.6.3. Other criteria include those in Clauses 5.4, 5.6.1, 5.7, and 5.9. The staff evaluated the data communications systems in the amendments to the AP1000 I&C systems design for conformance to the requirements of IEEE Std. 603-1991 and has the following findings:

- IEEE Std. 603-1991, Clause 5.4: This requirement has been fully satisfied, as documented in Section 7.9.3. In Table 2.5.2-8 of the AP1000 DCD, the staff identified ITAAC for the seismic, environmental, and Class 1E qualification of PMS equipment, including equipment used for data communications in the PMS.

- IEEE Std. 603-1991, Clause 5.6.1: This requirement has been fully satisfied, as documented in Section 7.9.2.3. The staff finds that the 20 criteria presented in Section 1 of DI&C ISG #4-HICRc have been satisfied in the design for interdivisional communication between divisions of the PMS.

- IEEE Std. 603-1991, Clause 5.6.3: This requirement has been fully satisfied, as documented in Section 7.9.3. The staff finds that the information presented in the AP1000 DCD and the supporting TRs have sufficiently demonstrated how independence is achieved for each of the five cases of safety and nonsafety communications.

- IEEE Std. 603-1991, Clause 5.7: This requirement has been satisfied, as documented in Section 7.9.2.5.

- IEEE Std. 603-1991, Clause 5.9: This requirement has been fully satisfied, as documented in Section 7.9.2. The AP1000 DCD and the supporting TRs have addressed how access controls are incorporated into the design of the PMS.

Regulations in 10 CFR 52.47(a)(9) require applications for light-water-cooled NPPs to evaluate the standard plant design against the NUREG-0800 revision in effect 6 months before the docket date of the application. The evaluation required by this section shall include an identification and description of all differences in design features, analytical techniques, and procedural measures proposed for the design and those corresponding features, techniques, and measures given in the NUREG-0800 acceptance criteria. NUREG-0800 Section 7.9 provides the design considerations for data communications systems, including criteria for performance and reliability considerations. The staff evaluated the data communications systems in the AP1000 DCD against the guidance provided in NUREG-0800 Section 7.9, which states that digital computer timing should be consistent with the limiting response times and characteristics of the computer hardware, software, and data communications systems. The staff found the applicant's commitment to modify the acceptance criteria in Item 11d) of ITAAC Table 2.5.2-8 in the AP1000 DCD to state "Performance of system tests and the documentation of system test results, including a response time test will be performed under maximum CPU loading to demonstrate the PMS can fulfill its response time criteria" is acceptable to address the criteria in NUREG-0800 Section 7.9 and, therefore, meets the requirements of 10 CFR 52.47(a)(9).

GDC 21 requires the protection system to be designed for high functional reliability and inservice testability, commensurate with the safety functions to be performed. Redundancy and independence designed into the protection system shall be sufficient to ensure that: (1) no single failure results in loss of the protection function; and (2) removal from service of any component or channel does not result in loss of the required minimum redundancy, unless the acceptable reliability of operation of the protection system can be otherwise demonstrated. The protection system shall be designed to permit periodic tests of its functioning when the reactor is in operation, including a capability to test channels independently to determine failures and losses of redundancy. Based on the staff's conclusions of the PMS Computer Security Plan, as discussed in Section 7.9.5 of this report, the staff finds that the applicant sufficiently addressed the criteria in Regulatory Positions C.2.1 through C.2.5 of RG 1.152, Revision 2 to meet the requirements of 10 CFR Part 50, Appendix A, GDC 21; Criterion III of Appendix B to 10 CFR Part 50; and IEEE Std. 603-1991, Clauses 5.6.3 and 5.9, as it relates to security and reliability of the PMS application and CIM. As such, the staff concludes that the AP1000 design meets the requirements of 10 CFR Part 50, Appendix A, GDC 21; Criterion III of Appendix B to 10 CFR Part 50; and IEEE Std. 603-1991, Clauses 5.6.3 and 5.9; as it relates to security and reliability of the PMS application and CIM.

GDC 24 requires the protection system to be separated from control systems to the extent that failure of any single control system component or channel, or failure or removal from service of any single protection system component or channel that is common to the control and protection systems, leaves intact a system satisfying all reliability, redundancy, and independence requirements of the protection system. Based on the review of the interfaces between the PMS and the PLS, the staff concludes that this requirement has been fully satisfied, as documented in Section 7.9.3. The staff finds that the information presented in the AP1000 DCD and the supporting TRs have sufficiently demonstrated how independence is achieved for each of the five cases of safety and nonsafety communications.

The additional detailed design information for the I&C architecture and communications results in increased standardization of this aspect of the design. Therefore, the change meets the finality criterion for changes in 10 CFR 52.63(a)(1)(vii).

APPENDIX 7.A: EVALUATION OF APP-GW-GLR-137, REVISION 0, "BASES OF DIGITAL OVERPOWER AND OVERTEMPERATURE DELTA-T (OPΔT/OTΔT) REACTOR TRIPS"

7.A.1 Introduction

This safety evaluation addresses changes made from Revision 15 to Revision 19 of the AP1000 DCD regarding a change in methodology for the thermal overtemperature delta-temperature (OTΔT) and thermal overpower delta-temperature (OPΔT) reactor trip design bases. Revision 15 of the DCD references WCAP-8745-P-A, "Design Bases for the Thermal Overpower ΔT and Thermal Overtemperature ΔT Trip Functions." This is the previously approved topical report for the analog calculation of the reactor trip functions. Revision 19 also references WCAP-8745-P-A; however, Revision 19 includes a change from an analog-based OTΔT and OPΔT design to a digital-based design with a different calculational methodology for the trip function. The basis of the setpoint calculations is unchanged from that presented in WCAP-8745-P-A, but the inputs to both margin-to-trip functions have changed. The digital-based core power indication described in APP-GW-GLR-137, Revision 1, proposes the use of density at the reactor core inlet and the enthalpy difference between the exit and inlet of the core, referred to as the "ΔT power signal," to provide a more accurate measurement of core power. The new TR also claims the setpoint functions have been simplified.

7.A.2 Evaluation

7.A.2.1 Background

RAI-SRP16-CTSB-42 requested that the applicant either submit a previously approved reference supporting the changes to the OTΔT and OPΔT trip functions or submit a reference that supports the changes. The RAI also requested that the applicant comply with generic letter (GL) 88-16, "Guidance for Technical Specification Changes for Cycle-Specific Parameter Limits," to include the appropriate and approved methodology regarding the revised trip functions in Technical Specification (TS) Section 3.3.1-1 and bases, which are addressed in Chapter 16 of this report.

The response to RAI-SRP16-CTSB-42 led to the generation of Open Item OI-SRP16-CTSB-42, since the response did not fully address the staff's request. SER Chapter 16, which is based on changes to the DCD between Revision 15 and Revision 17, references the open item.

The initial response to Open Item OI-SRP16-CTSB-42 was submitted to address staff concerns. A reference to APP-GW-GLR-137, Revision 1, was given to provide the information requested by the staff. Changes to the DCD for Revision 17 were also provided to maintain consistency between the submitted TR and the following DCD sections:

- Section 7.2.1.1.3
- Section 7.2.4
- TS Table 3.3.1, Notes 1 and 2

The staff submitted RAIs based on the review of APP-GW-GLR-137. After reviewing the responses, the staff found the information given in APP-GW-GLR-137 to be acceptable in support of the digital-based OPΔT and OTΔT reactor trip function methodology.

7.A.2.2 Proposed Change

The OPΔT and OTΔT trips are used to protect the specified acceptable fuel design limits (SAFDLs) so as to maintain the fuel in a geometry amenable to cooling. The design basis of the OTΔT trip is to prevent a departure from nucleate boiling (DNB) on all fuel surfaces, while the design basis of the OPΔT trip is to prevent excessive fuel centerline temperatures for all fuel rods.

In the analog technology of the OPΔT trip setpoint, as described in WCAP-8745-P-A, the setpoint is calculated as a function of the average coolant temperature (T_{AVG}) and a core power reduction term related to adverse axial offset. The OTΔT setpoint has the same inputs as the OPΔT trip setpoint with the addition of pressurizer pressure. The setpoints use T_{AVG}, axial offset, and pressurizer pressure (only for OTΔT) as inputs to a dynamically compensated function to determine the percent of rated thermal power (RTP) at which the reactor should trip. The analog signals are converted to ΔT signals by adjusting gains. The basis for the determination of both ΔT setpoints is derived from thermal design limits as explained in WCAP-8745-P-A.

The change from the analog technology to the digital technology is in both the reactor trip function and the RTP measurement. The analog method uses ΔT as a measure of core power, while the digital method uses actual core power. In the digital method, core power is determined by calculating an enthalpy difference between the core inlet and outlet. The inputs from the respective protection system divisions used to calculate the enthalpy terms are T_H for the outlet, T_C for the inlet, and pressurizer pressure, which is used in both terms. Core average temperature is eliminated as the major functional variable in the digital-based function.

In both the analog and digital technology, the OPΔT trip setpoint uses only a preset bias based on a percentage of RTP, which is based on pre-determined thermal limits, as discussed in WCAP-8745-P-A. This term is compared to core thermal power and then dynamically compensated to obtain a margin to trip signal.

In the proposed change to digital technology, the OTΔT trip setpoint directly translates DNB thermal design limits, which give core inlet temperature as a function of RTP for various pressurizer pressures, into inputs for the setpoint calculation. Core inlet temperature and pressurizer pressure information are linearly interpolated from a table that provides the corresponding RTP to serve as the appropriate setpoint. This setpoint is compared to the core thermal power calculation and then dynamically compensated to obtain a margin to trip signal.

7.A.2.3 Regulatory Basis

10 CFR Part 50, Appendix A, GDC 10, “Reactor Design,” states: “The reactor core and associated coolant, control, and protection systems shall be designed with appropriate margin to assure that specified acceptable fuel design limits are not exceeded during any condition of normal operation, including the effects of anticipated operational occurrences.” GDC 10, therefore, applies directly to the design of the OTΔT and OPΔT reactor trips since they are part of the reactor protection system.

Furthermore, GL 88-16 was issued to allow licensees to update all applicable cycle-specific limits without formal review by the NRC. These cycle-specific limits are now located in the core operating limits report (COLR) and are referenced throughout TS. The methodologies by which the cycle-specific limits are updated undergo a formal review by the NRC and are referenced in Section 3.3.1 and bases of the TS.

Since the applicant has revised the method by which the OPΔT and OTΔT reactor trip functions are calculated in the digital methodology, as discussed in APP-GW-GLR-137, the new methodology must be reviewed and approved by the staff. Furthermore, once the review is completed and approved, TS 3.3.1 and bases should be updated to reflect the methodologies that serve as the basis for determining the limits given in the COLR.

7.A.2.4 Evaluation

As previously discussed, all methodologies used to update limits given in the COLR must be reviewed and approved by the staff. The change in calculational methodology of the OPΔT and OTΔT reactor trip setpoints is given in APP-GW-GLR-137. The staff reviewed the document and submitted RAIs to better understand how the trip function calculations have changed and to ensure that SAFDLs will not be exceeded.

A review of the RAI responses in support of Open Item OI-SRP16-CTSB-42 closure is provided in the following discussion.

- Question 1 asks how the single failure criterion of 10 CFR 50.55a(h) is met when an individual resistance thermowell detector (RTD) in one of four divisions votes for a trip due to an approach to a saturation condition. In the response, it is stated that the single failure criteria is not impacted by an RTD in a saturated condition since the 2oo4 voting logic by division is unaffected. When a single RTD approaches saturation, it is removed from the average hot leg temperature calculation for that division. Further, it was stated that when two RTDs approach saturation, a trip vote occurs in the affected division. Based on the applicant's response, it was determined that 10 CFR 50.55a(h) has not been violated and Question 1 is resolved.

  Question 2 discusses the accuracy of the ∆T power signal and asks how the bias applied to the Thot-local signal leads to approximation of the mixed mean hot leg temperature. The concern is that the correction factor applied to the individual hot leg RTDs, which are used to calculate the average hot leg temperature, might lead to an inaccurate calculation of the ΔT power signal. The response states that the ΔT power signal is frequently calibrated, as required by TS;, consequently there is reasonable assurance that the streaming bias applied to the Thot-local signals will not affect the calculation of the ΔT power signal used in the margin to trip calculation. Based on the applicant's indication that the ΔT power signal is continuously monitored and validated, Question 2 is resolved and the applicant indicated that the TR will be updated for clarification. These changes were incorporated in a subsequent revision to the TR.

- Question 3 is related to the discussion of the redundant sensor algorithm and asks if the discussion is included in Chapter 7 of the DCD. The applicant stated that APP-GW-GLR-137, which includes the discussion, is referenced in Chapter 7 of the DCD. In Revision 19 to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

- Question 4 is concerned with how the weighted averaging of the $T_{hot\text{-}local}$ signals is performed for T_H determination. Specifically, the concern is that automatic adjustment of weighting factors might violate 10 CFR Part 50, Appendix B, Criterion III, "Design

Control." The response states that weighting factors are not changed. If one of the $T_{hot\text{-}local}$ signals is dropped from the determination of T_H, due to an approach to saturation condition, then the same weighted average is performed, only with two weighting factors instead of three. Based on the applicant's response, it is clear that the weighting factors are not adjusted and there is no violation of 10 CFR Part 50, Appendix B, Criterion III. The applicant committed to update the TR for clarification. These changes were incorporated in a subsequent revision to the TR.

- There was concern with how a failure of the core inlet temperature signal (TC) would affect the protection system. Question 5 asks how the system responds to a "BAD" quality TC signal. The response states that an alarm is actuated in the MCR to notify operators to take appropriate action. The value of the signal (e.g., failed off-scale low, failed off-scale high or otherwise) will determine whether or not a trip is voted for. Based on the applicant's response, it is clear that a failure of a TC signal will result in appropriate operator action and, therefore, Question 5 is resolved.

- To determine how the margin to trip function interfaces with the protection system bi-stable controller, Question 6 asks how the margin to trip signal feeds into the logic that generates a division trip vote and if the margin to trip signal is used elsewhere. The response states that the margin to trip signal is directly input to the trip bi-stable controller, which looks for a negative value to allow for a trip vote. The signal also goes to the MCR for alarm and display. It is also stated that the margin to trip signal is hardwired into the PLS and that the information is available for use by other systems if needed. Based on clarification of how the margin to trip signal interfaces with the protection system, Question 6 is resolved.

- Question 7 refers to the use of time constants in the TH, TC, and OPΔT and OTΔT margin to trip signal development. Clarification was requested regarding the extra lag term and also how the values of these constants differ from those in the previously approved analog methodology. The response indicates that the extra lag term is dedicated to signal noise filtering and does not affect the shape of the output signal (i.e., it is comparable to the output signal that uses a first order lag term). The TR discusses the possible factors that go into calculation of the net lead and lag constants, many of which are optional, and furthermore are determined in the plant-specific safety analysis of record to verify the adequacy of the protection system. The responses to Questions 9-11 give typical values assumed in performed analog versus digital comparative analyses. Based on the provided clarification, Question 7 is resolved.

- Question 8 refers to the use of the bias coefficient and the conversion factor used in calculating the ΔT power signal. The question asks how the constants are determined and how often they must be adjusted. The response states that the bias coefficient will be adjusted so that the ΔT power signal indicates zero at hot zero power. This action is mandatory as part of the channel calibration required by TS surveillance requirement (SR) 3.3.1.9, which requires calibration every 24 months. The conversion factor is a gain adjustment that is adjusted as necessary in compliance with SR 3.3.1.3, which requires comparing the ΔT power signal to the calorimetric power, similar to the neutron flux power range signal surveillance, every 24 hours. Based on the provided clarification, Question 8 is resolved.

- Questions 9 through 11 ask the applicant to discuss the differences between the analog and digital based dynamic response when a trip occurs. Provided in the response are the assumed time constants used in comparing the analog response to the digital response. The differences are shown in a comparative example. Additional concern was expressed with regard to the Chapter 15 design basis accidents, which credit the OPΔT and OTΔT reactor trips. It was asked if the Chapter 15 accidents were revised to include the revised digital-based reactor trip functions.

  The comparisons between the two trip responses given in response to RAI-TR36-012 show that the trip responses are similar, which provides reasonable assurance that the dynamic compensation terms applied to the digital-based method and the proposed trip functions are appropriate. It was stated that the Chapter 15 design basis accidents were not updated to reflect the digital-based functions since the comparative studies performed confirmed that the digital-based method closely simulates the analog-based method without a loss of safety margin. In Revision 19 of the DCD, the applicant replaced the analysis results in DCD Section 15.4.2 with the re-analysis results described in response to RAI-TR36-012, which were based on the same cases previously analyzed. Various parts of DCD Section 15.4.2 are revised to reflect the revised analysis and results, as shown in Table 15.4-1 and Figures 15.4.2-1 through 15.4.2-15. The revised analysis used the upgraded digital-based OTΔT reactor trip function and NRC-approved methods, including the revised thermal design procedure (RTDP) and the LOFTRAN code. The revised analysis maintains the consequential loss of offsite power occurring 3 seconds after the turbine trip. Because the AP1000 PMS design is such that turbine trip occurs 5 seconds following a reactor trip condition being reached, the loss of offsite power and the resulting RCP coastdown occur 8 seconds after the reactor trip. Since the minimum DNBR occurs immediately after the reactor trip, the loss of offsite power has no effect on the minimum DNBR results. The revised results continue to show that the DNBR does not fall below the design limit DNBR. Therefore, fuel integrity and adequate fuel cooling are maintained. The peak reactor coolant system (RCS) pressure remains less than 110 percent of the design pressure. Therefore, the revised analysis continues to meet the acceptance criteria of NUREG-0800 Section 15.4.2. Questions 9 through 11 are, therefore, resolved.

- Question 12 was asked to resolve a discrepancy between time constants reported in APP-GW-GLR-137 and those shown in Figure 7.2-1 (Sheet 5) of the DCD. An updated figure was provided with the RAI responses for consistency, and Question 12 is therefore resolved. In Revision 19 to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.

- Question 13 asked the applicant to ensure that the TS and bases are consistent with the information provided in APP-GW-GLR-137. The response states that appropriate changes are being made. In Revision 19 to the AP1000 DCD, the applicant made an appropriate change to the DCD text, which resolves this issue.
