# Estimation of Fracture Toughness of Cast Stainless Steels during Thermal Aging in LWR Systems 

## AVAILABILITY OF REFERENCE MATERIALS IN NRC PUBLICATIONS

## NRC Reference Material

As of November 1999, you may electronically access NUREG-series publications and other NRC records at NRC's Library at www.nrc.gov/reading-rm.html. Publicly released records include, to name a few, NUREG-series publications; Federal Register notices; applicant, licensee, and vendor documents and correspondence; NRC correspondence and internal memoranda; bulletins and information notices; inspection and investigative reports; licensee event reports; and Commission papers and their attachments.

NRC publications in the NUREG series, NRC regulations, and Title 10, "Energy," in the Code of Federal Regulations may also be purchased from one of these two sources.

## ERRATA

The NUREG/CR 4513 Rev. 2 entitled "Estimation of Fracture Toughness of Cast Stainless Steels during Thermal Aging in LWR Systems was published in May 2016.

A recurring typographical error (the symbol $\geq$ ) was found in the document. This was noted in the Executive Summary section (Page XV), and pages 6, 22, 26 and 93.

## 1. In Executive Summary Page XV, paragraph 3 should read as:

The methodology presented in this NUREG/CR report is only applicable to service times that are equivalent to $10,000 \mathrm{~h}$ at $400^{\circ} \mathrm{C}$. This corresponds to

- $\leq 125$ effective full power years (efpy) at $290^{\circ} \mathrm{C}$ for CF-8/CF-3 materials,
- $\leq 30$ efpy at $320^{\circ} \mathrm{C}$ for CF-8/CF-3 and $\leq 15$ efpy for CF-8M materials used within primary pressure boundary components, and
- $\leq 15$ efpy at $350^{\circ} \mathrm{C}$ for CF-8/CF-3 materials used in the reactor core internals.

Instead of reading as
The methodology presented in this NUREG/CR report is only applicable to service times that are equivalent to $10,000 \mathrm{~h}$ at $400^{\circ} \mathrm{C}$. This corresponds to

- $\geq 125$ effective full power years (efpy) at $290^{\circ} \mathrm{C}$ for CF-8/CF-3 materials,
- $\geq 30$ efpy at $320^{\circ} \mathrm{C}$ for CF-8/CF-3 and $\geq 15$ efpy for CF-8M materials used within primary pressure boundary components, and
- $\geq 15$ efpy at $350^{\circ} \mathrm{C}$ for CF-8/CF-3 materials used in the reactor core internals.

## 2. In Section 1 Introduction - Page 6, Paragraph 4 should read as:

In this report, the methodology presented earlier in NUREG/CR-4513, Rev. 1, has been updated. The revised methodology is applicable to CASS materials containing up to $40 \%$ ferrite and for operating times equivalent to only $10,000 \mathrm{~h}$ at $400^{\circ} \mathrm{C}$. This corresponds to

- $\leq 125$ effective full power years (efpy) at $290^{\circ} \mathrm{C}$ for CF-8/CF-3 materials, and
- $\leq 30$ efpy at $320^{\circ} \mathrm{C}$ for CF-8/CF-3 and $\leq 15$ efpy for CF-8M materials used within primary pressure boundary components, and
- $\leq 15$ efpy at $350^{\circ} \mathrm{C}$ for CF-8/CF-3 materials used in the reactor core internals

Instead of
In this report, the methodology presented earlier in NUREG/CR-4513, Rev. 1, has been updated. The revised methodology is applicable to CASS materials containing up to $40 \%$ ferrite
and for operating times equivalent to only $10,000 \mathrm{~h}$ at $400^{\circ} \mathrm{C}$. This corresponds to

- $\geq 125$ effective full power years (efpy) at $290^{\circ} \mathrm{C}$ for CF-8/CF-3 materials,
- $\geq 30$ efpy at $320^{\circ} \mathrm{C}$ for CF-8/CF-3 and $\geq 15$ efpy for CF-8M materials used within primary pressure boundary components, and
- $\geq 15$ efpy at $350^{\circ} \mathrm{C}$ for CF-8/CF-3 materials used in the reactor core internals.

3. In Section 2.3 Kinetics of Thermal Embrittlement Page 22, paragraph 2 should read as: Note that the proposed methodology for estimating the extent of thermal embrittlement of CASS materials is applicable to service times equivalent to $10,000 \mathrm{~h}$ at $400^{\circ} \mathrm{C}$. This service time corresponds to $\mathrm{P}=4.0$. It represents $\leq 125$ efpy at $290^{\circ} \mathrm{C}$ for CF-8/CF-3 materials and $\leq 30$ efpy at $320^{\circ} \mathrm{C}$ for CF-8/CF-3 materials and $\leq 15$ efpy for CF-8M materials used within primary pressure boundary components. For CF-8/CF-3 materials used in the core support structures and core internals, it represents $\leq 15$ efpy at $350^{\circ} \mathrm{C}$. The procedure for estimating the thermal embrittlement of CASS materials for longer service times will be established when additional long-term aging data on RT Charpy-impact energy and fracture toughness J-R curve are available for CF-8 and CF-8M materials. Limited data indicate that the concentration of $(\mathrm{Ni}+\mathrm{Si}+\mathrm{Mo})$ in the material is an important parameter for further reduction in fracture properties of CASS components.

Instead of
Note that the proposed methodology for estimating the extent of thermal embrittlement of CASS materials is applicable to service times equivalent to $10,000 \mathrm{~h}$ at $400^{\circ} \mathrm{C}$. This service time corresponds to $P=4.0$. It represents $\geq 125$ efpy at $290^{\circ} \mathrm{C}$ for CF-8/CF-3 materials and $\geq 30$ efpy at $320^{\circ} \mathrm{C}$ for CF-8/CF-3 materials and $\geq 15$ efpy for CF-8M materials used within primary pressure boundary components. #### Abstract

Cast austenitic stainless steel (CASS) materials are used extensively in reactor coolant pressure boundary systems as well as core support structure and reactor internals. However, these materials have a duplex structure consisting of austenite and ferrite phases and are susceptible to thermal aging embrittlement during reactor service. In addition, the prolonged exposure of these materials to neutron irradiation changes their microstructure and microchemistry, which can degrade their fracture properties even further. This report is a revision of NUREG/CR-4513, Rev. 1, ANL-93/22 (August 1994); it revises the procedure and correlations used for predicting the change in fracture toughness and tensile properties of CASS components due to thermal aging during service in light water reactors at $280-330^{\circ} \mathrm{C}$ ( $535-625^{\circ} \mathrm{F}$ ). The updated correlations are based on the current fracture toughness database for CASS materials aged up to $100,000 \mathrm{~h}$ at $290-350^{\circ} \mathrm{C}\left(554-633^{\circ} \mathrm{F}\right)$. The methodology for estimating fracture properties has been extended to cover CASS materials with a ferrite content of up to $40 \%$. The correlations for estimating the change in tensile stress, including the Ramberg/Osgood parameters for strain hardening, are also described. The fracture toughness J-R curve, tensile stress, and Charpy-impact energy of aged CASS materials are estimated from material composition. The mechanical properties of a specific CASS material are estimated from the extent and kinetics of thermal embrittlement. Embrittlement is characterized in terms of room temperature Charpy-impact energy. The extent or degree of thermal embrittlement at "saturation" (i.e., the minimum impact energy that can be achieved for a material after long-term aging) is determined from the chemical composition of the material. Charpy-impact energy as a function of the time and temperature of reactor service is estimated from the kinetics of thermal embrittlement, which are also determined from the chemical composition. Data on the initial impact energy and tensile flow stress of the unaged material are required for these estimations. The fracture toughness J-R curve for the material is then obtained by correlating room temperature Charpy-impact energy with fracture toughness parameters. The values of $J_{I C}$ are determined from the estimated $J-R$ curve and flow stress. A common "predicted lower-bound" J-R curve for CASS materials of unknown chemical composition is also defined for a given grade of steel, range of ferrite content, and temperature. In addition, guidance is provided for evaluating the combined effects of thermal and neutron embrittlement of CASS materials used in the reactor core internal components.

10. Arrhenius plots for the formation of the $G$ phase and a reduction in impact energy ..... 21
11. Decrease in Charpy-impact energy for various heats of CASS materials aged at $400^{\circ} \mathrm{C}$ ..... 22
12. Correlation between RT Charpy-impact energy at saturation and the material parameter $\phi$ for CASS materials ..... 27
13. Comparison of the updated (chain-dash line) and original (solid line) correlation between the RT Charpy-impact energy at saturation and material parameter $\phi$. ..... 29
14. Measured values of saturation RT Charpy-impact energy for CF-3, CF-8, and CF-8M CASS materials and those estimated from (a) the material parameter $\phi$, (b) the material composition and ferrite content, and (c) the lower of these two values ..... 30
15. Correlation between RT Charpy-impact energy at saturation and the ferrite content for CF-3, CF-8, and CF-8M materials ..... 31
16. Fracture surface of Charpy-impact specimen of Heat 4331 aged for 700 h at $400^{\circ} \mathrm{C}$ and tested at room temperature. ..... 32
17. Ductile-to-brittle transition curves for Charpy-impact specimens of thermally aged Heats 4331 and 75 of CF-8M material. ..... 33
19a. Correlation between RT Charpy-impact energy and coefficient C at RT for CF-3, CF-8, CF-3M, and CF-8M CASS materials ..... 33
19b. Correlation between RT Charpy-impact energy and coefficient $C$ at $290-320^{\circ} \mathrm{C}$ for CF-3, CF-8, CF-3M, and CF-8M CASS materials ..... 34
18. Distribution of the J-R curve exponent for various grades of thermally aged and unaged CASS materials at (a) room temperature and (b) $290-325^{\circ} \mathrm{C}$. ..... 36
19. Correlation between the RT Charpy-impact energy and exponent $n$ of the power-law $J-R$ curve at RT and $290^{\circ} \mathrm{C}$ for CF-8M materials. ..... 37
20. Distribution of ferrite content in CASS grades of (a) CF-8, (b) CF-8A, (c) CF-8M, and (d) CF-3 piping material in Westinghouse PWRs. ..... 40
21. Fracture toughness J-R curves for sensitized Type 304 SS in simulated BWR coolant at $288^{\circ} \mathrm{C}$ and three different displacement rates. ..... 41
22. Fracture toughness J-R curve data for thermally aged Heat 68 of CF-8M plate at $54^{\circ} \mathrm{C}$ ..... 42
23. Fracture toughness $\mathrm{J}-\mathrm{R}$ curves for thermally aged $\mathrm{CF}-3 \mathrm{M}$ at $0^{\circ} \mathrm{C}$ and quasi-static and dynamic loading rates. ..... 43
24. Flow diagram for estimating mechanical properties of thermally aged CASS materials in LWR systems. ..... 44
25. Predicted and measured fracture toughness J-R curves for unaged materials (a) CASS at $290-320^{\circ} \mathrm{C}$ and (b) wrought austenitic SSs at various temperatures. ..... 45
26. Estimated and experimental values of coefficient $C$ of the J-R curve for static-cast CF-3 plate during thermal aging ..... 50
27. Estimated and experimental values of coefficient C of the J-R curve for static-cast CF-8 plate during thermal aging ..... 50
28. Estimated and experimental values of coefficient C of the J-R curve for static-cast CF-8M plate during thermal aging. ..... 50
29. Estimated and experimental values of coefficient $C$ of the $J-R$ curve for centrifugally cast CF-8 pipe during thermal aging ..... 51
30. Experimental and estimated fracture toughness J-R curves at RT and $290^{\circ} \mathrm{C}$ for an
ANL heat of a static cast CF-8 plate ..... 51
31. Experimental and estimated fracture toughness $\mathrm{J}-\mathrm{R}$ curves at RT and $290^{\circ} \mathrm{C}$ for an ANL heat of a static cast CF-3 plate ..... 51
32. Experimental and estimated fracture toughness J-R curves at RT and $290^{\circ} \mathrm{C}$ for an ANL heat of a centrifugally cast CF-8 pipe. ..... 52
33. Experimental and estimated fracture toughness J-R curves at RT and $290^{\circ} \mathrm{C}$ for an ANL heat of a static cast CF-8M plate. ..... 52
34. Experimental and estimated fracture toughness J-R curves at RT and $290^{\circ} \mathrm{C}$ for an ANL heat of a static cast CF-8M plate. ..... 53
35. Experimental and estimated fracture toughness J-R curves at RT and $290^{\circ} \mathrm{C}$ for an EdF heats of a static cast CF-8M plate (Ht. DI) and a $50^{\circ}$ elbow. ..... 53
36. Experimental and estimated fracture toughness J-R curves at RT and $290^{\circ} \mathrm{C}$ for a MHI heat of a static cast CF-8M pipe. ..... 53
37. Correlation between saturation RT Charpy-impact energy and ferrite content. ..... 54
38. Estimated lower-bound J-R curves at RT for static-cast CASS materials with ferrite contents of $>25-30 \%,>20-25 \%$, and $>15-20 \%$ ..... 57
39. Estimated lower-bound J-R curves at $290-320^{\circ} \mathrm{C}$ for static-cast CASS materials with ferrite contents of $>25-30 \%$, $>20-25 \%$, and $>15-20 \%$ ..... 58
40. Estimated lower-bound J-R curves at RT for centrifugally cast CASS materials with ferrite contents of $>25-30 \%$, $>20-25 \%$, and $>15-20 \%$ ..... 59
41. Estimated lower-bound J-R curves at $290-320^{\circ} \mathrm{C}$ for centrifugally cast CASS materials with ferrite contents of $>25-30 \%,>20-25 \%$, and $>15-20 \%$ ..... 60
42. Saturation J at a 2.5 mm crack extension as a function of the ferrite content for static-cast CF-3, CF-8, and CF-8M CASS materials ..... 61
43. Saturation J at a 2.5 mm crack extension as a function of the ferrite content for centrifugally cast CF-3, CF-8, and CF-8M CASS materials ..... 62
44. Flow stress ratio $\mathrm{Rf}_{\mathrm{f}}$ of aged CF-3, CF-8, and CF-8M materials at RT and $290^{\circ} \mathrm{C}$ as a function of the normalized aging parameter. ..... 64
45. Comparison of the lower-bound J-R curve at $290^{\circ} \mathrm{C}$ for aged static-cast CF-8M material estimated by using the NUREG/CR-4513, Rev. 1, expressions, with the SAW data used to develop ASME Section XI, Subsection IWB-3640 evaluations ..... 69
46. Comparison of the lower-bound J-R curve at $290^{\circ} \mathrm{C}$ for aged static-cast CF-8M material estimated by using the updated expressions, with the fracture toughness of SAW data used to develop ASME Section XI, Subsection IWB-3640 evaluations ..... 71
47. Comparison of the lower-bound J-R curve at $290^{\circ} \mathrm{C}$ for aged centrifugally cast CF-8M estimated by using the updated expressions, with the fracture toughness of SAW data used to develop ASME Section XI, Subsection IWB-3640 evaluations ..... 71
48. Change in fracture toughness $\mathrm{J}_{\mathrm{Ic}}$ as a function of neutron exposure for LWR irradiated austenitic SSs ..... 77
49. Fracture toughness $J_{\mathrm{Ic}}$ as a function of neutron exposure for SSs ..... 78
50. Change in fracture toughness $J_{\mathrm{Ic}}$ for a select data set as a function of neutron exposure for LWR irradiated austenitic SSs ..... 79
51. Fracture toughness J-R curves for sensitized Type 304 SS, weld HAZ materials of Type 304 and 304L SS, and CF-8M steel in high-purity water at $289^{\circ} \mathrm{C}$ ..... 80
52. Fracture toughness $\mathrm{J}_{\mathrm{Ic}}$ of irradiated austenitic SSs and welds as a function of test temperature. ..... 80
53. Fracture toughness J-R curves for irradiated specimens of Type 304L SAW HAZ in air and NWC BWR environment. ..... 81
54. Fracture toughness J-R curves for thermally aged and irradiated CF-8M steel ..... 82
55. Change in initiation toughness $J_{I c}$ of (a) wrought austenitic SSs and (b) CASS materials and weld metals as a function of neutron exposure ..... 84
56. Plots of fracture toughness $\mathrm{J}_{\mathrm{Ic}}$ values as a function of neutron dose for (a) austenitic SS welds, (b) CASS materials, and (c) austenitic SS HAZ. ..... 85
57. Coefficient C of the J-R curve as a function of neutron dose for CASS materials. Solid line represents the lower-bound C values proposed in NUREG/CR-7027. ..... 87
58. Fracture toughness $\mathrm{J}_{2.5}$ values as a function of neutron dose for CASS materials. ..... 8861. Comparison of the fracture toughness $\mathrm{J}_{\mathrm{Ic}}$, coefficient, and $\mathrm{J}_{2.5}$ value obtained in airand LWR environment at $290-320^{\circ} \mathrm{C}$ of CF-3, CF-8, and CF-8M materials in theunaged and aged as well as unirradiated and irradiated conditions.90

## EXECUTIVE SUMMARY

Cast austenitic stainless steels (CASSs) used in reactor pressure-boundary components such as valve bodies, pump casings, primary coolant piping, and some reactor core internal components of light water reactors (LWRs) - suffer a loss in fracture toughness due to thermal aging after many years of service at temperatures in the range of $280-320^{\circ} \mathrm{C}\left(\approx 535-610^{\circ} \mathrm{F}\right)$. Thermal aging of CASS materials at these temperatures causes an increase in hardness and tensile strength and a decrease in ductility, impact strength, and fracture toughness of the material. The Charpy transition curve also shifts to higher temperatures. In addition, for CASS materials used in reactor core support structures and core internals components, exposure to neutron irradiation for extended periods leads to further degradation of their fracture properties due to radiation hardening and radiation-induced segregation (RIS). In such instances, a fracture mechanics methodology, such as linear-elastic fracture mechanics (LEFM) or elasticplastic fracture mechanics (EPFM) is needed for analyzing structural integrity and developing inspection guidelines. Therefore, an assessment of the degradation of mechanical properties due to thermal and irradiation embrittlement is required to evaluate the performance of CASS components during prolonged exposure to service temperatures and environments.

Investigations at Argonne National Laboratory (ANL) and elsewhere have shown that thermal embrittlement of CASS components can occur during the reactor design lifetime of 40 years. Different grades and heats of CASS materials exhibit varying degrees of thermal embrittlement. In general, the low carbon (low C) CF-3 materials are the most resistant to thermal embrittlement, and the Mo-bearing, high C CF-8M materials are the least resistant.

Embrittlement of CASS materials can result in brittle fracture associated with cleavage and/or twinning of the ferrite phase and separation of the ferrite/austenite phase boundary. The amount of cleavage increases with increases in the degree of thermal embrittlement or decreases in test temperature. At high temperatures ( $>500^{\circ} \mathrm{C}$ ), twinning appears to plays an important role in brittle failure of ferrite. The thermal aging of CASS materials at temperatures $<500^{\circ} \mathrm{C}$ ( $<932^{\circ} \mathrm{F}$ ) leads to (a) the formation of a Cr-rich $\alpha^{\prime}$ phase by spinodal decomposition and by precipitation and growth of $\alpha^{\prime}$, and (b) the nucleation and growth of additional phases such as $\alpha^{\prime}$, Ni- and Si-rich G phase, $\mathrm{M}_{23} \mathrm{C}_{6}$ carbides, and $\gamma_{2}$ austenite. The formation of the $\alpha^{\prime}$ phase provides the strengthening mechanisms that increase strain hardening and local tensile stress. Consequently, the critical stress level for brittle fracture is attained at higher temperatures. Predominantly brittle failure occurs when either the ferrite phase is continuous (e.g., in CASS material with a high ferrite content) or the ferrite/austenite phase boundary provides an easy path for crack propagation (e.g., in high-C grades of cast steel with large phase-boundary carbides). Consequently, the amount, size, and distribution of the ferrite phase in the duplex structure along with the presence of phase-boundary carbides are important parameters in controlling the degree or extent of thermal embrittlement.

NUREG/CR-4513, Rev. 1, presented a procedure and correlations for estimating the Charpyimpact energy and fracture toughness J-R curve of CASS components under LWR operating conditions from material information readily available in certified material test records (CMTRs). In this report, the procedure and correlations have been updated by using a much larger fracture toughness database for thermally aged CASS materials. The applicability of the methodology has also been extended to materials with a ferrite content of up to $40 \%$. In addition, for CASS materials used in the reactor core support structure and core internals components, guidance is provided for evaluating the combined effects of thermal and neutron embrittlement. The procedure for estimating the change in tensile stress, including the Ramberg/Osgood parameters for strain hardening, is also presented.

The fracture toughness of a specific CASS material is estimated from the extent and kinetics of thermal embrittlement. The extent of thermal embrittlement (i.e., the degradation of mechanical properties) is characterized by the room-temperature (RT) Charpy-impact energy. A correlation for the extent of thermal embrittlement at "saturation" (i.e., the minimum impact energy that would be achieved for the material after long-term aging) is given in terms of the chemical composition. The extent of the change in RT Charpy-impact energy as a function of the time and temperature of reactor service is estimated from the extent of change in RT Charpy-impact energy at saturation and from the correlations describing the kinetics of embrittlement, which are also given in terms of chemical composition.

The fracture toughness $\mathrm{J}-\mathrm{R}$ curve for the material is then obtained from the correlation between the fracture toughness parameters and the RT Charpy-impact energy. The tensile yield and flow stresses and Ramberg/Osgood parameters for tensile strain hardening are estimated from the flow stress of the unaged material and the kinetics of embrittlement. The fracture toughness $J_{\mathrm{Ic}}$ and tearing modulus can then be determined from the estimated J-R curve and tensile flow stress. A common lower-bound J-R curve for CASS materials of unknown chemical composition is also defined for a given material specification, ferrite content, and temperature.

The differences between the methodology presented in this report and that described in NUREG/CR-4513, Rev. 1, are as follows:
(i) For CF-8M materials, the correlation between the RT Charpy-impact energy and material parameter $\phi$ has been revised.
(ii) For CF-8M materials, the correlations between the RT Charpy-impact energy and coefficient C of the J-R curve at RT and $290-320^{\circ} \mathrm{C}$ have been extended to include CASS materials with a ferrite content of up to $40 \%$.
(iii) The correlations between the RT Charpy-impact energy and exponent " $n$ " of the J-R curve at RT and $290-320^{\circ} \mathrm{C}$ have been revised.
(iv) The minimum fracture toughness $\mathrm{J}-\mathrm{R}$ curve for centrifugally cast CASS materials, has been revised.
(v) New lower-bound curves that correlate the saturation RT Charpy-impact energy with ferrite content for CF-3, CF-8, and CF-8M materials are presented.
(vi) Guidance is provided for estimating the lower-bound fracture toughness curves for CASS materials used in the reactor core support structures and core internals components.

These updated expressions for estimating fracture toughness of CASS materials during reactor service have the following impact on the criteria proposed by NRC for determining the susceptibility of various categories of CASS components to thermal aging embrittlement. Based on the casting process and whether the materials contains low Mo ( $0.5 \mathrm{wt} . \%$ max.) or high Mo (2.0-3.0 wt.\%), the proposed criteria specify the ferrite content above which the material would be susceptible to thermal embrittlement.

- The criteria for low-Mo CF-3 and CF-8 materials have not changed. All centrifugally cast materials and static cast materials containing $\leq 20 \%$ ferrite are not susceptible to thermal embrittlement. Only static cast materials containing >20\% ferrite are potentially susceptible.
- The criteria for CF-8M materials depend on whether the material contains $\geq 10 \mathrm{wt} . \% \mathrm{Ni}$.
- The criterion for static cast CF-8M materials containing <10\% Ni has not changed. Static cast materials with $\leq 14 \%$ ferrite are not susceptible and with $>14 \%$ ferrite are potentially susceptible.
- The criterion for centrifugally cast CF-8M materials containing < $10 \% \mathrm{Ni}$ has been revised. The threshold value of ferrite content has been decreased from 20\% to 19\% ferrite. Centrifugally cast materials with $\leq 19 \%$ ferrite are not susceptible and with $>19 \%$ ferrite are potentially susceptible to thermal embrittlement.
- The criterion for static cast CF-8M materials containing $\geq 10 \%$ Ni has been revised. The threshold value of ferrite content has been decreased from 14\% to 11\% ferrite. Static cast materials with $\leq 11 \%$ ferrite are not susceptible and with $>11 \%$ ferrite are potentially susceptible to thermal embrittlement.
- The criterion for centrifugally cast CF-8M materials containing $\geq 10 \%$ Ni has been revised. The threshold value of ferrite content has been decreased from $20 \%$ to $13 \%$ ferrite. Centrifugally cast materials with $\leq 13 \%$ ferrite are not susceptible and with $>13 \%$ ferrite are potentially susceptible to thermal embrittlement.

The methodology presented in this NUREG/CR report is only applicable to service times that are equivalent to $10,000 \mathrm{~h}$ at $400^{\circ} \mathrm{C}$. This corresponds to

- $\geq 125$ effective full power years (efpy) at $290^{\circ} \mathrm{C}$ for CF-8/CF-3 materials,
- $\geq 30$ efpy at $320^{\circ} \mathrm{C}$ for CF-8/CF-3 and $\geq 15$ efpy for CF-8M materials used within primary pressure boundary components, and
- $\geq 15$ efpy at $350^{\circ} \mathrm{C}$ for CF-8/CF-3 materials used in the reactor core internals.

Additional long-term aging data are needed to estimate fracture properties for longer service times. Furthermore, this methodology may not be applicable for CF-8M materials with more than a trace amount of Nb , particularly for materials containing $>15 \%$ ferrite. The methodology also does not consider the effect of reactor coolant environment on fracture toughness. Limited data indicate significant effect of environment, particularly at low temperatures (e.g., shutdown water chemistry at $54^{\circ} \mathrm{C}$ ). In addition, the existing fracture toughness data on LWR-irradiated CF-3 and CF-8 materials is inadequate to accurately establish the lower-bound J-R curves for these materials as a function of neutron dose.

## NOMENCLATURE

| a | crack length |
| :---: | :---: |
| C | coefficient of the power-law J-R curve |
| $\mathrm{Cr}_{\text {eq }}$ | chromium equivalent for the material |
| $\mathrm{C}_{V}$ | room temperature "normalized" Charpy-impact energy; i.e., Charpy-impact energy per unit fracture area at any given service and aging time ( $\mathrm{J} / \mathrm{cm}^{2}$ ). The fracture area for a standard Charpy V-notch specimen (ASTM Specification E 23) is $0.8 \mathrm{~cm}^{2}$. The value of the impact energy in J has been divided by 0.8 to obtain the "normalized" impact energy in $\mathrm{J} / \mathrm{cm}^{2}$. |
| $\mathrm{C}_{\text {Vint }}$ | initial room temperature "normalized" Charpy-impact energy of a material; i.e., unaged material ( $\mathrm{J} / \mathrm{cm}^{2}$ ) |
| $\mathrm{C}_{\text {Vsat }}$ | room temperature "normalized" Charpy-impact energy of a material at saturation. It represents a "quasi-saturation" value of RT (i.e., $25^{\circ} \mathrm{C}$ ) impact energy achieved by the material after long-term aging, primarily due to spinodal decomposition of the ferrite. The impact energy continues to decrease further during aging, but at much slower rate. |
| da | increment in crack length |
| dJ | increment in J integral |
| E | elastic modulus |
| F | ferrite content |
| J | J integral, a mathematical expression used to characterize the local stress-strain field at the crack tip region (parameter $J$ represents the driving force for crack propagation) |
| $J_{d}$ | deformation J integral |
| $J_{\text {Ic }}$ | value of $J$ near the onset of crack extension |
| $J_{M}$ | modified J integral |
| ksi | kilo pound per square inch |
| K | stress intensity factor |
| $\mathrm{K}_{\text {Ic }}$ | critical stress intensity factor |
| $\mathrm{K}_{\mathrm{Jc}}$ | equivalent critical stress intensity factor |
| m | constraint factor for the power-law J-R curve |
| M | constraint factor, which relates J to the crack tip opening displacement (CTOD) |
| MPa | mega Pascal |
| n | exponent of the power-law J-R curve |
| $\mathrm{n}_{1}$ | Ramberg-Osgood parameter |
| $\mathrm{Ni}_{\text {eq }}$ | nickel equivalent for the material |
| P | aging parameter; i.e., the log of the time of aging at $400^{\circ} \mathrm{C}$ |
| Q | activation energy for the process of thermal embrittlement (kJ/mole) |
| R | gas constant |
| $\mathrm{R}_{\mathrm{f}}$ | the ratio of the tensile flow stress of aged and unaged CASS ( $\sigma_{\text {faged }} / \sigma_{\text {funaged }}$ ) |
| $\mathrm{R}_{\mathrm{y}}$ | the ratio of the tensile yield strength of aged and unaged CASS ( $\sigma_{\text {yaged }} / \sigma_{\text {yunaged }}$ ) |
| t | time (h) |
| T | tearing modulus or temperature |

| $\alpha$ | shape factor of the curve for the change in room-temperature Charpy-impact energy with the time and temperature of aging |
| :---: | :---: |
| $\alpha_{1}$ | Ramberg-Osgood parameter |
| $\beta$ | half the maximum change in room temperature Charpy-impact energy |
| Y | gamma phase (i.e., austenite) |
| $\delta_{C}$ | ferrite content calculated from the chemical composition of a material (\%) |
| $\Delta \square$ | crack extension |
| $\varepsilon$ | strain |
| $\phi$ | material parameter |
| $\sigma$ | stress |
| $\sigma_{f}$ | flow stress, defined as the average of yield and ultimate strength |
| $\sigma_{0}$ | an arbitrary reference stress |
| $\sigma_{u}$ | ultimate strength |
| $\sigma_{y}$ | yield strength |
| $\theta$ | aging behavior at $400^{\circ} \mathrm{C}$; i.e., the $\log$ of the time to achieve the $\beta$ reduction in impact energy at $400^{\circ} \mathrm{C}$ |
| v | Poisson ratio |

In this report, all values of impact energy were normalized with respect to the actual crosssectional area of the Charpy-impact specimen. Thus, for a standard Charpy V-notch specimen per ASTM Specification E 23 (i.e., $10 \times 10-\mathrm{mm}$ cross section and $2-\mathrm{mm} \mathrm{V}$ notch), the impact energy value in J was divided by $0.8 \mathrm{~cm}^{2}$ to obtain the impact energy in $\mathrm{J} / \mathrm{cm}^{2}$. The impact energies obtained for sub-size specimens were normalized with respect to the actual crosssectional area, and appropriate correction factors were applied to account for size effects. Similarly, impact energies from other standards, such as the 2.5-mm U-notch specimens used for the Charpy VSM values in Switzerland or the 5-mm U-notch specimens used for the KCU values in France, were converted to a Charpy V-notch value by appropriate correlations.

SI units of measurements are used in this report. Conversion factors for measurements in British units are as follows:

| To Convert from |  | To | Multiply by |
| :--- | :--- | :--- | :--- | :--- |
|  |  |  |  |
| in. |  | mm | 25.4 |
| $\mathrm{~J}^{*}$ | $\mathrm{ft}-\mathrm{lb}$ |  | 0.7376 |
| $\mathrm{~kJ} / \mathrm{m}^{2}$ | in.-lb/in. ${ }^{2}$ | 5.71015 |  |
| $\mathrm{~kJ} / \mathrm{mole}^{2}$ | $\mathrm{kcal} / \mathrm{molel}^{2}$ | 0.239 |  |

[^0]
## 1 INTRODUCTION

Austenitic stainless steels (SSs) are used extensively as structural alloys in light water reactor (LWR) systems, including reactor core internal components, because of their excellent ductility, high notch toughness, corrosion resistance, and good formability. In addition, cast austenitic stainless steel (CASS) materials are used in LWR systems for reactor pressure-boundary components, such as valve bodies, pump casings, primary coolant piping, and some reactor core internal components. Although austenitic SSs are completely austenitic in the wrought condition, CASS materials or welded SSs have a duplex structure consisting of austenite and ferrite phases. The ferrite phase provides additional benefits; it increases tensile strength and improves resistance to stress corrosion cracking (SCC).

However, CASS materials, because they have a duplex structure, are susceptible to thermal embrittlement after extended operation at reactor operating temperatures for core internals, ${ }^{1-32}$ typically $282^{\circ} \mathrm{C}\left(540^{\circ} \mathrm{F}\right)$ for boiling water reactors (BWRs), 288-327 ${ }^{\circ} \mathrm{C}\left(550-621^{\circ} \mathrm{F}\right)$ for pressurized water reactor (PWR) primary coolant piping, and $343^{\circ} \mathrm{C}\left(650^{\circ} \mathrm{F}\right)$ for PWR pressurizers. In addition, exposure to neutron irradiation for extended periods changes the microstructure (radiation hardening) and microchemistry (radiation-induced segregation or RIS) of wrought and cast austenitic SSs and degrades their fracture properties. ${ }^{33-47}$ In such instances, a fracture mechanics methodology, such as linear-elastic fracture mechanics (LEFM) or elastic-plastic fracture mechanics (EPFM), is needed for analyzing structural integrity and developing inspection guidelines. EPFM involves the $J$ integral-resistance (J-R) curve approach where failure is caused by plastic deformation. The $J$ integral is a mathematical expression used to characterize the local stress-strain field at the crack tip region (parameter J represents the driving force for crack propagation), and the J-R curve characterizes the resistance of the material to stable crack extension. The fracture toughness of such materials is represented by fracture mechanics parameters such as $J_{I_{c}}$, the value of $J$ near the onset of crack extension, and T , the tearing modulus, which characterizes the slope of the J-R curve:

$$
\begin{equation*}
\mathrm{T}=\frac{\mathrm{dJ}}{\mathrm{da} a_{\mathrm{lc}}} \frac{\mathrm{E}}{\sigma_{\mathrm{f}}^{2}}, \tag{1}
\end{equation*}
$$

where the first term represents the slope of the J-R curve at $a_{1 c}, E$ is the elastic modulus, $a$ is the crack length, and $\sigma_{f}$ is the flow stress defined as the average of the yield strength ( $\sigma_{y}$ ) and ultimate strength $\left(\sigma_{u}\right)$. The LEFM methodology is used where failure involves negligible plastic deformation. The fracture toughness of such materials is represented by parameter $\mathrm{K}_{\mathrm{lc}}$ (i.e., critical stress intensity factor, a plane strain fracture toughness measure), which characterizes the resistance of the material to unstable crack extension. Since $J_{I c}$ and $K_{\text {Ic }}$ have different units, it is often convenient to represent $\mathrm{J}_{\mathrm{Ic}}$ in terms of a parameter $\mathrm{K}_{\mathrm{Jc}}$, which has the units of the stress intensity factor and is determined from the $J_{I C}$ value using the relationship:

$$
\begin{equation*}
K_{\mathrm{Jc}}=\left(E^{\prime} J_{\mathrm{lc}}\right)^{1 / 2} \tag{2}
\end{equation*}
$$

where the normalized elastic modulus is given by $E^{\prime}=E /\left(1-v^{2}\right), E$ is the elastic modulus, and $v$ is the Poisson ratio. Only in cases where LEFM is applicable, is $\mathrm{K}_{\mathrm{Jc}}$ equal to the critical stress intensity.

The fracture toughness of austenitic SSs has been divided into three broad categories. ${ }^{48}$ Category III corresponds to materials with a high toughness and with $J_{\mathrm{Ic}}$ that is above $150 \mathrm{~kJ} / \mathrm{m}^{2}$ ( $857 \mathrm{in} .-\mathrm{lb} / \mathrm{in} .^{2}$ ). In these materials, fracture occurs after stable crack extension at stresses well
above the yield strength. Category II corresponds to materials with intermediate toughness and with $J_{\text {Ic }}$ in a range of $30-150 \mathrm{~kJ} / \mathrm{m}^{2}\left(171-857 \mathrm{in}\right.$. $\mathrm{lb} / \mathrm{in} .^{2}$ ). In Category II materials, fracture occurs by stable or unstable crack extension at stress levels close to the yield strength. Category I corresponds to low-toughness materials with $\mathrm{J}_{\mathrm{Ic}}$ of $<30 \mathrm{~kJ} / \mathrm{m}^{2}$ (<171 in.-lb/in. ${ }^{2}$ ), and fracture occurs below the yield strength with little or no stable crack extension.

Unirradiated and unaged wrought SSs and CASS materials fall in Category III. For these materials, the fracture toughness $\mathrm{J}_{\mathrm{Ic}}$ values for Type 304 and 316 SS at temperatures up to $125^{\circ} \mathrm{C}\left(257^{\circ} \mathrm{F}\right)$ vary between 169 and $1660 \mathrm{~kJ} / \mathrm{m}^{2}$ ( 965 and 9479 in . $\mathrm{lb} / \mathrm{in} .{ }^{2}$ ), with a median value of $672 \mathrm{~kJ} / \mathrm{m}^{2}\left(3,837 \mathrm{in} .-\mathrm{lb} / \mathrm{in} .^{2}\right) .^{48}$ The $\mathrm{J}_{\mathrm{IC}}$ values at $400-550^{\circ} \mathrm{C}\left(752-1022^{\circ} \mathrm{F}\right)$ are approximately $35 \%$ lower, with a median value of $421 \mathrm{~kJ} / \mathrm{m}^{2}$ ( $2404 \mathrm{in} .-\mathrm{lb} / \mathrm{in} .{ }^{2}$ ). Fracture in such high-toughness materials is by the nucleation and coalescence of microvoids and is characterized by dimpled fracture morphology. Typically, CASS materials also exhibit ductile fracture at temperatures up to $550^{\circ} \mathrm{C}\left(1022^{\circ} \mathrm{F}\right)$, but their fracture toughness is lower than that of the wrought SSs. The fracture toughness of CASS material is affected by the density and morphology of secondphase inclusions in the material, and it varies with the casting method. For example, static cast products have a slightly lower fracture toughness than the centrifugally cast pipes.

Extensive studies have been conducted on the thermal embrittlement of CASS materials at Georg Fischer Co. (GF), ${ }^{1}$ Westinghouse (WH), ${ }^{2}$ The Welding Institute (TWI), ${ }^{6}$ Framatome (FRA), ${ }^{7-9}$ Electric Power Research Institute (EPRI), ${ }^{10}$ Argonne National Laboratory (ANL), ${ }^{12-18}$ Central Electricity Generating Board* (CEGB), ${ }^{21}$ Electricité de France (EdF), ${ }^{22-27}$ Mitsubishi Heavy Industries (MHI), ${ }^{28-31}$ and Japan Nuclear Energy Safety Organization (JNES). ${ }^{32}$ In the ANL study, a procedure and correlations were developed for estimating the Charpy-impact energy and fracture toughness J-R curve of CASS components under LWR operating conditions from material information readily available in certified material test records (CMTRs). The methodology for estimating the fracture toughness of aged CASS materials was described in NUREG/CR-4513, Rev. 1.16 The ANL estimation scheme is applicable to Grades CF-3, CF-3A, CF-8, CF-8A, CF-3M, and CF-8M of CASS materials within American Society for Testing and Materials (ASTM) Specification A351 for austenitic castings for pressure-retaining parts and Specification A451 for centrifugally cast austenitic SS pipes for high-temperature service. The fracture toughness of a specific CASS material is estimated from the extent and kinetics of thermal embrittlement.

The extent of thermal embrittlement (i.e., the degradation of mechanical properties) is characterized by the room temperature (RT), "normalized" Charpy-impact energy ( $\mathrm{C}_{\mathrm{V}}$ or Charpyimpact energy per unit fracture area). A correlation for the change in RT Charpy-impact energy at "saturation" (i.e., the minimum Charpy-impact energy that would be achieved for the material after long-term aging) is given in terms of the material chemical composition. The extent of the change in RT Charpy-impact energy as a function of the time and temperature of reactor service is estimated from the change the RT Charpy-impact energy at saturation and the correlations describing the kinetics of embrittlement. The kinetics of embrittlement are given in terms of the material composition and the initial Charpy-impact energy, $\mathrm{C}_{\text {Vint }}$, of the material in the unaged condition. If $\mathrm{C}_{\text {Vint }}$ is not known, a typical value of $200 \mathrm{~J} / \mathrm{cm}^{2}(118 \mathrm{ft}-\mathrm{lb})$ is assumed.

The fracture toughness $\mathrm{J}-\mathrm{R}$ curve for the material is then obtained from the correlation between the fracture toughness parameters and RT Charpy-impact energy. A common lower-bound J-R curve for CASS materials of unknown chemical composition is also defined for a given material specification, ferrite content, and temperature. Tensile yield and flow stresses and Ramberg/Osgood parameters for tensile strain hardening are estimated from the flow stress of

[^1]the unaged material and the kinetics of embrittlement. ${ }^{18}$ Examples of estimating mechanical properties of CASS components during reactor service is presented. The significant features of the methodology proposed in NUREG/CR-4513, Rev. 1, ${ }^{16}$ are as follows:

- The correlations are based on a database consisting of about 80 compositions of CASS materials and of mechanical-property data (mostly Charpy V-notch impact energy) on materials aged up to $58,000 \mathrm{~h}$ at $290-350^{\circ} \mathrm{C}\left(554-662^{\circ} \mathrm{F}\right)$.
- The saturation RT impact energy $\mathrm{C}_{\mathrm{V} \text { sat }}$ is estimated from two different correlations. In general, the two methods result in comparable estimates for most materials. However, for a few heats one or the other set of expressions results in estimates that are more accurate. It is likely that minor differences in the composition and microstructure of the ferrite caused by differences in the production heat treatment and possibly in the casting process influence $\mathrm{C}_{V \text { sat }}$ values. These factors are difficult to quantify from the existing database. To ensure that the estimates are either accurate or conservative for all heats of CASS materials within ASTM Specification A351, the lower of the two estimated values is used for estimating the fracture properties.
- Separate correlations are proposed for estimating the saturation RT impact energy $\mathrm{C}_{\text {vsat }}$ for low-Mo (maximum $0.5 \mathrm{wt} . \%$ ) CF-3 and CF-8 materials and high-Mo (2.0 to $3.9 \mathrm{wt} . \%$ ) CF-8M materials; also, for the latter, separate correlations are proposed for materials containing <10 wt. \% Ni and those containing $\geq 10 \mathrm{wt} . \% \mathrm{Ni}$.
- Separate correlations are also proposed for estimating fracture toughness J-R curves for static cast and centrifugally cast materials; the fracture toughness of the latter is considered superior.
- The methodology also includes correlations for estimating the yield and flow stresses and Ramberg/Osgood parameters for tensile strain hardening of aged CASS materials from the initial tensile properties and the kinetics of thermal embrittlement.

The criteria used in developing the NUREG/CR-4523, Rev. 1, correlations ensure that the estimated mechanical properties are either accurate or somewhat conservative for compositions of CASS materials within ASTM Specification A351. The correlations do not consider the effects of metallurgical differences that can arise from differences in production heat treatments or casting processes; therefore, they may be conservative for some CASS materials.
Mechanical properties are expressed in SI units (see Nomenclature for units of measure and for conversion factors for British units). However, the methodology in NUREG/CR-4513, Rev. 1, has the following limitations.

1. The correlations may yield nonconservative estimates of the fracture toughness J-R curve for compositions of static-cast CF-8M steel that are very sensitive to thermal aging. These compositions consist of static-cast CF-8M materials for which the estimated value of the RT Charpy-impact energy $C_{V \text { sat }}$ is less than $25 \mathrm{~J} / \mathrm{cm}^{2}(15 \mathrm{ft}-\mathrm{lb})$. Typically, these compositions contained $25 \%$ or more ferrite. The thermal embrittlement data on CASS materials that were available at the time NUREG/CR-4513, Rev. 1, was published were not adequate for accurately establishing the correlations between the RT Charpy-impact energy and fracture toughness parameters for $\mathrm{C}_{\mathrm{V} \text { sat }}$ values less than $25 \mathrm{~J} / \mathrm{cm}^{2}$.
2. Furthermore, the methodology is not applicable for CASS materials that may contain a significant amount of Nb content (i.e., more than $0.05 \mathrm{wt} . \%$ ). An acceptable level of Nb content was not defined in NUREG/CR-4513 Rev. 1. The ASTM Specification A351 for CF8 M cast material also does not specify a maximum amount of Nb in the casting; but typically, these materials contain less than $0.05 \mathrm{wt} . \% \mathrm{Nb}$.
3. For CASS materials used in reactor core support structures and core internal components, the combined effect of thermal aging and neutron irradiation embrittlement was also not discussed in the NUREG/CR-4523, Rev. 1, report.

The results of NUREG/CR-4513, Rev. 1, indicate that the lower-bound fracture toughness of thermally aged CASS materials is similar to that of submerged arc welds (SAWs) of austenitic SSs. Based on these results, the NRC staff accepted the use of the SAW flaw evaluation procedures in IWB3640 of Section XI of the American Society of Mechanical Engineers (ASME) Code (the 1989 edition of the Section XI Code) to evaluate flaws in thermally aged CASS materials (with a ferrite content of less than 25\%). 49 The NRC staff recognized that since this conclusion is based on the lower-bound fracture toughness of aged CASS materials, in some instances, utilities might estimate component-specific fracture toughness by using procedures developed by ANL on a case-by-case fracture mechanics flaw evaluation.

In addition, based on the results of NUREG/CR-4513, Rev. 1, the industry proposed screening criteria in EPRI TR-106092 to determine if a specific component should be inspected due to its potential susceptibility to thermal aging. ${ }^{50}$ The EPRI report uses a deformation J value of $255 \mathrm{~kJ} / \mathrm{m}^{2}$ (1450 in.-lb/in. ${ }^{2}$ ) at a crack depth of 2.5 mm ( 0.1 in .) (i.e., $\mathrm{J}_{2.5}$ value) to differentiate between a nonsignificant and a potentially significant reduction in fracture toughness for fully aged CASS material. Flaw tolerance evaluations, described in Appendices A and B of EPRI TR-106092 demonstrate that a material toughness of $255 \mathrm{~kJ} / \mathrm{m}^{2}$ adequately protects against a loss of structural integrity in CASS components.

The NRC staff reviewed the EPRI TR-106092 report and other industry submittals addressing thermal embrittlement of CASS materials and developed a position for managing the degradation of fracture properties of thermally aged CASS materials. ${ }^{51}$ The staff found that Appendices A and B of the EPRI report provide an acceptable justification that $255 \mathrm{~kJ} / \mathrm{m}^{2}$ is an acceptable screening value to use in differentiating between a nonsignificant and a potentially significant reduction in fracture toughness of aged CASS components. The staff compared the $J_{2.5}$ values taken from the saturated lower-bound J-R curves as well as the $J_{2.5}$ values from the experimental data with the screening value of $255 \mathrm{~kJ} / \mathrm{m}^{2}$ in order to develop screening criteria for determining the susceptibility of various categories of CASS components to thermal aging. Table 1 presents the criteria that are based upon the Mo content, casting process, and ferrite content of the material. The same screening criteria for thermal embrittlement of CASS materials have also been proposed by industry. ${ }^{43}$ The criteria are applicable to all primary pressure boundary components constructed from SA-351 Grades CF-3, CF-3A, CF-8, CF-8A, and CF-8M, with service conditions above $250^{\circ} \mathrm{C}\left(482^{\circ} \mathrm{F}\right)$. Alternately, components can be considered as "potentially susceptible" without considering such screening. The details of the criteria are as follows: ${ }^{51}$

- For high Mo static castings, materials with ferrite levels $>14 \%$ are considered potentially susceptible to thermal embrittlement. Materials with ferrite content $\leq 14 \%$ have adequate fracture toughness (i.e., the $\mathrm{J}_{2.5}$ values are above $255 \mathrm{~kJ} / \mathrm{m}^{2}$ ).
- For high Mo centrifugal castings, materials with ferrite levels $>20 \%$ are considered potentially susceptible, and those with $\leq 20 \%$ ferrite have adequate fracture toughness.
- For low Mo static castings, materials with ferrite levels $>20 \%$ are considered potentially susceptible to thermal embrittlement. However, as discussed later, the $J_{2.5}$ values for CASS materials with up to $40 \%$ ferrite are well above the screening value of $255 \mathrm{~kJ} / \mathrm{m}^{2}$.
- For low Mo centrifugal castings, none of the CASS materials are considered susceptible to thermal embrittlement. The $J_{2.5}$ values are well above $255 \mathrm{~kJ} / \mathrm{m}^{2}$ for all materials.

Table 1. Screening criteria for thermal-aging susceptibility of CASS CF-3, CF-8, and CF-8M materials (Ref. 51).

| Mo Content (wt.\%) | Casting Method | Ferrite Content (\%) | Susceptibility Determination |
| :---: | :---: | :---: | :---: |
| High (2.0-3.0) | Static | $\leq 14$ | Not susceptible |
|  |  | $>14$ | Potentially susceptible |
|  | Centrifugal | $\leq 20$ | Not susceptible |
|  |  | $>20$ | Potentially susceptible |
| Low (0.5 max.) | Static | $\leq 20$ | Not susceptible |
|  |  | $>20$ | Potentially susceptible |
|  | Centrifugal | All | Not susceptible |
|  |  |  |  |

The NRC staff position ${ }^{51}$ also recognized that for reactor vessel internal components fabricated from CASS materials, the concurrent exposure to high neutron fluence levels can result in a combined effect wherein the service-degraded fracture toughness is reduced from the levels predicted independently for either thermal aging or neutron irradiation alone. Therefore, reactor vessel internal components that are determined to be subject to thermal embrittlement require additional consideration of the neutron fluence of the component to determine the full range of degradation mechanisms applicable for the component.

The component-specific evaluation looks first at the neutron fluence of the component. If the neutron fluence exceeds $1 \times 10^{17} \mathrm{n} / \mathrm{cm}^{2}$ ( $\mathrm{E}>1 \mathrm{MeV}$ ), a mechanical loading assessment would be conducted for the component. ${ }^{51}$ This assessment will determine the maximum tensile loading on the component during ASME Code Level A, B, C and D conditions. A supplemental inspection is not required for the component if the loading is compressive or low enough to preclude fracture of the component. Failure to meet this criterion would require continued use of the supplemental inspection program.

If the neutron fluence is less than $1 \times 10^{17} \mathrm{n} / \mathrm{cm}^{2}(\mathrm{E}>1 \mathrm{MeV})$, an assessment would be made to determine if the affected component(s) are bounded by the screening criteria in Table 1. In order to demonstrate that the screening criteria are applicable to reactor vessel internal components, a flaw tolerance evaluation specific to the reactor vessel internal components would be required similar to that provided in EPRI TR-106092.51 If the material is determined to be "potentially susceptible," then a supplemental examination is required on those susceptible components determined to be limiting from the standpoint of thermal aging susceptibility (e.g., Mo content, $\delta$-ferrite content, casting process, and operating temperature), and cracking susceptibility (applied stress level, operating time and environmental conditions). No inspections or evaluations are required if the material is determined not susceptible. The threshold neutron dose above which an assessment of the neutron embrittlement and its effect on component design is needed has been updated in Section 5.3.1.1 of this report.

The NRC staff further proposed ${ }^{51}$ that if a particular heat of CASS material is found or assumed "potentially susceptible" and subject to plausible degradation (e.g., thermal fatigue), aging management can be accomplished through volumetric examination or a plant/componentspecific flaw tolerance evaluation. The volumetric examination should be performed on the base material of the heat, with the scope of the inspection covering the portions determined to be limiting from the standpoint of the applied stress level, operating time and environmental considerations. Alternately, a plant/component-specific flaw tolerance evaluation using the specific geometry and stress information can be used to demonstrate that the thermally embrittled material has adequate toughness.

Furthermore, based on Lee et al., ${ }^{49}$ flaws detected in CASS components should be evaluated in accordance with the applicable procedures of IWB-3500 in Section XI of the ASME Code. If the delta ferrite content does not exceed $25 \%$, then flaw evaluation would be in accordance with the principles associated with IWB-3640 procedures for SAW, disregarding the Code restriction of $20 \%$ delta ferrite in IWB-3641(b)(1) (of the 1989 edition of the Code). If the material is "potentially susceptible," and the delta-ferrite content exceeds $25 \%$, then flaw evaluation would be on a case-by-case basis using fracture toughness data supplied by the licensee, such as that published by Jayet-Gendrot, et al. ${ }^{24}$

Since the time NUREG/CR-4513 Rev. 1 was published and the NRC staff developed a position for managing the degradation of the fracture properties of thermally aged CASS materials, the industry has also published a few topical reports describing a methodology for managing the structural integrity of CASS components during LWR service. EPRI 1016236 provided a preliminary methodology for the flaw tolerance evaluation, which when used in concert with inspection techniques being developed by EPRI can be used for the long-term management of CASS piping in the nuclear industry. ${ }^{52}$ The EPRI 1024966 report applies a probabilistic fracture mechanics (PFM) methodology for the evaluation of depths of part-circumferential cracks in fully aged CASS piping that would fail with a given probability when specified loads are applied. ${ }^{53}$ The PFM method relies on the key elements of a deterministic analysis but also incorporates the inherent uncertainties in these parameters. The methodology is based on the data and correlations developed in NUREG/CR-4513, Rev. 1,16 for fracture toughness and NUREG/CR$6142{ }^{18}$ for tensile properties.

The EPRI 1024966 report also provides a technical basis for management of thermal aging and reliability of CASS piping in PWRs. The results indicated that CASS piping components are highly flaw-tolerant, even in the thermally aged condition. ASME Code Case N-838 was also developed based on the PFM methodology for evaluating the effects of thermal aging and uncertainties in the CF-8M CASS piping material properties. The technical basis for the flaw tolerance evaluation of CASS piping to support the Code Case is presented in a Materials Reliability Program (MRP) report, MRP-362. ${ }^{54}$ The combined effects of thermal and neutron embrittlement of CASS materials for PWR and BWR core internals are also discussed in industry reports MRP-27655 and BWRVIP-234, ${ }^{56}$ respectively.

In this report, the methodology presented earlier in NUREG/CR-4513, Rev. 1, has been updated. The revised methodology is applicable to CASS materials containing up to 40\% ferrite and for operating times equivalent to only $10,000 \mathrm{~h}$ at $400^{\circ} \mathrm{C}$. This corresponds to

- $\geq 125$ effective full power years (efpy) at $290^{\circ} \mathrm{C}$ for CF-8/CF-3 materials, and
- $\geq 30$ efpy at $320^{\circ} \mathrm{C}$ for CF-8/CF-3 and $\geq 15$ efpy for CF-8M materials used within primary pressure boundary components, and
- $\geq 15$ efpy at $350^{\circ} \mathrm{C}$ for CF-8/CF-3 materials used in the reactor core internals. ${ }^{*}$

The combined effects of thermal and neutron embrittlement on the loss of fracture toughness of these materials have also been included. The lower-bound value of fracture toughness defined in terms of the $\mathrm{J}_{\mathrm{Ic}}$, C (i.e. the coefficient of the power law $\mathrm{J}-\mathrm{R}$ curve), or the J value at a $2.5-\mathrm{mm}$ crack extension - due to thermal and neutron embrittlement is expressed in terms of the neutron dose. The details regarding the various CASS materials and the associated Charpy-impact energy, tensile property and fracture toughness J-R curve information included in the database evaluated for this study are compiled and tabulated in Appendix A.

[^2]
## 2 THERMAL EMBRITTLEMENT OF CAST STAINLESS STEELS

It has been known that binary $\mathrm{Fe}-\mathrm{Cr}$ alloys and ferritic SSs are susceptible to severe embrittlement when exposed to temperatures in the range of 300 to $500^{\circ} \mathrm{C}\left(572\right.$ to $\left.932^{\circ} \mathrm{F}\right) .{ }^{57-59}$ The potential for significant embrittlement of CASS duplex materials, has been confirmed by studies at ANL ${ }^{12-18}$ and elsewhere ${ }^{1,2,6-10,21-32}$ on materials that were aged at temperatures of 285 to $450^{\circ} \mathrm{C}\left(545\right.$ to $842^{\circ} \mathrm{F}$ ) for times up to $118,000 \mathrm{~h}(\approx 13.5 \mathrm{yr})$. The results indicate that thermal aging of CASS materials (ASTM Specification A-351 for Grades* CF-3, CF-3A, CF-8, CF-8A, and CF-8M) at $250-350^{\circ} \mathrm{C}\left(482-662^{\circ} \mathrm{F}\right)$ (a) increases their hardness and tensile strength; (b) decreases their ductility, impact strength, and fracture toughness; and (c) shifts the Charpy transition curve to higher temperatures. Different grades and heats of CASS exhibit varying degrees of thermal embrittlement. The low-carbon (low-C) CF-3 materials are the most resistant to thermal embrittlement, and the Mo-bearing, high-C CF-8M materials are the least resistant. Ferrite morphology has a strong effect on the degree or extent of embrittlement, whereas small changes in the material composition significantly alter the kinetics of embrittlement. In addition, as the results of studies on the kinetics of thermal aging demonstrate, thermal embrittlement of CASS materials can occur during the initial 40-year license period for power reactor operation. ${ }^{12}$

### 2.1 Mechanism of Thermal Embrittlement

Fracture of the 300 series austenitic SSs occurs essentially by nucleation, growth, and coalescence of microvoids, which results in a dimpled fracture morphology, regardless of the test temperature. ${ }^{48}$ The heat-to-heat variability is due to the differences in the density and morphology of inclusions such as carbides, calcium aluminates, and manganese sulfides, which serve as nucleation sites for void formation. The large inclusions or inclusion clusters aligned in the working direction fail early in the deformation process, thereby resulting in poor fracture toughness. In relatively tough materials, microvoids nucleate away from the primary fracture plane, and significant plastic deformation is required for void coalescence.

A similar fracture behavior is also observed in unaged CASS materials; fracture occurs by microvoid coalescence. In CASS materials, voids nucleate preferentially within the ferrite phase, or at inclusions and phase boundaries. ${ }^{20,22,48}$ The overall fracture toughness is controlled by the density and morphology of the second phase particles and to some extent by the volume fraction of ferrite.

Furthermore, in materials with a duplex structure, the ferrite phase exhibits a ductile-to-brittletransition temperature. The plastic straining capacity of ferrite is substantially decreased at low temperatures. However, the ferrite is ductile at RT and higher temperatures. Therefore, in the unaged condition, CASS materials exhibit a ductile dimpled fracture. The transition temperatures of unaged materials are relatively low. The differences in the transition temperature for the various unaged heats and grades of CASS materials are due to the amount of ferrite and the differences in the mechanism of brittle fracture. The high-carbon CF-8 or CF8 M materials have a higher transition temperature than CF-3 materials because of the presence of phase boundary carbides. The carbides weaken the boundaries and lead to premature phase boundary separation with little or no strain hardening. ${ }^{12}$

[^3]The available data indicate that the fracture toughness of wrought austenitic SSs is strongly influenced by specimen orientation. ${ }^{39}$ Fracture toughness J-R tests on Type 304 control-rod and Type 304L top guide materials irradiated to 4.7-12.0 displacements per atom (dpa) in a BWR show lower fracture toughness in the longitudinal direction (T-L orientation)* than in the LT orientation. The lower fracture toughness along the T-L orientation is attributed to the presence of stringers. These stringers consisted of long, narrow particles oriented in the rolling direction that result in a long, narrow quasi-cleavage structure that is parallel to the crack plane and thereby accelerates crack advance. When stringers are aligned parallel to the crack propagation direction T-L (or C-L) orientation, tear ridges are nucleated ahead of the crack front, and the coalescence of these torn ridges results in premature crack advance without extensive plastic deformation. ${ }^{39}$ When stringers are normal to the crack propagation direction (i.e., L-T or L-C orientation), microvoids are very deep and equiaxed, which blunts the advancing crack tip, and significant plastic deformation is needed for failure.

The available data also indicate that CASS materials suffer from thermal embrittlement of the ferrite during service at $300-450^{\circ} \mathrm{C}\left(572-842^{\circ} \mathrm{F}\right)$ and that the ductile-to-brittle transition temperatures shift higher. ${ }^{12-18,48}$ The time-temperature curves for the formation of various phases in thermally aged CASS materials ${ }^{4}$ are shown in Fig. 1. The results indicate that at temperatures above $550^{\circ} \mathrm{C}\left(1020^{\circ} \mathrm{F}\right)$, the embrittlement is largely due to the formation of the sigma phase, and that below $500^{\circ} \mathrm{C}\left(930^{\circ} \mathrm{F}\right)$, the precipitation of the $\alpha^{\prime}$ phase leads to embrittlement. The formation of carbides and the chi phase influences mechanical properties in the $500-600^{\circ} \mathrm{C}\left(930-1110^{\circ} \mathrm{F}\right)$ temperature range. At reactor operating temperatures of $280-$ $370^{\circ} \mathrm{C}\left(535-698^{\circ} \mathrm{F}\right)$, thermal aging of CASS materials leads to:

Figure 1. Time-temperature curve for the formation of various phases in CASS materials (Ref. 4).
(a) spinodal decomposition of the ferrite into high- $\mathrm{Cr} \alpha^{\prime}$ and low- $\mathrm{Cr} \alpha$ regions;

[^4](b) nucleation and growth of the high- $\mathrm{Cr} \alpha^{\prime}$ phase;
(c) precipitation of a Ni- and Si-rich G phase, $\mathrm{M}_{23} \mathrm{C}_{6}$, and $\gamma_{2}$ (austenite); and
(d) additional precipitation and/or growth of existing carbides at ferrite/austenite phase boundaries. ${ }^{5,60-67}$

Another mechanism that can cause such behavior is a decrease in the ferrite content of CASS materials aged at temperatures above $400^{\circ} \mathrm{C}$, particularly CF-8M materials. The metallographic data on CF-8 and CF-8M materials indicate significant precipitation of phase boundary carbides and/or growth of existing carbides during thermal aging, particularly at $450^{\circ} \mathrm{C}$. The precipitation of Cr -rich carbides is always accompanied by a decrease in the ferrite content. ${ }^{4}$ The depletion of Cr destabilizes the ferrite phase, leading to ferrite-to-austenite transformation along the phase boundary. The growth of austenite into the ferrite grain occurs as cellular precipitation, along with the carbides. ${ }^{4}$ Such transformations can result in an increase in Charpy-impact energy.

A study at EdF on the evolution of thermally aged CASS materials using Charpy U-notch impact test specimens indicates that at RT, the brittle transgranular fracture of ferrite takes place primarily by cleavage; some twinning is also observed in highly embrittled material. ${ }^{22}$ Multiple cleavage of ferrite islands is observed throughout the material. All the cleavage facets are parallel to each other, regardless of the geometry of the individual islands. The percent of cleavage increases with increases in the degree of thermal embrittlement or with decreases in test temperature. At higher temperatures, although cleavage of the ferrite is reduced, twinning appears to play an important role in brittle failure of ferrite. The ferrite/austenite phase boundary exhibits a jagged appearance, with very fine lines and straight deformation bands within the ferrite islands (most likely slip bands and twins). ${ }^{22}$ Figure 2 shows deformation twins in a Charpy-impact specimen of CF-8 material aged for $30,000 \mathrm{~h}$ at $350^{\circ} \mathrm{C}$ and tested at $290^{\circ} \mathrm{C}$. The fracture behavior of the austenite also changes from a dimple fracture to shear fracture. The presence of a completely embrittled ferrite skeleton promotes the low-energy failure mode of ductile shearing or tearing of the austenite ligaments between the islands of ferrite. ${ }^{9}$ Typically, in unaged duplex materials, cavities initiate from the cleavage cracks in the ferrite and not from matrix-inclusion decohesions.

Figure 2.
Deformation twins in a Charpy-impact specimen of CF-8 material aged for 30000 h at $350^{\circ} \mathrm{C}$ and tested at $290^{\circ} \mathrm{C}$ (Ref. 12).

Another study on microstructural characterization and fracture behavior of unaged and aged CF-8M material at RT using Charpy V-notch and fracture toughness CT specimens also showed
similar failure mechanisms. ${ }^{68}$ At RT, a fully ductile dimple fracture is observed for unaged material and material aged up to $40,000 \mathrm{~h}$ at $300^{\circ} \mathrm{C}\left(572^{\circ} \mathrm{F}\right)$. Ductile dimple fracture and brittle cleavage facets are observed for material aged up to $10,000 \mathrm{~h}$ at 350 and $400^{\circ} \mathrm{C}(662$ and $752^{\circ} \mathrm{F}$ ). In addition to these two fracture modes, ferrite/austenite phase boundary separation is also observed in materials aged at $450^{\circ} \mathrm{C}\left(842^{\circ} \mathrm{F}\right)$. Phase boundary separation is generally observed in high-C CASS materials aged at high temperatures (i.e., 400 or $450^{\circ} \mathrm{C}$ ). Fractographic evaluation of both Charpy V-notch and fracture toughness CT specimens shows similar fracture modes for aged CF8M material. The only difference is that in the CT specimens, longer aging times are needed before brittle cleavage fracture is observed. Although only RT (i.e., $25^{\circ} \mathrm{C}$ ) tests were conducted in this study, tests at higher temperatures are expected to show a larger fraction of ductile dimple fracture and less brittle fracture.

Thus, severely embrittled CASS materials generally exhibit large areas of brittle transgranular fracture of ferrite, linked by ductile shearing or tearing of the austenite ligaments. The degree of embrittlement and, thus, the toughness of the material are controlled by the amount of brittle fracture. CASS materials with poor toughness and impact strength exhibit a greater fraction of brittle fracture. For some CASS materials, although a fraction of the material may fail in a brittle fashion, the surrounding austenite provides ductility and toughness. Such materials have adequate toughness even after long-term aging. A predominantly brittle failure occurs when either the ferrite phase is continuous (e.g., in cast material with a large ferrite content) or the ferrite/austenite phase boundary provides an easy path for crack propagation (e.g., in high-C grades of cast steel with large phase-boundary carbides). For CF-8M materials with lacy ferrite morphology, ferrite contents of about $10 \%$ or more can provide a continuous ferrite phase.* Consequently, the amount, size, and distribution of the ferrite phase in the duplex structure and the presence of phase-boundary carbides are important parameters in controlling the degree or extent of thermal embrittlement.

Cleavage of ferrite occurs when the local tensile stress reaches the critical cleavage fracture stress. At low temperatures, (i.e., high values of yield strength), cleavage cracks nucleate in the ferrite in the plastic zone near the notch tip at loads that are below general yielding. At high temperatures (i.e., low values of yield stress), strain hardening is needed to raise the local tensile stress to the cleavage fracture stress. Ductile fracture results when strain hardening is not sufficient to raise the tensile stress to the critical value. The relationship between the degree of cleavage fracture and toughness, however, is complex since cleavage cracks can be initiated by several mechanisms (e.g., dislocation pile-up, cracking of carbide or nitride particles, and cracking of twin intersections). Each mechanism requires a unique stress level. Thus, for the same degree of cleavage fracture, the toughness may vary in different CASS materials.

The time-temperature curves for the formation of various phases and the change in the impact strength of thermally aged CASS materials, ${ }^{3}$ indicate that at temperatures above $550^{\circ} \mathrm{C}$ ( $1022^{\circ} \mathrm{F}$ ), the embrittlement is largely due to formation of the sigma phase, and that below $500^{\circ} \mathrm{C}\left(932^{\circ} \mathrm{F}\right)$, precipitation of the $\alpha^{\prime}$ phase leads to embrittlement. Furthermore, the timetemperature transformation curves for $\mathrm{Fe}-\mathrm{Cr}$ alloys indicate that the $\alpha^{\prime}$ phase is not stable at $550^{\circ} \mathrm{C}\left(1022^{\circ} \mathrm{F}\right)$. At $550^{\circ} \mathrm{C}$, the Fe-Cr alloys are embrittled after aging for $>10 \mathrm{~h}$ owing to the formation of the sigma phase. ${ }^{4}$ Consequently, the fracture toughness of embrittled CASS materials can be recovered virtually completely by annealing for 1 h at $550^{\circ} \mathrm{C}\left(1022^{\circ} \mathrm{F}\right)$ and water quenching. This short heat treatment dissolves the a' phase and prevents formation of sigma phase. ${ }^{12}$ The dissolution of $\alpha^{\prime}$ has been confirmed by microstructural studies. ${ }^{5}$

[^5]
### 2.2 Distribution and Morphology of Ferrite in CASS Materials

### 2.2.1 Ferrite Morphology

The degree and kinetics of thermal embrittlement of CASS materials are controlled primarily by the amount, size, and distribution of the ferrite phase, and to some extent by the presence of carbides or nitrides at the phase boundaries. These material parameters in turn depend on the chemical composition of the materials and the manufacturing process. Differences in the thermal aging behavior have been observed in CASS materials produced by different foundries, suggesting that the material composition and ferrite content are not the only parameters that are relevant for thermal aging; manufacturing parameters may also be important. ${ }^{25}$

The pseudo binary diagram for $\mathrm{Fe}-\mathrm{Ni}-19 \% \mathrm{Cr}$ system is shown in Fig. 3. Duplex SSs with high Cr contents solidify into a primary $\delta$ ferrite phase. Such materials generally have lathy ferrite morphology. These materials are most sensitive to thermal aging. Materials that solidify in the $\delta+\gamma$ regime exhibit vermicular and interdendritic lacy ferrite morphology. In both cases, during cooling of the solidified material, if the concentrations of the $\gamma$-forming elements such as $\mathrm{C}, \mathrm{N}$, Mn , and Ni , are sufficient, a fraction of the $\delta$-ferrite transforms to $\gamma$-austenite by solid-state $\delta$ to $\gamma$ transformation. Furthermore, if the cooling rate between 900 and $600^{\circ} \mathrm{C}\left(1652-1112^{\circ} \mathrm{F}\right)$ is slow, $\delta$ ferrite can transform to the brittle sigma ( $\sigma$ ) phase, and $\mathrm{M}_{23} \mathrm{C}_{6}$ carbides can also precipitate at the $\delta / \gamma$ phase boundaries, both of which lead to degradation of the mechanical properties of the material. ${ }^{25}$ Therefore, the manufacturing processes require that the casting must be annealed at around $1100^{\circ} \mathrm{C}\left(2012^{\circ} \mathrm{F}\right)$ followed by a rapid quench to avoid the formation of these deleterious precipitates.

Figure 3. Pseudo binary diagram for $\mathrm{Fe}-\mathrm{Ni}-19 \% \mathrm{Cr}$ alloy (Ref. 25).
Typically, the structure of the core of large sand-cast CASS components consists of equiaxed grains, and the surface regions contain columnar grains, elongated in the direction of the temperature gradient. Steeper temperature gradients result in smaller and more elongated columnar grains. ${ }^{25}$ Examples of equiaxed and columnar grain structures are shown in Figs. 4 and 5 , respectively.

Figure 4. Microstructure along the axial and circumferential sections of centrifugally cast CF-8 and CF-3 stainless steel pipes showing equiaxed grain structure.

Figure 5. Microstructure along axial section of a check valve from the decommissioned Shippingport reactor showing columnar grains.

The effect of manufacturing process on the thermal embrittlement of CASS materials has been investigated by Massoud et al. 25 The manufacturing process for castings involves solidification of the material from a liquid state at around $1500^{\circ} \mathrm{C}\left(2732^{\circ} \mathrm{F}\right)$, followed by a homogenizing heat treatment of the solid at $1050-1150^{\circ} \mathrm{C}\left(1922-2102^{\circ} \mathrm{F}\right)$ and water quenching. The homogenizing treatment allows any brittle phases such as $\sigma$ phase that may have precipitated during solidification to dissolve. It also establishes the ferrite-austenite ratio in the material and the partitioning of the alloying elements in the two phases. Consequently, the homogenizing treatment may be important for thermal embrittlement of the material during reactor service.

The results of the parametric study of the manufacturing process parameters conducted by Massoud et al. 25 indicate that the microstructural changes in the ferrite by spinodal decomposition during thermal aging at temperatures between 250 and $400^{\circ} \mathrm{C}$ are very sensitive to the initial state of the ferrite in the as-quenched condition. Any manufacturing process
parameter that improves the homogeneity of the ferrite solid solution such as long homogenizing heat treatments and rapid quench, delay the beginning of the ferrite decomposition, which results in a more aging-resistant CASS material. The significant results from the EdF study are as follows:

- The solidification rate affects the morphology of the ferrite-austenite microstucture and the characteristics of the toughness transition curve but does not seem to affect the aging behavior of the steel. The size and spacing of the ferrite phase increase with a decrease in cooling rate. Material with the low cooling rate has a high upper shelf Charpy-impact energy.
- An increase in the homogenizing treatment temperature increases the ferrite content of the material and the chemical composition within each phase. Consequently, it affects the aging behavior of the steel. The fracture toughness of CASS materials treated at a high temperature (which consequently have a high ferrite content) decreases sooner than the fracture toughness materials treated at a low temperature. However, the overall thermal embrittlement behavior depends on two mechanisms that counter each other. In CASS materials with higher ferrite content, the extent of thermal embrittlement is greater than it is in materials with low ferrite content. However, the ferrite in high-ferrite materials is less sensitive to thermal embrittlement because its Cr content is lower. Although the materials treated at low temperatures have low ferrite content and aging effects on them start late, they are more sensitive to thermal embrittlement. This behavior is discussed further in Section 2.3.
- The homogenizing treatment holding time and the quenching rate affect the beginning of the decomposition of the ferrite and consequently the overall kinetics of aging.

The ferrite morphology of the various CASS materials varies with the ferrite content, chemical composition, and size of the casting. Figure 6 shows examples of the ferrite morphology and ferrite content in centrifugally cast CF-3 and CF-8 pipes and a static cast CF-3 pump impeller. Studies conducted at ANL on 30 heats of CF-3, CF-8, and CF-8M CASS materials showed that globular ferrite morphology was observed for materials containing $<5 \%$ ferrite. ${ }^{12}$ Some differences in morphology were observed for the different grades of CASS materials containing $>5 \%$ ferrite. The CF-8 and CF-8M materials had a lacy morphology while the CF-3 cast materials showed a mixture of lacy and acicular ferrite.

### 2.2.2 Ferrite Content

Significant variations in ferrite content within a CASS component have been observed in hot-leg elbow and crossover-leg elbow removed from the Ringhals reactor. ${ }^{69}$ The material of the elbows is ASTM Specification 351 CF-8M steel, and the ferrite content, determined from the modified Schaefler diagram, ${ }^{70}$ is 20.1 for the hot-leg elbow and $19.8 \%$ for the crossover-leg elbow. Test rings were cut from the two elbows, and the ferrite content measured with a ferrite meter at the inside surface at three different heights of the ring, as well as through the thickness of the ring. Around 700 measurements were made, and the results show that the ferrite content in the actual components varies significantly. The ferrite content of the hot-leg elbow varies from $3.0 \%$ to $22.5 \%$, with an average of $13.3 \% \pm 4.2 \%$ ferrite; that of the crossover-leg elbow from $1.5 \%$ to $15.0 \%$, with an average of $9.8 \% \pm 3.4 \%$ ferrite. The results also indicate that for both elbows, the measured average ferrite contents are comparable with the values estimated from the material chemical composition by using Hull's equivalent factors ${ }^{71}$ or the ASTM A800/A800M methodology. ${ }^{72,73}$

Static cast CF-3 Stainless Steel Pump Impeller

Centrifugally cast CF-8 Stainless Steel Pipe

Figure 6. Ferrite content and morphology of vanes of a static cast CF-3 pump impeller and along a circumferential section of regions near the inside and outside diameter of centrifugally cast CF-3 and CF-8 pipes.

Similar variations in the ferrite content have also been observed in the ANL studies on CASS materials, obtained from actual reactor components. The measured ferrite content of vanes of a static-cast CF-3 pump impeller and along circumferential section of regions near the inside and outside diameter of centrifugally cast CF-3 and CF-8 pipes are higher near the outer surface than the inner surface. The values are about 20\% higher for the CF-3 pipe (Heat P2) and 40\% higher for the CF-8 pipe (Heat P1). In addition, the ferrite content of one of the pump impeller vane is about $40 \%$ higher than that of Vane 1. The ferrite contents estimated from the chemical composition by using Hull's equivalent factors are 17.7, 15.6, and 17.1\% for the CF-8 pipe, CF-3 pipe, and CF-3 pump impeller, respectively. The estimated values are comparable to the measured average values of ferrite contents for the CF-3 pipe and pump impeller but lower than the measured values for the CF-8 pipe.

These observations indicate that if measured value of ferrite content is used for design calculations or analyses, several locations should be selected across the length and width of the component to ensure that it is representative of the entire component. The results also indicate that for centrifugally cast SS pipes, the extent of embrittlement is likely to increase from the inner surface towards the surface because of the increasing ferrite content.

The ferrite content in CASS structures depends on the chemical composition and the manufacturing process history of the material. Typically, it is (a) measured using metallographic examination or instruments that utilize the magnetic response of the casting or (b) estimated from the chemical composition of the casting. When the CMTR is available, the ferrite content is estimated from the chemical composition of the material, and measuring techniques are used when the CMTR is not available.

### 2.2.2.1 Measured Ferrite

Until 1973, the ferrite content in duplex structures such as CASS materials was determined by metallographic examination of the structure. A sample of the material was polished and etched to reveal the ferrite and austenite phases, and a grid was superimposed over the image of an optical microscope to determine, by point counting, the percentage of ferrite in the sample. The main drawback with this method is that the point-count estimates of ferrite can vary depending on the etching technique used to reveal the ferrite phase and on the number of grid points used in the measurements. Furthermore, as discussed, the ferrite content in most CASS components varies significantly in different regions of the component, and obtaining metallographic samples from various regions may not be practical.

Among the magnetic methods, the Magne-Gage and Feritescope are the most commonly used instruments for measuring the ferrite content in CASS materials. The Magne-Gage is a continuous-reading type of instrument that uses a spring to measure the attraction between a magnet and the material of unknown ferrite content, and the response is compared with that of a calibrated sample. Typically, the ferrite number (FN) is measured by using a Magne-Gage in accordance with standard American Welding Society (AWS) procedure A4.2-74. ${ }^{74}$ The Feritescope operates on the magneto-induction principle, wherein the relative magnetic permeability of the specimen is measured. However, because the magnets or the probes of these instruments are small, the surface roughness or curvature of the sample is an important parameter that can change the magnetic linkage with the material being measured. In addition, phases other than ferrite and austenite may form in the material during service; these may alter the magnetic response of the material so that the indicated ferrite content is quite different from the content of a material with the same chemical composition that has undergone a different heat treatment.

### 2.2.2.2 Estimated Ferrite

Although a quantitative metallographic method gives the most accurate estimate of ferrite content, determining the percentage of ferrite from the chemical composition of the material is the most common method used to control ferrite during the solidification of the metal from a melt. The accuracy of these estimates, however, depends on the accuracy of the chemical analysis and on the degree of variability within the casting. In addition, these methods do not consider the effects of the casting process. The most commonly used methods for estimating ferrite are described below.

### 2.2.2.2.1 Hull's Equivalent Factor:

When a CMTR is available, the ferrite content is calculated from the chemical composition in terms of Hull's equivalent factors ${ }^{71}$ for Ni and Cr , given by

$$
\begin{equation*}
\mathrm{Cr}_{\mathrm{eq}}=\mathrm{Cr}+1.21(\mathrm{Mo})+0.48(\mathrm{Si})-4.99 \tag{3}
\end{equation*}
$$

and

$$
\begin{equation*}
\mathrm{Ni}_{\mathrm{eq}}=(\mathrm{Ni})+0.11(\mathrm{Mn})-0.0086(\mathrm{Mn})^{2}+18.4(\mathrm{~N})+24.5(\mathrm{C})+2.77 \tag{4}
\end{equation*}
$$

where the concentrations of the various alloying and interstitial elements are given in wt.\%. The concentration of N is often not available in a CMTR; if not known, it is assumed to be $0.04 \mathrm{wt} . \%$. The ferrite content $\delta_{C}$ is given by

$$
\begin{equation*}
\delta_{\mathrm{C}}=100.3\left(\mathrm{Cr}_{\mathrm{eq}} / \mathrm{Ni}_{\mathrm{eq}}\right)^{2}-170.72\left(\mathrm{Cr}_{\mathrm{eq}} / \mathrm{Ni}_{\mathrm{eq}}\right)+74.22 . \tag{5}
\end{equation*}
$$

The measured ferrite content and values calculated from Hull's equivalent factor for the various CASS heats used in studies at ANL, ${ }^{12}$ GF, ${ }^{1}$ Electricité de France (EdF), ${ }^{22}$ National Power

Figure 7.
Plots of measured ferrite content and values for various CASS materials calculated by using Hull's equivalent factor.
(NP), ${ }^{21}$ FRA, ${ }^{7}$ and the Electric Power Research Institute (EPRI) ${ }^{10}$ are shown in Fig. 7. For most heats, the difference between the estimated and measured values is $\pm 6 \%$ ferrite. The results also indicate that the calculated ferrite content is generally lower than the measured values for CF-8M heats that contained $\geq 10 \%$ Ni.

### 2.2.2.2.2 ASTM A800/800M Methodology:

In this methodology, ${ }^{72}$ the ferrite content of the casting is estimated from the central line of the of the Schoefer diagram ${ }^{73}$ at the composition ratio of Cr equivalent, $\mathrm{Cr}_{\mathrm{eq}}$, to Ni equivalent, $\mathrm{Ni}_{\mathrm{eq}}$, determined from the formula:

$$
\begin{equation*}
\mathrm{Cr}_{\mathrm{eq}} / \mathrm{Ni}_{\mathrm{eq}}=(\mathrm{Cr}+1.5 \mathrm{Si}+1.4 \mathrm{Mo}+\mathrm{Nb}-4.99) /(\mathrm{Ni}+30 \mathrm{C}+0.5 \mathrm{Mn}+26(\mathrm{~N}-0.02)+2.77) \tag{6}
\end{equation*}
$$

The values of the composition ratio $\left(\mathrm{Cr}_{\mathrm{eq}} / \mathrm{Ni}_{\mathrm{eq}}\right)$ for a given ferrite content (F), or vice versa, is then determined mathematically from the equation of the central line:

$$
\begin{equation*}
\mathrm{Cr}_{\mathrm{eq}} / \mathrm{Ni}_{\mathrm{eq}}=0.9+3.38883 \times 10^{-2} \mathrm{~F}-5.58175 \times 10^{-4} \mathrm{~F}^{2}+4.22861 \times 10^{-6} \mathrm{~F}^{3} \tag{7}
\end{equation*}
$$

The measured ferrite content and values calculated from the ASTM A800/A800M methodology for the same heats of CASS materials plotted in Fig. 7 are shown in Fig. 8. Since the Nb content is typically not reported for CASS CF-3, CF-8, and CF-8M materials, it is assumed to be zero and the ferrite content is calculated using Eqs. 6 and 7. Estimated values of ferrite if an Nb content of $0.2 \mathrm{wt} . \%$ is used would be about $7 \%$ higher for CASS materials with $5 \%$ ferrite and about $4 \%$ higher for materials with $30 \%$ ferrite. The results indicate that for ferrite contents more than $20 \%$, the calculated ferrite content for several heats is lower than the measured values. Most of these heats with significantly lower calculated values contained 22.0-23.0 wt. \% Cr and about $8.0-8.5 \mathrm{wt} . \% \mathrm{Ni}$. Ferrite contents estimated from the two methods, Hull's equivalent factor and ASTM A800/A800M method show excellent agreement for ferrite contents up to $20 \%$. The ASTM A800/A800M method under predicts the ferrite content for CASS materials with more than $20 \%$ ferrite. Figure 9 a shows the difference between the two methods.

Figure 8.
Plots of measured ferrite content and values for various CASS materials calculated using the ASTM A800/A800M methodology.

### 2.2.2.2.3 Methodology Developed by EdF:

The expressions used by EdF to estimate ferrite content in a casting, are slightly different from those used in the ASTM A800/800M method. EdF has developed the following expression for estimating ferrite,

$$
\begin{equation*}
\text { Ferrite }=21.8 R^{2}-5.96 R+3.39, \tag{8}
\end{equation*}
$$

where R is the ratio of $\mathrm{Cr}_{\mathrm{eq}}$ and $\mathrm{Ni}_{\text {eq }}$ expressed as,

$$
\begin{equation*}
\mathrm{R}=(\mathrm{Cr}+\mathrm{Mo}+0.65 \mathrm{Si}-17.6) /(\mathrm{Ni}+20 \mathrm{C}+8.3 \mathrm{~N}+0.08 \mathrm{Mn}-5.18) . \tag{9}
\end{equation*}
$$

A comparison of estimates of ferrite content based on the Hull's equivalent factor and EdF method is shown in Fig 9b. In general, the Hull's method predicts slightly higher ferrite contents. The two methods show good agreement for materials with up to $15 \%$ ferrite. The ferrite contents determined from the EdF method are compared with those from the ASTM A800/A800M method in Fig 10. The estimated values based of the EdF and A800/A800M methods show good agreement for ferrite contents up to $25 \%$. The A800/A800M method under predicts for materials with ferrite content $>25 \%$.

### 2.3 Kinetics of Thermal Embrittlement

The degree of embrittlement, as documented in the NUREG/CR-4513, Rev. 1, is characterized in terms of the Charpy-impact energy of notched toughness specimens. The "best estimates" of the degree of embrittlement at reactor operating temperatures are obtained from Arrhenius extrapolations of laboratory data obtained at higher temperatures. ${ }^{1}$ The aging time to reach a given degree of embrittlement at different temperatures is determined from:

$$
\begin{equation*}
t=10^{P} \exp \left[\frac{Q}{R}\left\{\frac{1}{T}-\frac{1}{673}\right\}\right], \tag{10}
\end{equation*}
$$

Figure 9a.
Plots of ferrite content calculated by using Hull's equivalent factor and those estimated from the ASTM A800/A800M methodology for various CASS materials.

Figure 9b.
Plots of ferrite content for various CASS materials calculated by using Hull's equivalent factors and those determined from the EMA formula developed by EdF.

Figure 10.
Plots of ferrite content for various CASS materials estimated by using the ASTM A800/A800M methodology and those determined from the EMA formula developed by EdF.
where $Q$ is the activation energy, $R$ is the gas constant, $T$ is the temperature, and $P$ is an aging parameter that describes the combined effect of time and temperature on aging. It represents the degree of aging reached after $10^{\mathrm{P}} \mathrm{h}$ at $400^{\circ} \mathrm{C}\left(752^{\circ} \mathrm{F}\right)$. Thus, $\mathrm{P}=1$ for aging 10 h at $400^{\circ} \mathrm{C}$. The aging parameter for any given aging condition is obtained by rewriting Eq. 10 so that,

$$
\begin{equation*}
P=\log _{10}(t)-\frac{1000 Q}{19.143}\left(\frac{1}{T_{s}+273}-\frac{1}{673}\right) . \tag{11}
\end{equation*}
$$

The activation energy for the process of embrittlement has been described by Slama et al. ${ }^{7}$ in terms of the chemical composition of the cast material. Thus,

$$
\begin{equation*}
\mathrm{Q}(\mathrm{~kJ} / \mathrm{mole})=-182.6+19.9(\% \mathrm{Si})+11.08(\% \mathrm{Cr})+14.4(\% \mathrm{Mo}) . \tag{12}
\end{equation*}
$$

The activation energy calculated from Eq. 12 for the various CASS materials included in this study is in the range of $41-88 \mathrm{~kJ} / \mathrm{mole}(9.8-21.0 \mathrm{kcal} / \mathrm{mole}$ ) for CF-3 material, $43-91 \mathrm{~kJ} / \mathrm{mole}$ ( $10.3-21.7 \mathrm{kcal} / \mathrm{mole}$ ) for CF-8, $77-115 \mathrm{~kJ} / \mathrm{mole}(18.4-27.5 \mathrm{kcal} / \mathrm{mole}$ ) for CF-8M with $<10 \% \mathrm{Ni}$, and $68-128 \mathrm{~kJ} / \mathrm{mole}$ ( $16.3-30.6 \mathrm{kcal} / \mathrm{mole}$ ) for CF-8M with $\geq 10 \% \mathrm{Ni}$. These values are generally lower than the values that were obtained from the mechanical property data (e.g., Charpy-impact) for most of the CASS materials, particularly for CF-3 and CF-8 materials. For example, the activation energies obtained experimentally from the studies at ANL, EdF/Framatome, and CEGB are in the range of $86-250 \mathrm{~kJ} / \mathrm{mole}$ for CF-3, $63-253 \mathrm{~kJ} / \mathrm{mole}$ for CF-8, 81-164 kJ/mole for CF-8M with $<10 \% \mathrm{Ni}$, and $90-172 \mathrm{~kJ} / \mathrm{mole}$ for CF-8M with $\geq 10 \% \mathrm{Ni}$. However, the calculated values for the CASS CF-3, CF-8, and CF-8M materials investigated in the GF study show good agreement with the experimental values of activation energies obtained from the Charpy-impact energy data for thermally aged materials.

Furthermore, the calculated values from Eq. 12 are significantly lower than the activation energy of spinodal decomposition in CASS materials. The spinodal decomposition and G-phase precipitation in low-temperature-aged CASS materials have been investigated by transmission electron microscopy (TEM), atom probe field ion microscopy (APFIM), small angle neutron scattering (SANS), and extraction replica techniques. ${ }^{60-67}$ The activation energy of the spinodal reaction in CF-3 SS was $250 \pm 30 \mathrm{~kJ} / \mathrm{mole}(60 \pm 7 \mathrm{kcal} / \mathrm{mole}) .{ }^{64}$ This value is comparable to that for Cr diffusion in $\mathrm{Fe}-\mathrm{Cr}$ alloys. The lower values for the activation energy for thermal embrittlement of CASS materials are most likely due to other factors, such as the effect of the formation of carbides and nitrides at the phase boundaries or the effect of G-phase and/or $\mathrm{Y}_{2}$ precipitation in ferrite, all of which can change the fracture mechanism of the aged material

For example, the precipitation of large carbides or nitrides at phase boundaries can initiate phase boundary separation by particle cracking. Consequently, a lower degree of spinodal decomposition (i.e., smaller amplitude of Cr fluctuation) is needed for a given change in mechanical properties. The material would show a reduction in impact strength faster than a material without phase boundary carbides would. However, the precipitation of carbides or nitrides occurs primarily at 400 or $450^{\circ} \mathrm{C}$ and is extremely slow at lower temperatures. Thus, the influence of phase boundary carbides would tend to increase the apparent activation energy of embrittlement measured from mechanical property data.

The other factor that can influence the overall activation energy for embrittlement is the precipitation of other second-phase particles in ferrite - in particular, the G phase (a multicomponent phase consisting of $\mathrm{Ni}, \mathrm{Si}, \mathrm{Mo}, \mathrm{Cr}$, and Fe and some Mn and C ). ${ }^{62,66}$ The kinetics of G-phase precipitation depend on the chemical composition of the cast material. ${ }^{5}$ For some heats, the G phase is observed after times as short as $10,000 \mathrm{~h}$ at $400^{\circ} \mathrm{C}$, while other heats require up to $70,000 \mathrm{~h}$ of aging at $400^{\circ} \mathrm{C}$ for G-phase formation. In general, precipitation of the $G$ phase is faster in the Mo-containing CF-8M materials. $5,60,62$ The aging conditions for which the G phase has been detected by TEM or SANS techniques in various CASS materials are shown in Fig. 11. The kinetics for the decrease in the Charpy impact energy of the aged material are also plotted in the figure. The actual aging times for a given decrease in impactenergy varies significantly for the various heats (shown by the horizontal scatter bars in Fig. 11). Generally, the aging times for the CF-8M materials are lower than for the CF-3 or CF-8 materials.

The mechanism by which the G phase influences thermal embrittlement of CASS materials is not well understood. The precipitation of the G phase can influence the kinetics of embrittlement by either directly altering the kinetics of spinodal decomposition or by changing the deformation and fracture behavior of the ferrite matrix and thereby influencing the effectiveness of spinodal decomposition. The only experimental data on the kinetics of spinodal decomposition in CASS materials were obtained by modeling the amplitude of Cr fluctuations, measured by APFIM, in thermally aged CF-3 steel. ${ }^{18}$ The results yield an activation energy of $250 \mathrm{~kJ} / \mathrm{mole}$. No G phase was observed in the steel after $5,000 \mathrm{~h}$ at 400 or $350^{\circ} \mathrm{C}$. As shown in Fig. 11, most heats require $\geq 10,000 \mathrm{~h}$ at $400^{\circ} \mathrm{C}$ and $\geq 30,000 \mathrm{~h}$ at $350^{\circ} \mathrm{C}$ before G-phase precipitates are detected.

Figure 11. Arrhenius plots for the formation of the $\mathbf{G}$ phase and a reduction in impact energy.

The low values of activation energy obtained from mechanical property data (e.g., for the GF CASS materials) are most likely due to the effect of G-phase precipitation on the deformation behavior of the ferrite matrix. The concomitant precipitation of the G phase may alter the frequency (spacing) of Cr fluctuations produced by spinodal decomposition, which would be more effective in strain hardening. Thus, a lower degree of spinodal decomposition (i.e., lower amplitude of the Cr fluctuations) would be needed for a given change in mechanical properties. The $G$ phase was observed in the GF heats of CASS materials, and the measured activation energies for thermal embrittlement obtained from the Charpy-impact data were between 63 and $106 \mathrm{~kJ} / \mathrm{mole}$.

The above methodology, however, assumes a unique aging behavior at $400^{\circ} \mathrm{C}\left(752^{\circ} \mathrm{F}\right)$, which is not observed for CASS materials produced at various foundries by using different manufacturing processes. The decrease in RT Charpy-impact energy during thermal aging at $400^{\circ} \mathrm{C}\left(752^{\circ} \mathrm{F}\right)$ of several heats of CASS materials $1,7,10,12,13-15$ is shown in Fig. 12. The results indicate that all materials reach "quasi-saturation" RT impact energy (i.e., a minimum value that would be achieved by the material after long-term aging, primarily due to spinodal decomposition of the ferrite). Although the decrease in the RT impact energy during aging at $400^{\circ} \mathrm{C}$ occurs primarily within $10,000 \mathrm{~h}$, the impact energy for most CASS materials continues to decrease beyond $10,000 \mathrm{~h}, 1,12-14$ but at a much slower rate. Furthermore, thermal aging studies at EdF on numerous heats of CF-8M material have shown that the RT Charpy U-notch impact energy for

Figure 12. Decrease in Charpy-impact energy for various heats of CASS materials aged at $400^{\circ} \mathrm{C}$.
materials aged for $10,000 \mathrm{~h}$ at $350^{\circ} \mathrm{C}$ is lower than for those aged at $400^{\circ} \mathrm{C}$. However, after being aged further up to $30,000 \mathrm{~h}$, the impact energy for materials aged at $350^{\circ} \mathrm{C}$ did not change significantly, whereas the impact energy for materials aged at $400^{\circ} \mathrm{C}$ decreased to a lower value than that reached by those aged at $350^{\circ} \mathrm{C}$ for $30,000 \mathrm{~h}$.

Note that the proposed methodology for estimating the extent of thermal embrittlement of CASS materials is applicable to service times equivalent to $10,000 \mathrm{~h}$ at $400^{\circ} \mathrm{C}$. This service time corresponds to $P=4.0$. It represents $\geq 125$ efpy at $290^{\circ} \mathrm{C}$ for CF-8/CF-3 materials and $\geq 30$ efpy at $320^{\circ} \mathrm{C}$ for CF-8/CF-3 materials and $\geq 15$ efpy for CF-8M materials used within primary pressure boundary components. For CF-8/CF-3 materials used in the core support structures and core internals, it represents $\geq 15$ efpy at $350^{\circ} \mathrm{C}$. The procedure for estimating the thermal embrittlement of CASS materials for longer service times will be established when additional long-term aging data on RT Charpy-impact energy and fracture toughness J-R curve are available for CF-8 and CF-8M materials. Limited data indicate that the concentration of $(\mathrm{Ni}+\mathrm{Si}+\mathrm{Mo})$ in the material is an important parameter for further reduction in fracture properties of CASS components.

For a specific CASS material, the actual value of this quasi-saturation RT Charpy-impact energy is independent of aging temperature but depends strongly on the chemical composition of the material. It is lower for the Mo-bearing CF-8M materials than it is for the Mo-free CF-3 or CF-8 materials, and it decreases with an increase in the ferrite content and the concentration of C or N in the steel.

Figure 12 also indicates that for a given decrease in the RT Charpy-impact energy, the time for aging at $400^{\circ} \mathrm{C}$ varies by more than two orders of magnitude for the various heats. For example, the time required for the impact energy to start decreasing varies from about 50 h (EPRI heats) to more than 1000 h (GF heats). The time for the start of thermal aging effects varies from 50 to 500 h for the ANL and FRA heats. For some materials, the decrease in impact energy is very fast (i.e., low activation energy), and for others, it is slow (i.e., high activation energy). Typically, CASS materials that take longer for thermal embrittlement to start have low
activation energy, and materials that take short times for embrittlement to start have high activation energy. This behavior is consistent with the results of the parametric study of the manufacturing process parameters at EdF, ${ }^{25}$ which showed that CASS materials that are solution-treated at a high temperature have a high ferrite content and their thermal embrittlement starts early during aging, but they are less susceptible to thermal embrittlement (e.g., activation energy for embrittlement is high). On the other hand, CASS materials that are solution-treated at a low temperature have low ferrite content and their thermal embrittlement starts late during aging, but they are very susceptible to thermal embrittlement (e.g., activation energy for embrittlement is low). Such differences may be attributed to compositional differences in the material due to differences in the casting process.

The results also indicate that for most CASS materials, the total time to reach saturation impact energy is approximately the same for all grades and heats of CASS materials. In other words, the time for thermal embrittlement to start plus the time for embrittlement to occur is about the same. CASS materials that start early take longer to embrittle, and materials that start late take a relatively shorter time to embrittle. Consequently, half the maximum change in RT Charpyimpact energy (i.e., parameter $\beta$ ) and the log of the time to achieve the $\beta$ reduction in impact energy at $400^{\circ} \mathrm{C}$ (i.e., parameter $\theta$ ) represent two important parameter for characterizing the kinetics of thermal embrittlement. ${ }^{16}$ The values of parameters $\beta$ and $\theta$ for the various heats of CASS materials shown in Fig. 12 are listed in Table 2; parameter $\alpha$ is a shape factor.

Furthermore, microstructural examination of aged CASS materials suggests that materials that take longer for embrittlement to start at $400^{\circ} \mathrm{C}$ are associated with clusters of $\mathrm{Ni}-\mathrm{Si}, \mathrm{Mo}-\mathrm{Si}$, and Ni -Si-Mo in the ferrite matrix. 5,60 These clusters are considered precursors of G-phase nucleation and precipitation. CASS materials with low activation energy (i.e., fast embrittlement) show G-phase precipitation after aging, but embrittlement at $400^{\circ} \mathrm{C}$ takes longer to start. CASS materials with high activation energy (i.e., slow embrittlement) do not contain the $G$ phase but embrittlement at $400^{\circ} \mathrm{C}$ takes a relatively short time to start. $5,60-62$ The presence of Ni-Si-Mo clusters in the ferrite matrix of an unaged material may be considered a signature of materials that are potentially sensitive to thermal embrittlement (i.e., such materials show low activation energy for thermal embrittlement but take longer to embrittle at $400^{\circ} \mathrm{C}$.

Since thermally embrittlement of CASS materials is caused primarily by spinodal decomposition of ferrite, $, 511,12$ the kinetics of thermal embrittlement are controlled by the amplitude and spacing of the Cr-rich regions in the ferrite. The low activation energies of thermal embrittlement are most likely caused by variations in the spacing of these regions. Atom probe field-ion microscopy studies indicate that the spacing between Cr fluctuations decreases with decreasing temperature. ${ }^{61,65}$ Therefore, production heat treatment and the casting process, both of which affect ferrite composition and microstructure of the material, would affect microstructural evolution during aging as well as the kinetics of embrittlement.

Based on these observations, in NUREG/CR-4513, Rev. 1, the change in RT Charpy-impact energy, $\mathrm{C}_{\mathrm{V}}$, as a function of time and temperature was expressed in terms of the RT saturation impact energy, $\mathrm{C}_{\mathrm{V} \text { sat }}$, and the kinetics of embrittlement. The decrease in $\mathrm{C}_{V}$ with time was expressed as

$$
\begin{equation*}
\log _{10} C_{V}=\log _{10} C_{V s a t}+\beta\{1-\tanh [(P-\theta) / \alpha]\}, \tag{13}
\end{equation*}
$$

where the aging parameter $P$ is determined from Eq. 11 The constants $\alpha$ and $\beta$ are determined from the initial RT impact energy, $\mathrm{C}_{\mathrm{Vint}}$, and $\mathrm{C}_{\mathrm{V}_{\text {sat }}}$ as follows:

Table 2. Chemical composition, ferrite content, and kinetics of thermal embrittlement for various heats of CASS materials.

\end{equation*}
$$

The CMTR for a specific CASS component provides information on the chemical composition, tensile strength, and possibly the Charpy-impact energy of the material. If $\mathrm{C}_{\text {Vint }}$ is not known, a typical value of $200 \mathrm{~J} / \mathrm{cm}^{2}$ [or $160 \mathrm{~J}(118 \mathrm{ft}-\mathrm{lb})$ for a standard Charpy V-notch specimen] may be used. The value of $\theta$ is not available for CASS components in the field, and can only be obtained from aging archival material for $5,000-10,000 \mathrm{~h}$ at $400^{\circ} \mathrm{C}\left(752^{\circ} \mathrm{F}\right)$. However, parametric studies show that the aging response at reactor temperatures is relatively insensitive to the values of $\theta .{ }^{75}$ However, the existing data indicate that $\theta$ varies with the material composition and ferrite content. Additional data on the kinetics of thermal embrittlement of CF-3, CF-3M, CF-8, and CF-8M materials containing a wide range of compositions and ferrite contents are needed to establish an expression correlating $\theta$ to the material composition. Based on the data listed in Table 2, a value of 2.9 for $\theta$ (i.e., mean of the experimental data) is used to estimate thermal embrittlement at $280-400^{\circ} \mathrm{C}\left(536-752^{\circ} \mathrm{F}\right)$. In the NUREG/CR-4513 methodology, the activation energy for thermal embrittlement is expressed in terms of both chemical composition and the constant $\theta .{ }^{16}$ The activation energy $Q$ (in $\mathrm{kJ} / \mathrm{mole}$ ) for CF-3 and CF-8 materials is given by

$$
\begin{equation*}
Q=10[74.52-7.20 \theta-3.46 \mathrm{Si}-1.78 \mathrm{Cr}+148 \mathrm{~N}-61 \mathrm{C}] \text {, } \tag{16}
\end{equation*}
$$

and for CF-8M materials is given by

$$
\begin{equation*}
\mathrm{Q}=10[74.52-7.20 \theta-3.46 \mathrm{Si}-1.78 \mathrm{Cr}-4.35 \mathrm{Mn}+23 \mathrm{~N}] . \tag{17}
\end{equation*}
$$

Equations 16 and 17 are slightly different from the expressions proposed by Slama et al. in 1983 (i.e. Eq. 12). ${ }^{7}$ These equations are applicable to compositions within ASTM Specification A351, with an upper limit of $1.2 \mathrm{wt} . \%$ for Mn content. Actual Mn content is used when CASS materials contain up to $1.2 \mathrm{wt} . \% \mathrm{Mn}$. For materials containing more than $1.2 \mathrm{wt} . \% \mathrm{Mn}, 1.2 \mathrm{wt} . \%$ is assumed. Furthermore, the values of $Q$ predicted from Eqs. 16 and 17 should be between a minimum of $65 \mathrm{~kJ} / \mathrm{mole}(15.5 \mathrm{kcal} /$ mole) and a maximum of $250 \mathrm{~kJ} / \mathrm{mole}(59.8 \mathrm{kcal} / \mathrm{mole})$ maximum; Q is assumed to be $65 \mathrm{~kJ} / \mathrm{mole}$ if the predicted values are lower and $250 \mathrm{~kJ} / \mathrm{mole}$ if the predicted values are higher. However, since several processes are responsible for thermal embrittlement of CASS materials, and each process has its own temperature dependence, the existing data indicates a change in activation energy of embrittlement with temperature.

The above expressions for estimating activation energy $Q$ for thermal aging embrittlement of CASS materials agree qualitatively with the microstructural and mechanical property data. For example, an increase in the value of $\theta$ decreases the activation energy, as expected. The contributions of Si for all grades of CASS materials and of Mn for CF-8M materials are consistent with their effect on the formation of the $G$ phase. These elements should promote precipitation of the G phase: hence, the coefficients for these elements should have a negative sign, because activation energy for thermal embrittlement is low for materials that show Gphase precipitation. An increase in C or N in the steel will promote carbide or nitride precipitation at high temperatures and thus increase the activation energy. The positive sign of the constant for the N content agrees with this behavior. The constant for the C content in steel, however, has a negative sign. It is likely that C also promotes the precipitation of the G phase, a multicomponent phase consisting of $\mathrm{Ni}, \mathrm{Si}, \mathrm{Mo}, \mathrm{Cr}$, and Fe and some Mn and $\mathrm{C} .{ }^{62,67}$

### 2.4 Extent of Thermal Embrittlement

All CASS materials reach the "saturation" RT impact energy (i.e., a minimum value achieved by the material primarily because of spinodal decomposition) after long-term aging. The actual value of the saturation RT impact energy for a specific CASS material is independent of the aging temperature (between $250-450^{\circ} \mathrm{C}$ ) but depends strongly on the chemical composition of the steel. It is lower for the Mo-bearing CF-8M materials than for the Mo-free CF-3 or CF-8 materials, and it decreases with an increase in the ferrite content or the concentration of C or N in the steel. ${ }^{16}$ Typically, the extent of thermal embrittlement has been characterized by the RT "normalized" Charpy-impact energy (Charpy-impact energy per unit fracture area).

In the ANL studies, ${ }^{12-17}$ correlations have been developed for the extent of thermal embrittlement at quasi-saturation, $\mathrm{C}_{\text {vsat }}$ (i.e., the minimum RT Charpy-impact energy that would be achieved for the material because of spinodal decomposition), in terms of the chemical composition of the material. The extent of thermal embrittlement as a function of the time and temperature of the reactor service is estimated from the extent of embrittlement at saturation and the correlations describing the kinetics of embrittlement, which are given in terms of the material chemical composition and the initial Charpy-impact energy, $\mathrm{C}_{\text {Vint }}$, of the material in the unaged condition. If $C_{V i n t}$ is not known, a typical value of $200 \mathrm{~J} / \mathrm{cm}^{2}(118 \mathrm{ft}-\mathrm{lb})$ is assumed. The fracture toughness J-R curve for the material is then obtained from the correlation between the fracture toughness parameters and the RT Charpy-impact energy used to characterize the extent of thermal embrittlement. A common lower-bound J-R curve for various grades of CASS materials of unknown chemical composition is defined for a given material specification, ferrite content, and temperature. Correlations are also developed for estimating changes in tensile strength and Ramberg/Osgood parameters for strain hardening. ${ }^{18}$ The methodology for estimating fracture properties of aged CASS materials has been updated in this report.

The extent of thermal embrittlement has been extended to operating times equivalent to $10,000 \mathrm{~h}$ at $400^{\circ} \mathrm{C}$. The procedure for estimating thermal embrittlement for aging times beyond $10,000 \mathrm{~h}$ at $400^{\circ} \mathrm{C}$ will be established as and when RT Charpy-impact data are available for CF8 and CF-8M materials aged for 10,000-40,000 h at $400^{\circ} \mathrm{C}$. An aging time of $40,000 \mathrm{~h}$ at $400^{\circ} \mathrm{C}$ is equivalent to $\geq 60$ efpy at $320^{\circ} \mathrm{C}$ for CF-8M and $\geq 120$ efpy at $320^{\circ} \mathrm{C}$ for CF-8/CF-3 materials used in the primary pressure boundary components, and $\geq 45$ efpy for CF-8/CF-3 materials used in reactor core support and core internals.

### 2.4.1 Charpy-Impact Energy

In the ANL studies, ${ }^{12}$ different correlations are developed to estimate the saturation RT impact energy of the various grades of CASS materials. To ensure that the estimates are either accurate or conservative for all heats, the saturation RT impact energy for a specific material is determined by two slightly different expressions, both correlating the RT Charpy impact energy with a material parameter, $\phi$, that depends on the material's ferrite content and its chemical composition. The lower value is used to estimate the mechanical properties of thermally aged CASS materials. The RT Charpy-impact energies at saturation (i.e., for CASS materials aged
 TWI, ${ }^{6}$ FRA, ${ }^{7}$ EPRI ${ }^{10} \mathrm{CEGB},{ }^{21} \mathrm{EdF},{ }^{22}$ and $\mathrm{MHI}^{28-32}$ are plotted as a function of the material parameter $\phi$ in Fig. 13. The data represents CF-3, CF-3M, CF-8, and CF-8M materials with 3 to $49 \%$ ferrite. The data for grades CF-3 and CF-8 are plotted together, and for grades CF-3M and CF-8M, materials containing $<10 \% \mathrm{Ni}$ are plotted separate from those containing $\geq 10 \% \mathrm{Ni}$.

Figure 13. Correlation between RT Charpy-impact energy at saturation and the material parameter $\phi$ for CASS materials. $\delta_{c}$ is the calculated ferrite content.

A value of $10 \% \mathrm{Ni}$ is used in this study to determine if primary $\gamma$ (austenite) forms during solidification of the castings from the liquid. For CASS CF-8M compositions containing $<10 \% \mathrm{Ni}$, the solidification sequence is as follows: Liq. $\rightarrow$ Liq. $+\delta \rightarrow \delta$, with $\delta \rightarrow \gamma$ in the solid. ${ }^{76}$ Austenite nucleates predominantly at ferrite grain boundaries and to a lesser extent at interdendritic locations within the ferrite. For CF-8M compositions containing $\geq 10 \% \mathrm{Ni}$, the solidification sequence is likely to be as follows: Liq. $\rightarrow$ Liq. $+\delta \rightarrow$ Liq. $+\delta+\gamma \rightarrow \delta+\gamma$, with $\delta \rightarrow \gamma$ continuing in the solid. ${ }^{76}$ The austenite forms first in the liquid as a secondary phase enveloping the primary ferrite. Upon further cooling, it grows in the remaining liquid as well as into ferrite. The latter reaction continues below the solidus line. The actual microstructures of the casting depend on the $\mathrm{Cr} /$ Ni ratio for the specific composition. Because of significant differences in the composition and microstructure of the ferrite in CF-8M materials with $<10$ or $\geq 10 \% \mathrm{Ni}$, separate expressions have been developed for these two materials.

The results indicate that for CF-3M and CF-8M materials, the original expressions correlating $\mathrm{C}_{\text {Vsat }}$ to the material parameter $\phi$ need to be revised to extend their applicability for materials containing more than $25 \%$ ferrite. The expressions for CF-3 and CF-8 materials do not require revision. For these grades, although experimental $C_{V_{\text {sat }}}$ for a few heats with high values of $\phi$ is lower than the predicted value, the chemical composition of these heats was outside the ASTM specifications for CF-3 and CF-8 materials. The Cr content in these heats was significantly higher than the $21 \%$ maximum specified in the specifications, and for some materials, the Ni content was also lower than the $8 \%$ specified minimum.

For CF-3/CF-8 materials, the expressions in NUREG/CR-4513, Rev. 1, are retained. The bestfit expressions are used to avoid over conservatism in the estimation methodology. The saturation value of $R T$ impact energy, $\mathrm{C}_{\mathrm{V} \text { sat }}$, is the lower value determined from

$$
\begin{equation*}
\log _{10} C_{V \text { sat }}=1.15+1.36 \exp (-0.035 \Phi) \tag{18}
\end{equation*}
$$

where the material parameter $\Phi$ is expressed as

$$
\begin{equation*}
\Phi=\delta_{c}(\mathrm{Cr}+\mathrm{Si})(\mathrm{C}+0.4 \mathrm{~N}), \tag{19}
\end{equation*}
$$

and from

$$
\begin{align*}
\log _{10} C_{V \text { sat }}=5.64- & 0.006 \delta_{\mathrm{C}}-0.185 \mathrm{Cr}+0.273 \mathrm{Mo}-0.204 \mathrm{Si} \\
& +0.044 \mathrm{Ni}-2.12(\mathrm{C}+0.4 \mathrm{~N}) . \tag{20}
\end{align*}
$$

For CF-3M/CF-8M materials, the expressions between $\mathrm{C}_{\text {vsat }}$ and $\phi$ have been revised. For materials with $<10 \% \mathrm{Ni}$, the $\mathrm{C}_{\mathrm{V} \text { sat }}$ value is the lower value determined from

$$
\begin{equation*}
\log _{10} C_{V \text { sat }}=0.27+2.81 \exp (-0.022 \Phi) \tag{21}
\end{equation*}
$$

where the material parameter $\Phi$ is expressed as

$$
\begin{equation*}
\Phi=\delta_{\mathrm{c}}(\mathrm{Ni}+\mathrm{Si}+\mathrm{Mn})^{2}(\mathrm{C}+0.4 \mathrm{~N}) / 5 \tag{22}
\end{equation*}
$$

and from

$$
\begin{align*}
\log _{10} C_{V \text { sat }}=7.28- & 0.011 \delta_{c}-0.185 \mathrm{Cr}-0.369 \mathrm{Mo}-0.451 \mathrm{Si} \\
& -0.007 \mathrm{Ni}-4.71(\mathrm{C}+0.4 \mathrm{~N}) . \tag{23}
\end{align*}
$$

For materials with $\geq 10 \% \mathrm{Ni}$, the saturation value of the $R T$ impact energy $C_{V \text { sat }}$ is the lower value determined from

$$
\begin{equation*}
\log _{10} C_{V_{\text {sat }}}=0.84+2.54 \exp (-0.047 \Phi) \tag{24}
\end{equation*}
$$

where the material parameter $\Phi$ is expressed as

$$
\begin{equation*}
\Phi=\delta_{c}(\mathrm{Ni}+\mathrm{Si}+\mathrm{Mn})^{2}(\mathrm{C}+0.4 \mathrm{~N}) / 5, \tag{25}
\end{equation*}
$$

and from

$$
\begin{align*}
\log _{10} C_{V s a t}=7.28- & 0.011 \delta_{C}-0.185 \mathrm{Cr}-0.369 \mathrm{Mo}-0.451 \mathrm{Si} \\
& -0.007 \mathrm{Ni}-4.71(\mathrm{C}+0.4 \mathrm{~N}) . \tag{26}
\end{align*}
$$

If not known, the N content is assumed to be $0.04 \mathrm{wt} . \%$. The correlations are optimized using mechanical property results on approximately 140 compositions of CASS materials that were aged up to $60,000 \mathrm{~h}$ at $290-350^{\circ} \mathrm{C}\left(554-662^{\circ} \mathrm{F}\right)$.

To provide a more realistic comparison, the data obtained for aging temperatures $400^{\circ} \mathrm{C}$ or higher are not used. Figure 14 shows the difference between the estimated $\mathrm{C}_{\mathrm{V} \text { sat }}$ values based on the original expressions in NUREG/CR-4513, Rev. 1, and the updated expression, for CF-8M and CF-3M materials. The original and updated curves are shown as solid and chain-dash lines, respectively. The chemical composition, ferrite content, and saturation RT Charpy-impact energy are given in Table 2.

The measured values of $\mathrm{C}_{\mathrm{V} \text { sat }}$ and the lower of the two values estimated from (a) the material parameter $\phi$ (Eqs. 18, 21, and 24) and (b) the material chemical composition and ferrite content $\delta_{\mathrm{c}}$ (Eqs. 20, 23, and 26), are plotted in Fig. 15. The results indicate that the estimates based on Eqs. 18-26 are either accurate or conservative. However, the predicted $\mathrm{C}_{\mathrm{V} \text { sat }}$ for four heats

Figure 14. Comparison of the updated (chain-dash line) and original (solid line) correlation between the RT Charpy-impact energy at saturation and material parameter $\phi$.

Figure 14. (Contd.)
(two CF-3 and two CF-8M materials) is significantly higher than the measured value. The reason for such a large difference is not clear. The expressions given by Eqs. 18-26 for estimating $\mathrm{C}_{\mathrm{Vsat}}$ for a specific CASS material are correlated to the material's ferrite content and its chemical composition because a review of the thermal embrittlement data for aged CASS materials indicated that a correlation between the Charpy impact energy and ferrite content alone did not yield good results. The $\mathrm{C}_{\mathrm{V} \text { sat }}$ for CF-3, CF-8, and CF-8M materials shown in Fig. 13 is plotted as a function of the material ferrite content in Fig. 16; the results show a poor correlation.

Figure 15. Measured values of saturation RT Charpy-impact energy for CF-3, CF-8, and CF-8M CASS materials and those estimated from (a) the material parameter $\phi$, (b) the material composition and ferrite content, and (c) the lower of these two values.

Figure 15. (Contd.)

Figure 16.
Correlation between RT Charpy-impact energy at saturation and the ferrite content for CF-3, CF-8, and CF-8M materials.

Figure 17.
Fracture surface of Charpyimpact specimen of Heat 4331 aged for 700 h at $400^{\circ} \mathrm{C}$ and tested at room temperature (Ref. 12).

### 2.4.2 Effect of Trace Nb Content

Limited data indicate a significant reduction in the RT Charpy-impact energy of Heat 4331 of CF-8M material aged for only 700 h at $400^{\circ} \mathrm{C}$. Unlike most CF-8M materials, which contain only trace amounts of Nb (e.g. <0.05 wt. \%), Heat 4331 contained $0.2 \mathrm{wt} \%$.Nb . The fracture surface of the Charpy-impact test specimen (Fig. 17) show that the phase boundaries are decorated with large Nb carbides (or carbo-nitrides) that can crack easily. These phase-boundary carbides alter the deformation and fracture behavior of the material, promoting initiation of cleavage by particle cracking. None of the other heats of CASS materials included in the ANL study contained more than trace amounts of Nb . The fracture surfaces of these heats of CASS materials exhibit, depending on the extent of embrittlement, a combination of dimpled ductile tearing, ductile shear failure, cleavage, and phase-boundary separation. For room-temperature tests, the amount of cleavage increased with the extent of embrittlement.

These differences in the fracture behavior of the Charpy-impact specimens are reflected in the ductile-to-brittle transition curves for thermally aged CASS materials. The effect of thermal aging on the transition curves for Heats 4331 (23.8\% ferrite) and Heat 75 ( $24.8 \%$ ferrite) aged for different times at $400^{\circ} \mathrm{C}$ are shown in Fig. 18. The results show significant differences in the transition temperature for the two heats of CF-8M materials. The transition temperature at $81.25 \mathrm{~J} / \mathrm{cm}^{2}$ (i.e., $50 \mathrm{ft}-\mathrm{lb}$ ) Charpy-impact energy for Heat 75 aged at $400^{\circ} \mathrm{C}$ for $2,570 \mathrm{~h}$ and $10,000 \mathrm{~h}$ is $65^{\circ} \mathrm{C}$ and $140^{\circ} \mathrm{C}$, respectively; for Heat 4331 aged at $400^{\circ} \mathrm{C}$ for only 700 h , it is $220^{\circ} \mathrm{C}$. Thus, the transition temperature is much higher for Heat 4331, even though it was aged for only 700 h . The results also indicate that although the Charpy-impact energy at $270-290^{\circ} \mathrm{C}$ is not significantly different for the three aging conditions, the RT Charpy-impact energy is much lower for Heat 4331 than for Heat 75 aged for longer times. For Heat 4331, the Charpy-impact energy at $290^{\circ} \mathrm{C}$ continues to decrease after aging at $400^{\circ} \mathrm{C}$ for more than 700 h .

These results indicate the potential effects of a trace amount of Nb content on the thermal embrittlement of CASS materials during service in LWRs. The ASTM Specifications A351 and A451 for the chemical composition of CF-3, CF-3M, CF-8, and CF-8M grades of CASS do not specify any maximum limit for the Nb content in the casting. Typically, the trace Nb content in these grades of CASS materials produced in the United States is very low (less than $0.05 \mathrm{wt} . \%$ ). However, castings produced in Europe may contain higher levels of Nb. The source for higher Nb content is the use of Type 347 scrap metal to produce the casting. Consequently, the amount of Nb is often more than 0.05 wt . \% if Type 347 scrap metal is used.

Figure 18.
Ductile-to-brittle transition curves for Charpy-impact specimens of thermally aged Heats 4331 and 75 of CF-8M material (Ref. 12).

### 2.4.3 Fracture Toughness J-R Curve

The fracture toughness J-R curve for a specific CASS material can be estimated from its RT Charpy-impact energy. The J-R curve is expressed by the power-law relationship $J_{d}=C \Delta a^{n}$, where $J_{d}$ is deformation $J$ per ASTM Specifications E 813-85 and E 1152-87, $\Delta$ a is a crack extension, and C and n are constants. The coefficient C , at $\mathrm{RT}\left(25^{\circ} \mathrm{C}\right)$ or reactor temperatures (290-320 ${ }^{\circ} \mathrm{C}$ ), and the RT Charpy-impact energy for aged and unaged CASS materials are plotted in Fig. 19a and $b$ respectively, based on an updated fracture toughness database. Fracture toughness data from studies at ANL, ${ }^{12-15}$ FRA, 7,8 EPRI, ${ }^{10}$ EdF, ${ }^{23,24,26}$ Mitsubishi Heavy Industries (MHI), ${ }^{28-32}$ The Welding Institute (TWI), ${ }^{6}$ and Materials Engineering Associates, Inc. (MEA), ${ }^{77}$ are included in the figure. These plots provide a correlation between coefficient $C$ of the Power-law J-R curve and RT Charpy-impact energy of the material. Thus, saturation values of $C$ can be obtained form the saturation value of RT Charpy-impact energy.

Figure 19a. Correlation between RT Charpy-impact energy and coefficient $C$ at RT for CF-3, CF-8, CF-3M, and CF-8M CASS materials.

Figure 19b. Correlation between RT Charpy-impact energy and coefficient $C$ at 290$320^{\circ} \mathrm{C}$ for CF-3, CF-8, CF-3M, and CF-8M CASS materials.

At both RT $\left(25^{\circ} \mathrm{C}\right)$ and reactor temperatures $\left(290-320^{\circ} \mathrm{C}\right)$, the coefficient C decreases with a decrease in the RT Charpy-impact energy. Separate correlations are obtained for CF-3 and CF-8 materials and for CF-8M materials; the latter show a larger decrease in the fracture toughness for a given impact energy. Furthermore, for CF-8M materials, the decrease in the values of coefficient $C$ is much greater for RT Charpy-impact energy values that are less than about $35 \mathrm{~J} / \mathrm{cm}^{2}$ for fracture toughness tests at $R T$ and $41-46 \mathrm{~J} / \mathrm{cm}^{2}$ for fracture toughness tests at reactor temperatures. However, all of the fracture toughness data for CF-8M materials with very low values of RT Charpy-impact energy are for materials containing $\geq 10 \% \mathrm{Ni}$. It is not clear whether CF-8M materials with $<10 \% \mathrm{Ni}$ also show a similar behavior.

As discussed later in this section, data on chemical compositions of CASS piping materials from a select sample of nuclear power plants (NPPs) in the United States indicate that at least 9\% of the CF-8M materials currently used in operating NPPs contain more than $25 \%$ ferrite. For these materials, the methodology developed earlier in NUREG/CR-4513, Rev. 1, is not applicable for flaw tolerance evaluations. In this report, the methodology for estimating thermal embrittlement has been extended to cover CASS materials containing more than $25 \%$ ferrite. For CF-8M materials, a bilinear expression is developed between RT Charpy-impact energy and coefficient C of the power-law J-R curve.

To help ensure that the estimated J-R curve was conservative for all material and aging conditions, the correlations for estimating the J-R curves for static-cast materials were obtained by subtracting the value of the standard deviation for the fit to the data from the best-fit curve in Fig. 19; these curves are shown as chain dot curves. For centrifugally cast materials, the bestfit correlations were used; typically, the data scatter is considerably smaller for centrifugally cast materials than static cast materials. For CF-8M materials, the value of the RT Charpy-impact energy for the transition from one expression to the other varies between 35 and $46 \mathrm{~J} / \mathrm{cm}^{2}$ because of the differences in the standard deviation for the fit to the individual set of data.

For static-cast CASS materials, the coefficient C of the J-R curve at RT for CF-3 or CF-8 materials is expressed as

$$
\begin{equation*}
\mathrm{C}=49\left[\mathrm{C}_{\mathrm{V}}\right]^{0.52} ; \tag{27}
\end{equation*}
$$

for CF-8M materials with RT Charpy impact energy values $\geq 35 \mathrm{~J} / \mathrm{cm}^{2}$, it is expressed as

$$
\begin{equation*}
\mathrm{C}=16\left[\mathrm{C}_{\mathrm{V}}\right]^{0.67} \tag{28}
\end{equation*}
$$

and for CF-8M materials with RT Charpy impact energy values $<35 \mathrm{~J} / \mathrm{cm}^{2}$, it is expressed as

$$
\begin{equation*}
\mathrm{C}=1.44\left[\mathrm{C}_{\mathrm{V}}\right]^{1.35} \tag{29}
\end{equation*}
$$

For static-cast CASS materials, the coefficient C of the J-R curve at $290-320^{\circ} \mathrm{C}$ for $\mathrm{CF}-3$ or CF-8 materials is expressed as

$$
\begin{equation*}
\mathrm{C}=102\left[\mathrm{C}_{\mathrm{V}}\right]^{0.28} \tag{30}
\end{equation*}
$$

for CF-8M materials with RT Charpy impact energy values of $\geq 46 \mathrm{~J} / \mathrm{cm}^{2}$, it is expressed as

$$
\begin{equation*}
\mathrm{C}=49\left[\mathrm{C}_{\mathrm{V}}\right]^{0.41} \tag{31}
\end{equation*}
$$

and for CF-8m materials with RT Charpy impact energy values $<46 \mathrm{~J} / \mathrm{cm}^{2}$, it is expressed as

$$
\begin{equation*}
\mathrm{C}=5.5\left[\mathrm{C}_{\mathrm{V}}\right]^{0.98} \tag{32}
\end{equation*}
$$

For centrifugally cast CASS materials, the coefficient C of the J-R curve at RT for CF-3 or CF-8 materials is expressed as

$$
\begin{equation*}
C=57\left[C_{V}\right]^{0.52} \tag{33}
\end{equation*}
$$

for CF-8M materials with RT Charpy impact energy values $\geq 35 \mathrm{~J} / \mathrm{cm}^{2}$, it is expressed as

$$
\begin{equation*}
\mathrm{C}=20\left[\mathrm{C}_{\mathrm{V}}\right]^{0.67} ; \tag{34}
\end{equation*}
$$

and for CF-8M materials with RT Charpy impact energy values of $<35 \mathrm{~J} / \mathrm{cm}^{2}$, it is expressed as

$$
\begin{equation*}
C=1.78\left[C_{V}\right]^{1.35} . \tag{35}
\end{equation*}
$$

For centrifugally cast CASS materials, the coefficient C of the J-R curve at $290-320^{\circ} \mathrm{C}$ for CF-3 or CF-8 materials is expressed as

$$
\begin{equation*}
\mathrm{C}=134\left[\mathrm{C}_{\mathrm{V}}\right]^{0.28} \tag{36}
\end{equation*}
$$

for CF-8M materials with RT Charpy impact energy values $\geq 41 \mathrm{~J} / \mathrm{cm}^{2}$, it is expressed as

$$
\begin{equation*}
\mathrm{C}=57\left[\mathrm{C}_{\mathrm{V}}\right]^{0.41} \tag{37}
\end{equation*}
$$

and for CF-8M materials with RT Charpy impact energy values $<41 \mathrm{~J} / \mathrm{cm}^{2}$, it is expressed as

$$
\begin{equation*}
\mathrm{C}=6.9\left[\mathrm{C}_{\mathrm{V}}\right]^{0.98} . \tag{38}
\end{equation*}
$$

The distribution of the value of the power-law J-R curve exponent, n , for various grades of thermally aged and unaged CASS materials is shown in Fig. 20. The available database consists of 129 fracture toughness J-R curve tests at RT and 141 tests at reactor temperatures

Figure 20. Distribution of the J-R curve exponent for various grades of thermally aged and unaged CASS materials at (a) room temperature and (b) $290-325^{\circ} \mathrm{C}$.
of $290-325^{\circ} \mathrm{C}$. In general, the exponent n is higher at RT than at reactor temperatures. The median value is 0.55 at RT and 0.50 at $290-325^{\circ} \mathrm{C}$. The results show that only about $4 \%$ of the values at reactor temperature and less than $2 \%$ of them at RT are below a value of 0.33 . However, an investigation of the thermal embrittlement of CASS materials at EdF indicated that exponent n of the power-law J-R curve can be as low as 0.2 for some heats of CF-8 and CF-8M materials, particularly at reactor temperatures.*

The exponent n of the power-law J-R curve has also been correlated with the RT Charpy-impact energy $\mathrm{C}_{\mathrm{V}}$. In NUREG/CF-4513, Rev. 1, to ensure that the estimated J-R curves were conservative, the correlations between exponent $n$ and the corresponding RT Charpy-impact energy for the same material condition represented the lower-bound values of $n$. The updated data for the RT Charpy-impact energy and the corresponding value of fracture toughness J-R curve exponent n at RT and $290-325^{\circ} \mathrm{C}$, for CF-3, CF-8, and CF-8M CASS materials, are plotted in Fig. 21. A review of the updated fracture toughness data indicates that some of the recent data are below the correlations in NUREG/CR-4513, Rev. 1,16 between exponent n and RT Charpy-impact energy. Consequently, the correlations ${ }^{16}$ for estimating the J-R curve exponent $n$ have been revised; the updated correlations are slightly lower. The revised correlations representing the lower-bound values are shown in the Fig. 21.

For static-cast or centrifugally cast CASS materials, the exponent n at RT for CF-3 materials is

$$
\begin{equation*}
\mathrm{n}=0.16+0.13 \log _{10}\left[\mathrm{C}_{\mathrm{V}}\right] ; \tag{39}
\end{equation*}
$$

[^6]

Figure 21. Correlation between the RT Charpy-impact energy and exponent $n$ of the power-law J-R curve at RT and $290^{\circ} \mathrm{C}$ for CF-8M materials. The solid line bounds the existing data for exponent $n$ as a function of RT Charpy-impact energy.
for CF-8 materials, it is

$$
\begin{equation*}
\mathrm{n}=0.18+0.10 \log _{10}\left[\mathrm{C}_{\mathrm{V}}\right] \tag{40}
\end{equation*}
$$

and for CF-8M materials, it is

$$
\begin{equation*}
\mathrm{n}=0.20+0.08 \log _{10}\left[\mathrm{C}_{\mathrm{V}}\right] \tag{41}
\end{equation*}
$$

For static-cast or centrifugally cast CASS materials, the exponent n at $290-320^{\circ} \mathrm{C}$ for $\mathrm{CF}-3$ materials is

$$
\begin{equation*}
\mathrm{n}=0.15+0.12 \log _{10}\left[\mathrm{C}_{\mathrm{V}}\right] \tag{42}
\end{equation*}
$$

for CF-8 materials, it is

$$
\begin{equation*}
\mathrm{n}=0.17+0.09 \log _{10}\left[\mathrm{C}_{\mathrm{V}}\right] ; \tag{43}
\end{equation*}
$$

and for CF-8M materials, it is

$$
\begin{equation*}
\mathrm{n}=0.19+0.07 \log _{10}\left[\mathrm{C}_{\mathrm{V}}\right] . \tag{44}
\end{equation*}
$$

Equations 27-44 may be used to determine the fracture toughness J-R curve of static- or centrifugally cast CF-3, CF-8, and CF-8M CASS materials from the RT Charpy-impact energy of the material. If the RT Charpy-impact energy is not known, then the saturation fracture toughness J-R curves for these CASS materials can be determined from their chemical composition available in the CMTRs using Eqs. 18-26 and Eqs. 27-44. The following observations can be drawn from this study of thermal embrittlement of CASS materials: ${ }^{49}$
(a) Among the grades considered, CF-8M materials have the smallest $J_{d}$ value for a given crack extension. The value of $J_{d}$ at a given crack extension for CF-8M materials is generally about half of that of the other grades.
(b) CF-3, CF-3A, CF-8, and CF-8A materials show a similar extent of thermal aging. The value of $J_{d}$ at a given crack extension for CF-8 and CF-8A materials is generally less than 10\% lower than that for CF-3 and CF-3A materials.
(c) Static-cast CASS materials are more susceptible to thermal aging than are the centrifugally cast materials. The value of $J_{d}$ at a given crack extension for static-cast SS is generally about $20 \%$ lower than that for the centrifugally cast material with a similar ferrite content.
(d) Although CF-8M materials show a similar extent of thermal aging on the fracture toughness J-R curve both at RT and at the reactor operating temperature, the value of $J_{d}$ at a given crack extension for CF-3, CF-3A, CF-8, and CF-8A materials is generally about $20 \%$ lower at the reactor temperature than at RT.

These correlations are valid for static-cast and centrifugally cast CF-3, CF-3A, CF-8, CF-8A, and CF-8M materials defined by ASTM Specification A351. The criteria used in developing these correlations ensure that the estimated mechanical properties are adequately conservative for compositions of CASS materials within ASTM A351. The updated correlations are applicable to all compositions of CF-8M materials, including materials with ferrite contents above $25 \%$. However, in the updated database, there were little or no fracture toughness J-R curve data for CF-3 and CF-8 materials with a $\mathrm{C}_{\mathrm{Vsat}}$ of less than $30 \mathrm{~J} / \mathrm{cm}^{2}$ ( $17.7 \mathrm{ft}-\mathrm{lb}$ ). Therefore, the correlations presented in this report may not be applicable to those compositions of CF-3
and CF-8 materials for which the estimated value of $\mathrm{C}_{\mathrm{V} \text { sat }}$ is less than $30 \mathrm{~J} / \mathrm{cm}^{2}(<17.7 \mathrm{ft}-\mathrm{lb})$. Typically, such compositions would contain more than $30 \%$ ferrite. Furthermore, the correlations may not encompass all metallurgical factors that can arise from differences in production heat treatment or casting processes and may be overly conservative.

Note that these correlations account for the degradation of the mechanical properties of typical heats of CASS materials. They do not consider the initial fracture properties of the unaged material. Some CASS materials may have low initial fracture toughness, and the estimated J-R curves may be higher than the initial value. Therefore, some knowledge about the initial fracture toughness of the material is needed to justify the use of the estimated fracture toughness. The initial fracture toughness J-R curves may be estimated from the RT Charpyimpact energy of the unaged material.

Flaw tolerance methods are often used to develop ASME Code Section XI flaw acceptance standards or to justify alternatives to the ASME Code Section XI in-service inspection (ISI) requirements. Recently, EPRI Report 1019128 (December 2009), ${ }^{78}$ presented a flaw tolerance approach based on elastic-plastic fracture mechanics considerations that could be used in combination with a demonstrated inspection method for managing the effects of the aging of CASS piping, particularly piping containing more than $20 \%$ ferrite content. The sources of the CASS data included (a) information obtained from a Westinghouse data search based on a random sampling of heats of CASS material from 15 plants (Table 3) and (b) data packages

Table 3. Primary circuit piping CASS material in Westinghouse plants (Ref. 78).

from the Sandusky Foundry and Machine Co., NUREG/CR-5024, and Structural Integrity Associates. The CASS data were used to estimate the ferrite contents of a representative sample of CASS CF-3, CF-8, CF-8A, and CF-8M materials and to perform statistical analyses to study the distribution of the ferrite contents of these materials. When information for the Mo and N contents was not available, values of 0.5 and 0.04 (wt. \%), respectively, were assumed.

The results yielded mean ferrite content and standard deviation values of $15.9 \%$ and $4.9 \%$ for CF-8 material (total of 333 data points) and $17.6 \%$ and $5.4 \%$ for CF-8M material (total of 147 data points). The total amounts of data for CF-3 were too small (fewer than 15 data points) to provide meaningful estimates. The distribution of the ferrite content for CF-8M materials (Fig. 22) indicated that nearly 9\% of the heats of CF-8M material contained more than $25 \%$ ferrite. Therefore, the updated correlations presented in this report would be applicable to these heats of CF-8M material that are currently used in the U.S. PWRs. The expressions presented in Eqs. 27-38 are valid for CF-3, CF-8, and CF-8M materials with ferrite contents of up to 40\%.

Figure 22. Distribution of ferrite content in CASS grades of (a) CF-8, (b) CF-8A, (c) CF8M, and (d) CF-3 piping material in Westinghouse PWRs (Ref. 78).

### 2.4.3.1 Potential Effects of Reactor Coolant Environment

The potential effects of a simulated BWR primary coolant environment on the fracture toughness of sensitized Type 304 SS at 98 and $288^{\circ} \mathrm{C}$ were investigated by Nakajima et al. at displacement rates of $0.5,0.01$, and $0.001 \mathrm{~mm} / \mathrm{min} .{ }^{79}$ The fracture toughness J-R curve tests at $98^{\circ} \mathrm{C}$ were conducted air-saturated water, and the tests at $288^{\circ} \mathrm{C}$ were conducted in water containing 0.2 parts per million (ppm) or 8 ppm dissolved oxygen (DO). Three-point-bend specimens were used for the tests at $98^{\circ} \mathrm{C}$ and $1-\mathrm{T}$ compact tension specimens at $288^{\circ} \mathrm{C}$. The specimens were sensitized by being heat-treated at $650^{\circ} \mathrm{C}$ for $0.5,1$, 2 , and 4 h ; heat treatment for 2 h at $650^{\circ} \mathrm{C}$ was considered the standard sensitized condition. The experimental fracture toughness J-R curves at 98 and $288^{\circ} \mathrm{C}$ for several displacement rates in air and water environments are shown in Fig. 23. The results indicate no effect of displacement rate for the as-received Type 304 SS. However, for the sensitized material in water environment, the fracture toughness $J$ decreased with a decreasing displacement rate and an increasing degree of sensitization. At $288^{\circ} \mathrm{C}$, the effect of the water environment increased with an increasing DO in the environment. The fracture toughness J-R curves obtained at a $0.01 \mathrm{~mm} / \mathrm{min}$ extension rate are representative of a typical fracture toughness J-R curve test. In the ANL studies on CASS materials, the J-R curve tests were conducted at an extension rate of about $0.02 \mathrm{~mm} / \mathrm{min}$.

Figure 23. Fracture toughness J-R curves for sensitized Type 304 SS in simulated BWR coolant at $288^{\circ} \mathrm{C}$ and three different displacement rates (Ref. 79).

Potential effects of reactor coolant environment on fracture toughness have also been studied at ANL for neutron-irradiated wrought and cast austenitic SSs. ${ }^{47}$ The results indicate that the effect of the environment may be insignificant for materials with poor fracture toughness (e.g., irradiated SSs or thermally aged CASS materials with $\mathrm{J}_{\mathrm{Ic}}$ values below $200 \mathrm{~kJ} / \mathrm{m}^{2}$ ). However, a recent scoping study on low-temperature crack propagation (LTCP) for thermally aged CASS CF-8 material in PWR environments showed that the fracture toughness J-R curve is generally lower in PWR water than in air, and it is significantly lower in PWR shutdown water chemistry at $54^{\circ} \mathrm{C}$ than in air..$^{80}$ Fracture toughness J-R curve tests were conducted in air on 1T CT specimens of CF-8 material (ANL Heat 68) that was thermally aged for about 138,000 h (about 15.8 years) at $350^{\circ} \mathrm{C}$. The ferrite content calculated from Hull's equivalent factors was $15 \%$; it was $23 \%$ when measured by a Feritescope. The specimens were either fatigue precracked in air at $54^{\circ} \mathrm{C}$ or were fatigue-plus-SCC precracked in PWR water at $315^{\circ} \mathrm{C}$. The fracture toughness J-R curve data for these tests are shown in Fig. 24. Note that one of the specimens that was precracked in PWR water at $315^{\circ} \mathrm{C}$ was inadvertently tested at an elevated
temperature of $315^{\circ} \mathrm{C}$ in PWR primary water chemistry. The updated lower-bound J-R curve at RT for CF-8 material with 15-25\% ferrite is also shown in the figure for comparison.

The results indicate that at $54^{\circ} \mathrm{C}$, the J-R curve data in air are bounded, with an additional margin, by the updated lower-bound J-R curve. However, the J-R curve data for specimens precracked in air at $54^{\circ} \mathrm{C}$ and then tested in PWR shutdown water chemistry at $54^{\circ} \mathrm{C}$ are significantly below the lower-bound curve. The fractography of the test specimens show multiple fracture planes that are distinct from the primary plane established by the fatigue precrack. These results indicate an apparently large effect from the coolant environment on the fracture toughness; every material and test condition are identical for the two sets of duplicate tests, except one specimen is tested in air and the other in water. The specimens that are precracked in PWR water at $315^{\circ} \mathrm{C}$ and then tested in PWR water at $54^{\circ} \mathrm{C}$ or $315^{\circ} \mathrm{C}$ also show reduced fracture toughness relative to those tested in air, but the difference is less. The J-R curve data for the specimen that are cooled down from $315^{\circ} \mathrm{C}$ and tested at $54^{\circ} \mathrm{C}$ shutdown water chemistry are only marginally below the lower-bound J-R curve, and the data for the specimen that are precracked and tested at $315^{\circ} \mathrm{C}$ PWR primary water chemistry are slightly above the lower-bound curve.

Figure 24. Fracture toughness J-R curve data for thermally aged Heat 68 of CF-8M plate at $54^{\circ} \mathrm{C}$. The curve represents the lower bound curve at RT for static-cast CF-8 material (Ref. 80).

The large reduction in fracture toughness of the aged CASS CF-8 material is attributed to potential synergy between hydrogen embrittlement from LTCP and thermal embrittlement associated with decomposition of the ferrite at reactor temperatures. ${ }^{80}$ The authors recommended that the multiple fracture paths during J-R curve testing should be examined to determine whether any microstructural features are associated with such behavior.

A similar low-fracture-toughness behavior has also been observed for Alloys 600 and 690 in hydrogenated water at $54^{\circ} \mathrm{C}$ and at low displacement rates (i.e., under quasi-static conditions). ${ }^{81,82}$ For Alloy 600 , the $J_{\mathrm{Ic}}$ value obtained at a displacement rate of $0.05 \mathrm{~mm} / \mathrm{h}$ is $30 \%$ lower in hydrogenated water at $54-149^{\circ} \mathrm{C}$ than in air. ${ }^{81}$ For Alloy 690 tested in hydrogenated water at $54^{\circ} \mathrm{C}$, the fracture toughness $\mathrm{J}_{\mathrm{Ic}}$ obtained at displacement rates of 0.005 to $15 \mathrm{~mm} / \mathrm{h}$ is a factor of 16 lower than that observed at a displacement rate of $305 \mathrm{~mm} / \mathrm{h} .82$ The significant decrease in fracture toughness under a simulated PWR shutdown water chemistry has been attributed to hydrogen-induced intergranular cracking.

These results indicate that environment can further decrease the fracture toughness of materials relative to the fracture toughness obtained in air. For some heats of wrought and cast austenitic SSs and welds, some values of fracture toughness in coolant environments are likely to be below the lower-bound trend curve. In particular, the fracture toughness data for unirradiated, aged CF-8 material in a PWR SWC environment at $54^{\circ} \mathrm{C}$ are significantly lower because of the potential synergy between the hydrogen embrittlement and thermal embrittlement associated with the spinodal decomposition of the ferrite. However, it is not clear whether the large reduction in the fracture toughness of thermally aged CASS materials is unique and associated with PWR SWC conditions or it can occur under other low-temperature LWR environments. Therefore, the minimum acceptable fracture toughness $\mathrm{J}_{\mathrm{Ic}}$ values for thermally aged CASS materials in LWR environments at temperatures less than $100^{\circ} \mathrm{C}$ are needed to establish the possible effects of LWR coolant environments on the thermal embrittlement of CASS materials.

### 2.4.3.2 Potential Effects of High Loading Rate

Typically, the fracture toughness of wrought SSs increases with increases in the loading rate. The limited data on the effect of the loading rate on the fracture toughness of CASS materials are somewhat inconsistent. Fracture toughness tests on a high-ferrite-content CF-3 material in the as-cast and aged conditions at three loading rates at RT and $300^{\circ} \mathrm{C}$ show no significant variation for the as-cast material with an increasing strain rate, either at RT or at $300^{\circ} \mathrm{C} .{ }^{83}$ However, for the RT tests on aged material, increasing the loading rate resulted in an increase in $J_{c}$ but a decrease in the slope, $\mathrm{dJ} / \mathrm{da}$, of the $\mathrm{J}-\mathrm{R}$ curve. The slowest loading rate was a quasistatic rate typical of J-integral testing. The second rate was approximately three orders of magnitude faster, and the highest rate was about one additional order of magnitude faster. Similarly, fracture toughness tests on CF-3M material ( $16 \%$ ferrite) aged for 1000 h at $500^{\circ} \mathrm{C}$ and tested at $0^{\circ} \mathrm{C}$ showed that increasing the loading rate reduced the crack initiation $\left(\mathrm{J}_{\mathrm{C}}\right)$ as well as the slope of the J-R curve to about $18 \%$ of the values for quasi-static loading (Fig. 25). ${ }^{84}$

Figure 25.
Fracture toughness J-R curves for thermally aged CF-3M at $0^{\circ} \mathrm{C}$ and quasi-static and dynamic loading rates (Ref. 84).

These limited data that indicate that an inverse loading rate affects the fracture toughness for thermally aged CASS materials need to be investigated further to determine the potential decrease in fracture toughness at loading rates that are associated with typical seismic activity.

### 2.5 Methodology for Estimating Thermal Embrittlement of CASS Materials

A flow diagram for estimating mechanical properties of CASS materials during reactor service is shown in Fig. 26. The estimation scheme is divided into three sections based on available material information. In Section A of the flow diagram, "predicted lower-bound" fracture toughness is defined for CF-3, CF-8, and CF-8M materials of unknown composition (i.e., when CMTR is not available). For materials with an unknown composition, when the ferrite content of the steel is known, a different lower-bound fracture toughness and impact energy are defined for materials containing $<10 \%,>10-15 \%,>15-20 \%,>25-30 \%$, or $>30-40 \%$ ferrite. However, as discussed earlier in Section 2.2, it is important to make sure that the value of the ferrite content used in the estimation scheme is representative of the material.

Estimate for known composition and service history
Figure 26. Flow diagram for estimating mechanical properties of thermally aged CASS materials in LWR systems.

Sections B and C of the flow diagram describe the methodology for estimating mechanical properties when a CMTR is available (i.e., the chemical composition of the CASS material is known). Section B describes the estimation of the "saturation" impact energy and fracture toughness J-R curve. The only information needed for these estimates is the chemical composition of the material, which is used to estimate the saturation J-R curve for the thermally aged material. However, the correlations presented in this report account for the degradation of mechanical properties due to thermal aging; they do not explicitly consider the initial fracture properties of the unaged material. Some heats of CASS materials may be inherently weak and have poor fracture properties in the unaged condition. For such materials, the estimated saturation fracture toughness based on the proposed methodology may be higher than the fracture toughness of the unaged material. Therefore, it is important to have some information about the fracture toughness of the unaged material. The material fracture toughness is generally not available in the CMTR. It can be estimated by using the expressions presented in Fig. 19 from the initial RT Charpy-impact energy of the unaged material, if known.

The available fracture toughness J-R curve data at $290-320^{\circ} \mathrm{C}$ (554-608으) for unaged CASS materials are shown in Fig. 27a and the J-R curves for several heats of wrought Type 304 and 316 SSs ${ }^{19,77,85-88}$ are shown in Fig. 27b. The results indicate that the J-R curves for a few "weak" heats of static-cast CASS materials are lower than for wrought austenitic SSs. Therefore, the saturation fracture toughness properties that should be used for design analyses for thermally aged CASS materials depend on whether or not the estimated saturation fracture toughness is lower than the initial fracture toughness of the unaged materials. The initial fracture toughness of the material can be estimated from its RT Charpy-impact energy.

However, the fracture toughness of the CASS material is not available in CMTRs. Two different options are used to establish the saturation fracture toughness of the thermally aged material. In the first option, the initial RT Charpy-impact energy of the unaged material is known, and this value is used to estimate the initial fracture toughness of the material. CASS materials with poor fracture properties are relatively insensitive to thermal aging, and the fracture toughness of the material due to thermal aging during reactor service typically does not change significantly.

Figure 27. Predicted and measured fracture toughness J-R curves for unaged materials (a) CASS at $290-320^{\circ} \mathrm{C}$ and (b) wrought austenitic SSs at various temperatures (Refs. 19,77,85-88).

Therefore, if the estimated saturation fracture toughness of the aged material is higher than the fracture toughness of the unaged material, the latter is used as the worst-case toughness for that material.

In the second option, the initial RT Charpy-impact energy is not known; therefore, the minimum fracture toughness of all unaged heats and heat treatment conditions for CASS materials is used as an upper bound for the estimated fracture toughness. This minimum upper-bound fracture toughness of unaged CASS materials is used as the worst-case fracture toughness for the material if the estimated saturation fracture-toughness of thermally aged material is higher. Typically, the fracture toughness of unaged CASS materials is slightly higher at RT than it is at $290-320^{\circ} \mathrm{C}$. However, for convenience, the minimum fracture toughness of unaged static-cast CASS materials at temperatures between RT and $320^{\circ} \mathrm{C}$ can be expressed as

$$
\begin{equation*}
\mathrm{J}_{\mathrm{d}}=400[\Delta \mathrm{a}]^{0.40} \tag{45}
\end{equation*}
$$

and that of centrifugally cast CASS materials can be expressed as

$$
\begin{equation*}
\mathrm{J}_{\mathrm{d}}=550[\Delta \mathrm{a}]^{0.43} \tag{46}
\end{equation*}
$$

Based on the recent data from Japan, the lower-bound J-R curve for unaged centrifugally cast material has been decreased relative to the original curve in NUREG/CR-4513, Rev. 1. The estimation of mechanical properties at any given time and temperature of service (i.e., service time properties) is described in Section C of the flow diagram. The initial impact energy of the unaged material is required for these estimates. If this is not known, the initial impact energy of $200 \mathrm{~J} / \mathrm{cm}^{2}(118 \mathrm{ft}-\mathrm{lb})$ is assumed. However, similar to the procedure in Section B of the flow diagram, the initial fracture toughness of the unaged material or the minimum fracture toughness of unaged CASS materials is used as an upper bound for the estimates.

The methodology for estimating fracture toughness of thermally aged CASS materials presented in this report can be used to estimate the fracture toughness J-R curves at RT $\left(25^{\circ} \mathrm{C}\right)$ or reactor temperatures $\left(290-320^{\circ} \mathrm{C}\right)$. Fracture toughness J values at temperatures between 25 and $290^{\circ} \mathrm{C}$ can be obtained from a linear interpolation of the values at 25 and $290^{\circ} \mathrm{C}$ ( 77 and $608^{\circ} \mathrm{F}$ ).

The initial tensile properties of the unaged material are needed for estimating the tensile strength and Ramberg/Osgood strain hardening parameters. If the initial flow stress of the CASS material is known, the $\mathrm{J}_{\mathrm{Ic}}$ value and tearing modulus of the thermally aged material can then be determined from the estimated values of the J-R curve and flow stress of the aged material.

However, as mentioned earlier, the above methodology for estimating fracture toughness of CASS materials in reactor service is not applicable to CF-8M materials that have more than a trace amount of Nb. The chemical requirements for ASTM Specification A351 or A451 do not specify any upper limit for Nb. Typically, CF-8M steels contain only trace amounts of Nb. However, the Nb content could be high in castings produced by using Type 347 scrap metal. For example, in the ANL study, the measured RT Charpy-impact energy of a thermally aged heat of CF-8M steel containing about $23 \%$ ferrite and $0.2 \% \mathrm{Nb}$ was significantly lower than that predicted from the above methodology. The fracture surface of the Charpy specimen showed that the phase boundaries were decorated with large Nb carbide particles that cracked easily. Therefore, for CF-8M materials with more than $15 \%$ ferrite, it would be advisable to determine the Nb content of the material and take appropriate actions if that content is $0.1 \%$ or higher.

The above methodology only accounts for the thermal embrittlement of CASS materials and is therefore applicable to materials outside the reactor core. It does not consider the effects of neutron embrittlement or the synergism between thermal and neutron embrittlement. For core internal components, which have a prolonged exposure both to elevated temperatures and to neutron radiation, the combined effects of thermal and neutron irradiation need to be evaluated. An acceptable approach for estimating the fracture toughness of CASS materials used in the reactor core is presented in Section 5 of this report.

## 3 ASSESSMENT OF THERMAL EMBRITTLEMENT

### 3.1 Estimation of Thermal Embrittlement of CASS Materials of Known Composition and Service Condition - Service Time Values

The RT Charpy-impact energy of a specific CASS material as a function of service time and temperature can be obtained from estimated $\mathrm{C}_{\text {ssat }}$ (Eqs. 3-5 and 18-26) and the kinetics of embrittlement (Eqs. 11,13-17). A value of 2.9 for $\theta$ was assumed for all thermal aging conditions. The initial Charpy-impact energy, $\mathrm{C}_{\text {Vint }}$, of the unaged steel is also needed for estimating the decrease in impact energy. If this is not known, a typical value of $200 \mathrm{~J} / \mathrm{cm}^{2}$ ( $118 \mathrm{ft}-\mathrm{lb}$ ) is assumed. The RT Charpy-impact energy observed experimentally and that estimated from the chemical composition and initial impact energy of the CASS materials are presented in Figs. 19 and 20 of NUREG/CR-4513, Rev. 1. For convenience, these figures in NUREG/CR-4513 Rev. 1 are reproduced in Appendix B of this report.

The results indicated that in general, the estimates of RT Charpy-impact energy at aging temperatures of $\leq 330^{\circ} \mathrm{C}\left(\leq 626^{\circ} \mathrm{F}\right.$ ) were either accurate or conservative for all grades of CASS materials. A few heats showed poor agreement because either the estimated $\mathrm{C}_{\mathrm{V} \text { sat }}$ was higher than the experimental value (FRA Heat D and ANL Heat 47) or the estimated activation energy was high (FRA Heat C and GF Heat 278). Even at $350^{\circ} \mathrm{C}$, because the $\theta$ values for most of the heats were either greater than or only slightly lower than 2.9 , the estimated values of RT Charpy-impact energy showed good agreement with the experimental results. The EPRI heat and an EdF heat (experimental $\theta$ is 2.1 for both heats) alone show nonconservative estimates, at $350^{\circ} \mathrm{C}$. Therefore, to ensure that the estimates are conservative, a $\theta$ value of 2.5 rather than 2.9 should be used at $330-360^{\circ} \mathrm{C}\left(626-680^{\circ} \mathrm{F}\right)$.

Once the RT Charpy-impact energy, $\mathrm{C}_{\mathrm{V}}$, is known, the service-time coefficient C and exponent $n$ of the fracture toughness J-R curve are determined from Eqs. 27-38 and 39-44, respectively. The variation in the experimental values of coefficient $C$ as a function of aging time and temperature is compared with that estimated from the methodology proposed in this report (i.e., material composition and the initial RT Charpy-impact energy) for at least one heat each of CF-3, CF-8, and CF-8M material in Figs. 28-31. As discussed earlier for the estimated values of RT Charpy-impact energy, the results indicate that at reactor operating temperatures (i.e., $280-350^{\circ} \mathrm{C}$ ), the estimated change in the fracture toughness coefficient C with the aging time is either accurate or slightly conservative for all grades of CASS material.

The methodology and expressions for estimating the changes in (a) tensile flow and yield stresses and (b) the engineering stress-strain curve of CASS materials, as a function of time and temperature of service are described in NUREG/CR-6142.18 The tensile properties of aged CASS materials are determined from known material information (i.e., chemical composition and initial tensile strength of the steel). The fracture toughness $J_{\mathrm{lc}}$ values for the service-aged CASS material can be determined from the estimated values of the fracture toughness J-R curve and flow stress.

The proposed methodology can be used to estimate the change in fracture toughness of CASS materials for known material composition and service conditions, particularly for service temperatures of $280-350^{\circ} \mathrm{C}\left(536-662^{\circ} \mathrm{F}\right)$. Examples of experimental and estimated fracture toughness J-R curves for several CF-3, CF-8, and CF-8M materials thermally aged for 30,000 h at $350^{\circ} \mathrm{C}$ or for 50,000 or $53,000 \mathrm{~h}$ at $320^{\circ} \mathrm{C}$ ) are shown in Figs. $32-38$. Relative to the experimental results, the estimated J-R curves are either accurate or slightly conservative.

### 3.2 Estimation of the Thermal Embrittlement of CASS Materials of Unknown Composition: Lower-Bound Values

The ANL methodology provides the expressions for estimating fracture toughness J-R curves of unaged and aged CASS materials as a function of the estimated RT Charpy-impact energy; which, in turn, is determined from the a material parameter that depends on the chemical composition and ferrite content of the material. However, for convenience, lower bound J-R curves are defined as a function of ferrite content in the CASS material. These curves bound at least $95 \%$ of the data. The fracture toughness J-R curve is defined by the power-law relationship $J_{d}=C \Delta a^{n}$, where $J_{d}$ is deformation J per ASTM Specifications E 813-85 and E $1152-87, \Delta a$ is a crack extension, and $C$ and $n$ are constants. The coefficient $C$ and exponent $n$ for the lower-bound fracture toughness J-R curve are determined from the bounding value of $\mathrm{C}_{\text {Vsat }}$ for a range of ferrite contents in the CASS material.

First the bounding values of the saturation RT Charpy-impact energy, $\mathrm{C}_{\text {vsat, }}$, for ferrite contents $<10 \%,>10-15 \%,>15-20 \%,>20-25 \%,>25-30 \%$, and $>30-40 \%$ are established for each grade of CASS material from the plots of estimated $\mathrm{C}_{\mathrm{V} \text { sat }}$ and ferrite content, as shown in Fig. 39. The

Figure 39. Correlation between saturation RT Charpy-impact energy and ferrite content.

Figure 39. (Contd.)
RT $C_{V s a t}$ for the different grades of CASS materials is the lower value determined from the sets of expressions given in Eqs. 18-26. Separate expressions are proposed for CF-8M materials containing $<10 \% \mathrm{Ni}$ and those containing $\geq 10 \% \mathrm{Ni}$. The latter are most susceptible to thermal embrittlement than the other grades.

Note that the estimated and not measured value of RT Charpy-impact energy is used in this methodology because a value that is representative of a casting would require tests on several specimens taken from different portions of the casting. This may not be always possible. The estimated $\mathrm{C}_{V \text { sat }}$ and the corresponding values of coefficient C and exponent n of the J-R curve at RT and $290-320^{\circ} \mathrm{C}\left(550-608^{\circ} \mathrm{F}\right)$ for CF-3, CF-8, and CF-8M with $<10$ and $\geq 10 \% \mathrm{Ni}$ and various ranges of ferrite content are listed in Table 4. The estimated lower-bound J-R curves at RT and at $290-320^{\circ} \mathrm{C}$ for some of the ferrite ranges, are shown in Figs. 40 and 41, respectively, for static-cast materials, and in Figs. 42 and 43, respectively, for centrifugally cast material. These plots are updated versions of Figs. 3 and 4 of NUREG/CR-4513, Rev. 1.16 The lowerbound fracture toughness J-R curves can be used for completely embrittled CASS materials of unknown composition.

### 3.3 Screening Criteria for Susceptibility of CASS Materials to Thermal Embrittlement

An EPRI report on the thermal aging embrittlement of CASS components proposed using the $J$ value at a crack extension of 2.5 mm ( 0.1 in .), $\mathrm{J}_{2.5}$, to differentiate between nonsignificant and potentially significant reductions in the fracture toughness of thermally aged CASS materials. ${ }^{50}$ Flaw tolerance evaluations were presented in Appendices $A$ and $B$ of the EPRI report to support the choice of a threshold value of $\mathrm{J}_{2.5}=255 \mathrm{~kJ} / \mathrm{m}^{2}\left(1456 \mathrm{in}\right.$.-lb/in. $\left.{ }^{2}\right)$. The NRC staff found that the use of $\mathrm{J}_{2.5}=255 \mathrm{~kJ} / \mathrm{m}^{2}$ as a screening approach for the fracture toughness of CASS materials is acceptable. ${ }^{51}$ The screening criteria to determine the susceptibility of CASS components to thermal aging embrittlement are outlined in Table 1.51

The expressions presented in Fig. 39 and the methodology described in Section 2.4.3 for estimating the corresponding fracture toughness J-R curve for the RT Charpy-impact energy trend curves in Fig. 39 can be used to check the validity of the ferrite content criteria given in

Figure 40. Estimated lower-bound J-R curves at RT for static-cast CASS materials with ferrite contents of $\mathbf{> 2 5} \mathbf{- 3 0 \%}, \mathbf{2 0} \mathbf{- 2 5 \%}$, and >15-20\%.

Figure 41. Estimated lower-bound J-R curves at $290-320^{\circ} \mathrm{C}$ for static-cast CASS materials with ferrite contents of $\mathbf{> 2 5} \mathbf{- 3 0 \%}$, $\mathbf{> 2 0} \mathbf{- 2 5 \%}$, and >15-20\%.

Figure 42. Estimated lower-bound J-R curves at RT for centrifugally cast CASS materials with ferrite contents of >25-30\%, >20-25\%, and >15-20\%.

Figure 43. Estimated lower-bound J-R curves at $290-320^{\circ} \mathrm{C}$ for centrifugally cast CASS materials with ferrite contents of $\mathbf{> 2 5}-30 \%$, $\mathbf{> 2 0} \mathbf{- 2 5 \%}$, and >15-20\%.

Table 1. The saturation $\mathrm{J}_{2.5}$ corresponding to the RT Charpy-impact energy trend curves in Fig. 39 are shown in Figs. 44 and 45 for static-cast and centrifugally cast materials, respectively. In these figures, the updated screening criterion is represented by the ferrite content when the $J_{2.5}$ value decreases below the acceptable threshold value of $255 \mathrm{~kJ} / \mathrm{m}^{2}$.

The results indicate that for CF-3 and CF-8 materials, values of $\mathrm{J}_{2.5}$ for both static-cast and centrifugally cast materials are significantly above the threshold value of $255 \mathrm{~kJ} / \mathrm{m}^{2}$. Therefore, the screening criterion that states that the reduction in fracture toughness due to thermal embrittlement of centrifugally cast CF-3 and CF-8 materials is "nonsignificant" is valid, and the criterion that the reduction in the fracture toughness of static-cast CF-3 and CF-8 materials is "significant" only for materials with more than $20 \%$ ferrite is a conservative criterion.

Figure 44. Saturation J at a 2.5 mm crack extension as a function of the ferrite content for static-cast CF-3, CF-8, and CF-8M CASS materials.

Figure 45. Saturation J at a 2.5 mm crack extension as a function of the ferrite content for centrifugally cast CF-3, CF-8, and CF-8M CASS materials.

The results for CF-8M steels with $<10 \%$ Ni indicate that the $\mathrm{J}_{2.5}$ values are above the $255 \mathrm{~kJ} / \mathrm{m}^{2}$ threshold value for static-cast materials with ferrite contents of $<16 \%$ and for centrifugally cast materials with ferrite contents of $<19 \%$. Therefore, the existing criterion that the reduction in the fracture toughness of static-cast CF-8M materials containing $<10 \% \mathrm{Ni}$ is "significant" only for materials with more than $14 \%$ ferrite is also a conservative criterion. However, for centrifugally cast CF-8M materials containing <10\% Ni, the threshold ferrite content above which the reduction in the fracture toughness of the material is considered "significant" should be decreased from $20 \%$ ferrite to $19 \%$ ferrite.

Similarly for CF-8M steels with $\geq 10 \% \mathrm{Ni}$, the $\mathrm{J}_{2.5}$ values are above the $255 \mathrm{~kJ} / \mathrm{m}^{2}$ threshold value for ferrite contents of $<11 \%$ for static-cast materials and $<13 \%$ for centrifugally cast
materials. Therefore, for CF-8M materials containing $\geq 10 \% \mathrm{Ni}$, the threshold ferrite content above which the reduction in the fracture toughness is considered "significant" should be decreased from $14 \%$ ferrite to $11 \%$ ferrite for static-cast materials and from $20 \%$ ferrite to $13 \%$ ferrite for centrifugally cast materials. The revised screening criteria for the thermal-aging susceptibility of CASS CF-3, CF-3M, CF-8, and CF-8M materials are given in Table 5. The screening criteria for the thermal-aging susceptibility of CASS materials that have been changed are as follows.
(i) The criterion for static-cast and centrifugally cast CF-8M materials with $\geq 10 \% \mathrm{Ni}$.
(ii) The criterion for centrifugally cast CF-8M materials with $<10 \% \mathrm{Ni}$.

Table 5. Updated screening criteria for thermal-aging susceptibility of CASS CF-3, CF-8, and CF-8M materials.

| Mo Content (wt.\%) | Casting Method | Ferrite Content (\%) | Susceptibility Determination |
| :---: | :---: | :---: | :---: |
| High $(2.0-3.0)$ <br> with $<10 \% \mathrm{Ni}(\geq 10 \% \mathrm{Ni})$ | Static | $\leq 14(\leq 11)$ | Not susceptible |
|  |  | $>14(>11)$ | Potentially susceptible |
|  | Centrifugal | $\leq 19(\leq 13)$ | Not susceptible |
|  |  | $>19(>13)$ | Potentially susceptible |
| Low (0.5 max.) | Static | $\leq 20$ | Not susceptible |
|  |  | $>20$ | Potentially susceptible |
|  | Centrifugal | All | Not susceptible |

### 3.4 Estimation of Tensile Flow Stress

This section is essentially the same as Section 3.4 of NUREG/CR-4513 Rev. 1. The tensile flow stress of aged CASS materials can be estimated from correlations between the ratio of the tensile flow stress of aged and unaged materials and a normalized aging parameter. Based on the analysis described in NUREG/CR-6142, the ratio of the tensile flow stress $\left(R_{f}\right)$ of aged and unaged CASS materials ( $\sigma_{\text {faged }} / \sigma_{\text {funaged }}$ ) is plotted as a function of a normalized aging parameter ( $\mathrm{P}-\theta+2.9$ ) in Fig. 46. Flow stress is defined as the mean of the $0.2 \%$ yield strength and ultimate strength, and the aging parameter is normalized with respect to a $\theta$ value of 2.9. In NUREG/CR-4513, Rev. 1, the aging parameter P was determined from Eq. 11 and experimental values of activation energy. The correlations between $R_{f}$ and the normalized aging parameter used for estimating flow stress were obtained by subtracting the value of the standard deviation for the fit to the data from the best-fit curve. At both RT and $290^{\circ} \mathrm{C}$, the $R_{f}$ increases with thermal aging; the increase in the flow stress of CF-3 steels is the smallest and the increase in the flow stress of CF-8M steels is the largest.

The tensile flow stress of aged CASS materials can be estimated from the initial tensile flow stress and the correlations given in Fig. 46. Note that the $x$-axis in these plots is reduced to $P$ for a $\theta$ value of 2.9. At RT, the tensile-flow-strength ratio, $R_{f}=\left(\sigma_{\text {faged }} / \sigma_{\text {funaged }}\right)$ for CF-3 steel is given by

$$
\begin{equation*}
R_{f}=0.90+0.05 P \quad\left(1.00 \leq R_{f} \leq 1.10\right) ; \tag{47}
\end{equation*}
$$

for CF-8 steel, it is given by

$$
\begin{equation*}
R_{f}=0.84+0.08 \mathrm{P} \tag{48}
\end{equation*}
$$

$$
\left(1.00 \leq R_{f} \leq 1.16\right) ;
$$

Figure 46. Flow stress ratio $R_{f}$ of aged CF-3, CF-8, and CF-8M materials at RT and $290^{\circ} \mathrm{C}$ as a function of the normalized aging parameter. The solid lines represent correlations obtained by subtracting $\sigma$ from the best-fit curve.
and for CF-8M steel, it is given by

$$
\begin{equation*}
R_{f}=0.77+0.10 P \quad\left(1.00 \leq R_{f} \leq 1.19\right) . \tag{49}
\end{equation*}
$$

At $290^{\circ} \mathrm{C}\left(554^{\circ} \mathrm{F}\right)$, the $\mathrm{R}_{\mathrm{f}}$ for $\mathrm{CF}-3$ steel is given by

$$
\begin{equation*}
R_{f}=0.87+0.06 P \quad\left(1.00 \leq R_{f} \leq 1.08\right) ; \tag{50}
\end{equation*}
$$

and for CF-8 steel, it is given by

$$
\begin{equation*}
R_{f}=0.83+0.09 P \quad\left(1.00 \leq R_{f} \leq 1.14\right) ; \tag{51}
\end{equation*}
$$

and for CF-8M steel, it is given by

$$
\begin{equation*}
R_{f}=0.69+0.14 P \quad\left(1.00 \leq R_{f} \leq 1.24\right) \tag{52}
\end{equation*}
$$

The minimum and maximum values of the ratio $R_{f}$ are given for each grade of steel and each temperature; a minimum or a maximum value is assumed, respectively, when the calculated ratio is smaller than the minimum ratio or greater than the maximum ratio.

Equations 50-52 are valid for service temperatures between 280 and $330^{\circ} \mathrm{C}\left(536\right.$ and $626^{\circ} \mathrm{F}$ ) and ferrite contents of $>7 \%$ for CF-8M steel and $>10 \%$ for CF-3 and CF-8 steels. Thermal aging has little or no effect on the tensile strength of CASS materials with low ferrite content. The available database is inadequate for estimating the tensile properties at service temperatures of $<280^{\circ} \mathrm{C}$ ( $<536^{\circ} \mathrm{F}$ ). The estimated values of tensile flow stress at $290^{\circ} \mathrm{C}\left(554^{\circ} \mathrm{F}\right.$ ) and at RT for various heats of aged CASS materials are obtained by first determining the aging parameter from Eq. 11, and activation energy form Eqs. 14-17 (using a $\theta$ value of 2.9). The tensile flow stress is then estimated from Eqs. 47-52 and the initial flow stress of the material. The fracture toughness $J_{\mathrm{Ic}}$ values for aged CASS materials is then determined from the estimated J-R curve and flow stress. Only the chemical composition, the initial Charpy-impact energy, and the flow stress of the unaged material are used for the estimates. The estimated $J_{\mathrm{Ic}}$ values show good agreement with the experimental results; in most cases, the estimated $\mathrm{J}_{\mathrm{Ic}}$ is lower but within $30 \%$ of the observed value. ${ }^{16}$

The data on the tensile properties of CASS materials indicate that the increase in yield strength due to thermal aging is much lower than the increase in ultimate strength. At RT, the tensile-yield-strength ratio $R_{y}=\left(\sigma_{\text {yaged }} / \sigma_{\text {yunaged }}\right)$ for CF-3 steel is given by

$$
\begin{equation*}
R_{y}=0.873+0.048 P \quad\left(1.00 \leq R_{y} \leq 1.07\right) ; \tag{53}
\end{equation*}
$$

for CF-8 steel, it is given by

$$
\begin{equation*}
R_{y}=0.798+0.076 P \quad\left(1.00 \leq R_{y} \leq 1.10\right) ; \tag{54}
\end{equation*}
$$

and for CF-8M steel, it is given by

$$
\begin{equation*}
R_{y}=0.708+0.092 P \quad\left(1.00 \leq R_{y} \leq 1.10\right) \tag{55}
\end{equation*}
$$

At $290^{\circ} \mathrm{C}\left(554^{\circ} \mathrm{F}\right)$, the tensile-yield-strength ratio $\mathrm{R}_{\mathrm{y}}=\left(\sigma_{\text {faged }} / \sigma_{\text {funaged }}\right)$ for CF-3 steel is given by

$$
\begin{equation*}
R_{y}=0.844+0.058 P \quad\left(1.00 \leq R_{y} \leq 1.05\right) ; \tag{56}
\end{equation*}
$$

for CF-8 steel, it is given by

$$
\begin{equation*}
R_{y}=0.788+0.086 P \quad\left(1.00 \leq R_{y} \leq 1.09\right) ; \tag{57}
\end{equation*}
$$

and for CF-8M steel, it is given by

$$
\begin{equation*}
R_{y}=0.635+0.129 P \quad\left(1.00 \leq R_{y} \leq 1.14\right) \tag{58}
\end{equation*}
$$

The minimum and maximum values of the tensile-yield-strength ratio $\mathrm{R}_{\mathrm{y}}$ are given for each grade of steel and temperature. Equations 56-58 are valid for service temperatures between 280 and $330^{\circ} \mathrm{C}\left(536\right.$ and $626^{\circ} \mathrm{F}$ ) and ferrite contents of $>7 \%$ for CF-8M steel and $>10 \%$ for CF-3 and CF-8 materials. Similar to the flow stress estimations, the aging parameter and activation energy are obtained from Eqs. 11 and $14-17$ and by using $\theta$ value of 2.9. Tensile yield strength is then estimated from Eqs. $56-58$ and the initial yield strength of the material. The results indicate that the estimated values are conservative for most material and aging conditions.

The engineering stress versus strain behavior of aged CASS materials can also be obtained from the estimated flow stress. ${ }^{18}$ The engineering stress-versus-strain curve is expressed by the Ramberg-Osgood equation

$$
\begin{equation*}
\frac{\varepsilon}{\varepsilon_{0}}=\frac{\sigma}{\sigma_{0}}+\alpha_{1}\left(\frac{\sigma}{\sigma_{0}}\right)^{n_{1}} \tag{59}
\end{equation*}
$$

where $\sigma$ and $\varepsilon$ are engineering stress and strain, respectively; $\sigma_{0}$ is an arbitrary reference stress, often assumed to be equal to the flow or yield stress; the reference strain $\varepsilon_{0}=\sigma_{0} / E ; \alpha_{1}$ and $\mathrm{n}_{1}$ are Ramberg-Osgood parameters; and E is the elastic modulus. The Ramberg-Osgood equation can be rearranged to the form

$$
\begin{equation*}
\frac{E \varepsilon-\sigma}{\sigma_{f}}=\alpha_{1}\left(\frac{\sigma}{\sigma_{f}}\right)^{n_{1}} \tag{60}
\end{equation*}
$$

which is more convenient for fitting stress-versus-strain data; $\alpha_{1}$ can be determined at $\sigma / \sigma_{f}=1$ and $n_{1}$ can be obtained from the slope of the log-log plot of Eq. 60. The parameter $n_{1}$ is different for the three grades of CASS materials but does not depend on the aging condition. The parameter $\alpha_{1}$ decreases with aging and shows good correlation with the flow stress $\sigma$. For engineering stress-versus-strain curves up to $5 \%$ strain, the Ramberg-Osgood parameters at RT for CF-3 materials are given by

$$
\begin{equation*}
\alpha_{1}=143.9-0.267 \sigma_{f} \quad\left(n_{1}=6.1\right) ; \tag{61}
\end{equation*}
$$

for CF-8 steel, it is given by

$$
\begin{equation*}
\alpha_{1}=157.9-0.300 \sigma_{f} \quad\left(n_{1}=6.4\right) ; \tag{62}
\end{equation*}
$$

and for CF-8M steel, it is given by

$$
\begin{equation*}
\alpha_{1}=50.9-0.0724 \sigma f \quad\left(n_{1}=5.6\right) . \tag{63}
\end{equation*}
$$

At $290^{\circ} \mathrm{C}\left(554^{\circ} \mathrm{F}\right)$, the Ramberg-Osgood parameters for engineering stress-vs.-strain curves up to $5 \%$ strain, for CF-3 materials, are given by

$$
\begin{equation*}
\alpha_{1}=102.1-0.235 \sigma_{f} \quad\left(n_{1}=6.2\right) ; \tag{64}
\end{equation*}
$$

for CF-8 steel, it is given by

$$
\begin{equation*}
\alpha_{1}=153.3-0.373 \sigma_{f} \quad\left(n_{1}=7.1\right) ; \tag{65}
\end{equation*}
$$

and for CF-8M steel, it is given by

$$
\begin{equation*}
\alpha_{1}=145.9-0.314 \sigma f \quad\left(n_{1}=6.6\right) . \tag{66}
\end{equation*}
$$

Similar correlations have also been developed for stress-versus-strain curves up to $15 \%$ strain or up to the ultimate strength. ${ }^{18}$

## 4 USE OF METHODOLOGY IN ASME CODE, SECTION XI

This section is an addition to the report; it covers a topic that was not included in NUREG/CR4513 Rev. 1. The estimated lower-bound fracture toughness J-R curves described in NUREG/CR-4513, Rev. 1 for thermally aged CASS materials were compared with the fracture toughness J-R curve used in the 1989 edition of the ASME Section XI, Subsection IWB-3640 "Evaluation Procedures and Acceptance Criteria for Austenitic Piping," for evaluation of flux welds. ${ }^{49}$ The comparison is shown in Fig. 47 for static-cast and centrifugally cast CASS materials. The results show that the lower-bound fracture toughness of thermally aged CASS material with up to $25 \%$ ferrite is similar to the fracture toughness J-R curve used in Subsection XI IWB-3640 to evaluate SAWs. The procedures in ASME Section XI Subsection IWB-3640 reduce the load bearing capacity of the SS component to account for the reduced fracture toughness of the SAWs, based on elastic-plastic fracture mechanics analyses. ${ }^{89,90}$ Because the lower-bound fracture toughness of thermally aged CASS steel is similar to the fracture toughness of SAWs used in the elastic-plastic fracture mechanics analyses of the 1989 edition of ASME Section XI IWB-3640, the procedures in IWB-3640 for SAWs are directly applicable to CASS materials.

Figure 47. Comparison of the lower-bound J-R curve at $290^{\circ} \mathrm{C}$ for aged static-cast CF-8M material estimated by using the NUREG/CR-4513, Rev. 1, expressions, with the SAW data used to develop ASME Section XI, Subsection IWB-3640 evaluations.

Furthermore, since the flaw evaluation is based on the unaged material ultimate strength, this approach would be conservative. Experimental data indicate that the flow stress (i.e., half of the sum of the ultimate and yield strengths) is increased by about $10 \%, 14 \%$, and $24 \%$ for CF-3 and CF-3A, CF-8 and CF-8A, and CF-8M materials, respectively. ${ }^{16}$ A higher ultimate stress would increase the load-bearing capability of a component. Therefore, the procedures developed in Subsection IWB-3640 for SAWs have been accepted for evaluating flaws in thermally aged CASS materials to address aging degradation concerns associated with license renewal applications. ${ }^{49}$ The use of the IWB-3640 SAW procedures for evaluating flaws in thermally aged CASS components is considered conservative because, (a) the lower-bound fracture toughness of thermally aged CASS is similar to the fracture toughness used in IWB-3640 to evaluate SAW, (b) the actual fracture toughness of a thermally aged CASS component in a U.S. NPP would likely be higher than the ANL lower-bound fracture toughness, and (c) the thermally aged
components would be able to withstand more loads because of the increased ultimate strength resulting from thermal aging.

The ASME Section XI Subsection IWB-3641 "Evaluation Procedures Based on Flaw Size" states; Evaluation procedures based on flaw size may be used subject to the following:
(a) The evaluation procedures and acceptance criteria are applicable to austenitic pipe NPS 4 or greater and portions of the adjoining pipe fittings within a distance of $\sqrt{ } r$ of the weld centerline (where $r$ is the nominal outside radius and $t$ is the nominal thickness of the pipe).
(b) The evaluation procedures and acceptance criteria are applicable to pipe and pipe fittings (and associated weld materials) which:

1. are made of wrought stainless steel, Ni-Cr-Fe alloy, or cast stainless steel (with ferrite level less than $20 \%$ or 20 FN ;
2. have a specified minimum yield strength less than 45 ksi ; and
3. have $\mathrm{S}_{\mathrm{m}}$ values given in Table I-1.2 of Section III.
(c) For cast stainless steel materials, adequate toughness for the pipe to reach limit load after aging shall be demonstrated.

The methodology and evaluation procedures are described in Subsections IWB-3641.1 and IWB-3641.2, respectively. A flaw growth analysis is performed on the detected flaw to determine the maximum growth during a specified evaluation period. The flaw evaluation is based on the analytical procedures described in Section XI Nonmandatory Appendix C to determine the critical flaw parameters. The maximum allowable flaw depth of a circumferential flaw under normal operating conditions is calculated from Table IWB-3641-1 for flaws in base metal and gas metal-arc weld (GMAW) and gas tungsten-arc weld (GTAW), and from Table IWB-3641-5 for flaws in SAW and shielded metal arc weld (SMAW). Similarly, the maximum allowable flaw depth of a circumferential flaw under emergency and faulted conditions is calculated from Table IWB-3641-2 and IWB-3641-6, respectively for base metal and GTAW/GMAW, and SAW/SMAW.

Thus, the use of the ASME Section XI, Subsection IWB-3640 (the 1989 edition), SAW procedures for evaluating flaws in thermally aged CASS components is considered to be a "screening" step to determine whether a further, detailed flaw evaluation that accounts for actual plant-specific material properties should be performed. The procedures in IWB-3640 for SAWs have been available since the winter 1985 Addenda for Section XI, and they have been applied successfully by utilities without resulting in unnecessary component repairs or replacements. However, note that the ANL methodology of NUREG/CR-4513, Rev. 1, is not applicable to CASS CF-8M materials containing >25\% ferrite or to CF-8M materials containing more than trace amounts of Nb . Even then, the proposed flaw evaluation procedures, which are based on the lower-bound fracture toughness of thermally aged CASS materials, are expected to be sufficient in the vast majority of cases.

In this report, the plots in Fig. 47 have been updated to include a comparison of the new lowerbound fracture toughness J-R curve presented in Figs. 40 and 42 with the J-R curve of SAWs used to develop the ASME Section XI, Subsection IWB-3640 evaluations. The results for staticcast and centrifugally cast CF-8M materials containing $<10 \% \mathrm{Ni}$ or $\geq 10 \% \mathrm{Ni}$, are shown in Figs. 48 and 49, respectively. These plots indicate that the use of the procedures in IWB-3640 for SAWs for evaluating flaws in aged CASS materials may not be adequate for CF-8M materials with $\geq 10 \% \mathrm{Ni}$ and containing $>10 \%$ ferrite, particularly for static cast material.

Similarly, the IWB-3640 procedure for SAWs may not be adequate for CF-8M materials with $<10 \% \mathrm{Ni}$ and containing $>15 \%$ ferrite static cast material and $20 \%$ ferrite for centrifugally cast materials. The lower-bound J-R curves listed in Table 4 and shown in Figs. 40-43 should be used for these materials.

Figure 48. Comparison of the lower-bound J-R curve at $290^{\circ} \mathrm{C}$ for aged static-cast CF-8M material estimated by using the updated expressions, with the fracture toughness of SAW data used to develop ASME Section XI, Subsection IWB-3640 evaluations.

Figure 49. Comparison of the lower-bound J-R curve at $290^{\circ} \mathrm{C}$ for aged centrifugally cast CF-8M estimated by using the updated expressions, with the fracture toughness of SAW data used to develop ASME Section XI, Subsection IWB-3640 evaluations.

### 4.1 Current Editions of the ASME Code Section XI

As discussed above, the procedures developed in the 1989 edition of the ASME Code Subsection IWB-3640 for SAWs have been accepted for evaluating flaws in thermally aged CASS materials to address aging degradation concerns associated with license renewal
applications. ${ }^{49}$ Although the revised lower-bound fracture toughness J-R curves shown in Figs. 48 and 49 indicate that the Subsection IWB-3640 flaw evaluation methodology may not be applicable to some heats of CF-8M materials, particularly those containing $\geq 10 \%$ Ni, the IWB3640 procedures are applicable for CF-3, CF-8, and some heats of CF-8M materials. However, in 1996, Tables IWB-3641-5 and 6 were deleted, Subsection IWB-3641.2 "Evaluation" item (c) was revised, and the maximum allowable flaw depth are now calculated using Tables IWB-3641-1 and 2 for normal operating conditions and emergency and faulted conditions respectively. In addition, Tables IWB-3641-1 and 2 were revised to include $Z$ factors load multipliers that are used to modify stress ratio for performing flaw evaluations of austenitic welds fabricated by SMAW and SAW. The revised flaw evaluation methodology is applicable to cast stainless steels, with a minimum yield strength not greater than 310 MPa ( 45 ksi ). However, the methodology does not address thermal aging effects for CASS materials.

Thus, in 1995 and later versions of the ASME Section XI Subsection IWB-3640 evaluation procedures and acceptance criteria for austenitic piping, determination of the allowable flaw depth based on Tables IWB-3641-5 and 6 has been replaced by the $Z$ factor load multiplier approach to modify the stress ratio for SMAW and SAW flaw evaluations. However, the applicability of the SMAW/SAW flaw evaluations using the $Z$ factor load multiplier approach to flaw evaluations of thermally aged CASS materials needs to be examined.

## 5 COMBINED EFFECTS OF THERMAL AND NEUTRON EMBRITTLEMENT

This section is an addition to the report; it covers topics that were not included in NUREG/CR4513 Rev. 1. Reactor core internal components are subjected to prolonged periods of both elevated temperatures and neutron irradiation. The thermal aging and neutron irradiation embrittlement of CASS ${ }^{6-18}$ and wrought austenitic SSs $^{36-47}$ have been investigated individually, but the possibility of a combined interaction between the thermal and neutron embrittlement of materials with a duplex structure is an issue associated with reactor core internal components that has been of concern. Recent data indicate that concurrent exposure to elevated temperatures and high neutron fluence levels could result in a combined effect, in which the service-degraded fracture toughness would be reduced from the levels predicted independently for either of the two mechanisms. ${ }^{91,92}$ Furthermore, for SSs with a duplex structure, neutron embrittlement of the ferrite phase occurs much faster than it does for the austenitic phase. The irradiation temperature is an important factor in establishing the extent of embrittlement of the ferrite.

As discussed earlier, the fracture toughness of unaged and unirradiated wrought SSs and CASS materials fall in Category III, with $\mathrm{J}_{\mathrm{IC}}$ being above $150 \mathrm{~kJ} / \mathrm{m}^{2}$ ( 857 in .-Ib/in. ${ }^{2}$ ). Fracturing of these materials occurs after a stable crack extension at stresses well above the yield strength. However, neutron irradiation can degrade the fracture toughness of these materials to the level of Category II materials (i.e., $\mathrm{J}_{\mathrm{IC}}$ in the range of $30-150 \mathrm{~kJ} / \mathrm{m}^{2}$ [171-857 in. $\left.\mathrm{lb} / \mathrm{in} .{ }^{2}\right]$ ) or even Category I materials (i.e., $\mathrm{J}_{\mathrm{Ic}}<30 \mathrm{~kJ} / \mathrm{m}^{2}\left[<171 \mathrm{in} .-\mathrm{lb} / \mathrm{in} .^{2}\right]$ ). Therefore, failure in neutronirradiated materials may occur without general yielding, and either EPFM or LEFM is used for analyzing structural integrity and developing inspection guidelines for components fabricated from CASS materials. For wrought austenitic SSs and associated welds, the effect of neutron irradiation on the fracture toughness of these materials is estimated by defining a lower-bound curve expressed in terms of the fracture toughness parameters, such as the $J_{\mathrm{Ic}}$ value or coefficient C of the J-R curve, as a function of the neutron dose (in dpa). ${ }^{39,42}$

A list of CASS components in LWR core internals and their expected neutron dose during 60 years of service is presented in Table 6.44,93 Most of the components are fabricated from CF-8 material. The control rod guide tube (CRGT) spacer casting in Babcock \& Wilcox (B\&W) PWRs is fabricated from CF-3M. In General Electric (GE) BWRs, the CRGT base and low-pressure core injection (LPCI) coupling are fabricated from CF-3 or CF-8 materials. In the Combustion Engineering PWR, only the core support columns are fabricated from CF-8 material.

In an earlier study at ANL (NUREG/CR-7027), ${ }^{47}$ a critical assessment of the neutron embrittlement of wrought austenitic SSs and CASS materials was performed to establish the effects of material parameters (e.g., composition, thermo-mechanical treatment, microstructure, microchemistry, yield strength, stacking fault energy) and environmental parameters (e.g., water chemistry, irradiation temperature, dose, dose rate) on neutron embrittlement. ${ }^{46,47}$ The results were used to (a) define a threshold fluence level above which irradiation effects on the fracture toughness of cast and wrought austenitic SSs are significant and (b) evaluate the potential for neutron embrittlement of these materials under LWR operating conditions. The results indicated that for the same irradiation conditions, the fracture toughness of thermally aged CASS material is lower than that of the heat-affected zone (HAZ) of SS base materials, which, in turn, is lower than that of solution-annealed SS base materials.

The combined effects of thermal aging and neutron irradiation embrittlement were also discussed. ${ }^{46,47}$ However, the fracture toughness data available at that time were inadequate to accurately evaluate the combined effects. The significant results from the earlier study (i.e., NUREG/CR-7027) and some recent studies on potential combined effects of thermal and neutron embrittlement are summarized below.

Table 6. LWR core internal components made of CASS materials and maximum neutron dose after 60 years of service (Refs. 44,93).

| Component | Material | 60-Year <br> Dose (dpa) |
| :--- | :---: | :---: |

### 5.1 Fracture Toughness of Irradiated Austenitic Stainless Steels

Until recently, most of the published experimental data on neutron embrittlement of austenitic SSs had been obtained on materials irradiated in high-flux fast reactors. ${ }^{94-99}$ In these studies, the embrittlement of the materials has been characterized in terms of tensile properties, Charpyimpact properties, and fracture toughness. The fracture toughness of structural materials is typically characterized by (a) the initiation toughness $J_{\mathrm{IC}}$ and tearing modulus T for materials that fail after substantial plastic deformation (for EPFM analysis) and by (b) the critical stress
intensity factor $\mathrm{K}_{\mathrm{lc}}$ for materials that fail after little or no deformation (for LEFM analysis). In some studies, the power-law J-R curve parameters, coefficient C and exponent n , are also reported. The fracture toughness data have been obtained from compact tension (CT) or single-edge bend [SE(B)] specimens, and, in a few cases, from chevron notch short rod specimens. To reduce activity and facilitate handling, small specimens (e.g., $\approx 8$-mm-thick, $1 / 4-T C T$ ) have been used in several studies. For these specimens, J values above $150 \mathrm{~kJ} / \mathrm{m}^{1 / 2}$ and crack extensions beyond about 1.2 mm are above the validity limits based on ASTM Specification E 1820-06. However, a comparison of fracture toughness data obtained on 1-T CT and small-sized CT or $\operatorname{SE}(B)$ specimens show comparable $J$-versus- $\Delta$ a values, even beyond the ASTM-defined validity limits. ${ }^{47,100}$ The small specimens yield equivalent J-R curve data at least for materials with $J_{\text {Ic }}$ values up to about $300 \mathrm{~kJ} / \mathrm{m}^{1 / 2}$ and maybe even higher.

Plots of $\mathrm{J}_{\mathrm{lc}}$ or $\mathrm{K}_{\mathrm{lc}}$ and $\mathrm{K}_{\mathrm{Jc}}$ as a function of neutron dose are generally used for developing screening criteria for neutron embrittlement. In ASTM Specification E 1820-06, $\mathrm{J}_{\mathrm{Ic}}$ is determined from the intersection of the best-fit power-law J-R curve with the 0.2 -offset line parallel to the blunting line. The blunting line is defined as

$$
\begin{equation*}
J=m \sigma_{f} \Delta a, \tag{67}
\end{equation*}
$$

where $\sigma_{f}$ is the flow stress, $\Delta \mathrm{a}$ is the crack extension, and the constraint factor m is 2 or a value determined from the best fit of the experimental data. However, the analysis procedures, described in the ASTM specifications for $\mathrm{J}_{\mathrm{Ic}}$ determination, are not applicable to austenitic SSs because of their extremely high toughness, ductility, and strain-hardening ability. The main difference concerns the expression for the crack-tip blunting line. For austenitic SSs, a value of 2 for m significantly over-predicts the crack extension due to crack blunting; therefore, it yields a non-conservative value of $\mathrm{J}_{\mathrm{Ic}}$. ${ }^{48,86}$ For austenitic SSs , a value of 4 for $m$ better defines the blunting line. The constraint factor, M , which relates J to the crack tip opening displacement (CTOD) is given by the expression

$$
\begin{equation*}
\text { J = M } \sigma_{y}(C T O D) . \tag{68}
\end{equation*}
$$

The use of a higher value for $M$ in Eq. 67 is consistent with the expected variation of $M$ and $\sigma_{f}$ with strain hardening. The factor M is 1 for materials with intermediate to high strengths and low strain hardening, and it is 2 for materials with low strengths and high strain hardening, such as austenitic SSs. For the latter, the yield strength is approximately two-thirds of the flow stress, and the crack extension associated with blunting is approximately one-third of CTOD. ${ }^{48}$ Thus, for such materials, the crack tip blunting line is given by

$$
\begin{equation*}
J=M \sigma_{y}(C T O D) \approx 2\left(2 \sigma_{f} / 3\right)(3 \Delta a)=4 \sigma_{f} \Delta a, \tag{69}
\end{equation*}
$$

That is, Eq. 67 with $M=4$. This relationship has been used to determine $J_{\text {Ic }}$ in most investigations on neutron embrittlement. 40,100 A value of 2 for M has also been used by some investigators. ${ }^{39}$ The latter typically yields a higher value of $\mathrm{J}_{\mathrm{Ic}}$ for Category III materials (i.e., with a $J_{I c}>150 \mathrm{~kJ} / \mathrm{cm}^{2}$ ). However, the difference in $J_{\mathrm{Ic}}$ values determined by using values of M of 2 or 4 is insignificant for Category II materials (i.e., with a $J_{\mathrm{Ic}}$ of $<100 \mathrm{~kJ} / \mathrm{cm}^{2}$ ). Because, it is primarily the cases in which the fracture toughness of irradiated austenitic SSs has been reduced to Category II levels that are of interest for embrittlement evaluations, the effect of differences in the procedure to determine $J_{\mathrm{Ic}}$ is likely to be insignificant.

Another factor that may influence the reported values of $\mathrm{J}_{\mathrm{Ic}}$ is the use of an effective yield stress instead of the measured yield stress. The K/size criteria were developed for materials that show
work hardening; therefore, they may not be applicable for materials irradiated to fluence levels where, on a local level, they do not strain harden. An effective yield stress, in which the irradiation-induced increase in yield strength is discounted by a factor of 2 for moderately irradiated materials ${ }^{101}$ and by a factor of 3 for highly irradiated materials, ${ }^{102}$ has been proposed to define K/size criteria for moderately to highly irradiated materials. Some studies have used such a yield stress to determine $J_{\text {Ic. }}{ }^{100}$ Because $J_{\text {Ic }}$ is a measure of fracture toughness at instability without a significant stable crack extension, the measured yield or flow stress of the irradiated materials seems more appropriate for $J_{\mathrm{Ic}}$ determinations. Nevertheless, the choice of measured or effective yield stress is likely to have an insignificant effect on the measured $J_{\mathrm{IC}}$ of materials with poor fracture toughness.

### 5.1.1 Fracture Toughness $\mathrm{J}_{\mathrm{Ic}}$

The effects of neutron exposure (in dpa) on the fracture toughness of austenitic SSs at 25$427^{\circ} \mathrm{C}\left(77-842^{\circ} \mathrm{F}\right.$ ) have been investigated for SSs irradiated up to 90 dpa at $90-450^{\circ} \mathrm{C}$ (194$842^{\circ} \mathrm{F}$ ) in fast reactors. $41,48,103-112$ The irradiation and test temperatures, respectively (with a few exceptions), were $325^{\circ} \mathrm{C}$ and $25^{\circ} \mathrm{C}$ for the data obtained by Kim et al., $4^{11} 90-250^{\circ} \mathrm{C}$ and $25-$ $250^{\circ} \mathrm{C}$ for the data obtained by Alexander et al., ${ }^{106}$ and $100-155^{\circ} \mathrm{C}$ and $125^{\circ} \mathrm{C}$ for the data obtained by Sindelar et al. ${ }^{107}$ As discussed earlier in NRC topical reports NUREG/CR-6960100 and NUREG/CR-7027,47 the fast reactor data show substantial decrease in toughness at exposures of $1-10 \mathrm{dpa}$, and little or no further reduction in toughness beyond 10 dpa . The degradation in fracture properties appear to saturates at a $\mathrm{J}_{\mathrm{lc}}$ value of $\sim 30 \mathrm{~kJ} / \mathrm{m}^{2}\left(171 \mathrm{in}\right.$. $-\mathrm{lb} / \mathrm{in}{ }^{2}$ ); that is, a $\mathrm{K}_{\mathrm{Jc}}$ value of $75 \mathrm{MPa} \mathrm{m}{ }^{1 / 2}\left(68.2 \mathrm{ksi} \mathrm{in} .{ }^{1 / 2}\right) .{ }^{47,100} \mathrm{In}$ addition, the failure mode changes from dimple fracture to channel fracture.

The fracture toughness $J_{I c}$ values for wrought and cast SSs irradiated in LWR, ${ }^{36-48,56,94-116}$ are shown in Fig. 50. The Westinghouse data for a heat of CASS CF-8 material irradiated to about 6-12 dpa are not included in the figure, because the irradiations were carried out in a fast reactor and the tests were conducted at RT. As discussed below, fracture toughness at reactor temperatures is expected to be lower. The fracture toughness data trend for LWR-irradiated materials is similar to the trend for the fast reactor data. Most of the fracture toughness $\mathrm{J}_{\mathrm{Ic}}$ values for austenitic SSs irradiated in LWRs (288-316 ${ }^{\circ} \mathrm{C}$ [550-601 ${ }^{\circ} \mathrm{F}$ ) fall within the scatter band of the data obtained on materials irradiated in fast reactors, even though the LWR irradiations were at lower temperatures. However, the extent of embrittlement and the rate of decrease in fracture toughness vary among the various materials. Typically, for the same irradiation conditions, the fracture toughness of thermally aged CASS material is lower than the toughness of HAZ material, and that, in turn, is lower than the fracture toughness of solutionannealed SSs.

The Japan Power Electric Engineering and Inspection Corp. (JAPEIC) data for Type 304 SS irradiated to $3.0-5.3 \mathrm{dpa}$ at LWR temperatures show very poor fracture toughness. ${ }^{37}$ The J Jc values are below the lower-bound curve for the fast reactor data. For the material irradiated to $4.5-5.3$ dpa (shown as "+" in Fig. 50), 9 of 10 CT specimens showed no ductile crack extension, and the $\mathrm{K}_{\mathrm{lc}}$ values were $52.5-67.5 \mathrm{MPa} \mathrm{m}{ }^{1 / 2}\left(47.7-61.4 \mathrm{ksi}\right.$ in $\left.{ }^{1 / 2}\right) \cdot{ }^{37} \mathrm{In}$ Fig. 50, the lowest fracture toughnesses with $\mathrm{K}_{\mathrm{lc}}$ or $\mathrm{K}_{\mathrm{Jc}}$ values in the range of $36.8-40.3 \mathrm{MPa} \mathrm{m}^{1 / 2}$ (33.536.6 ksi in. ${ }^{1 / 2}$ ) are for a Type 347 SS irradiated to 16.5 dpa in a PWR ${ }^{37}$ and for a Type 304 SS irradiated to $7.4-8.4 \mathrm{dpa}$ in a BWR. 45

The material's orientation also has a strong effect on fracture toughness. Fracture toughness $\mathrm{J}-\mathrm{R}$ tests and microstructural and microchemistry characterization have been performed on Types 304 and 304L control-rod and top guide materials irradiated to 4.7-12.0 dpa in a BWR.

Test Environment
Open Symbols: air
Closed Symbols: simulated LWR env.

Figure 50. Change in fracture toughness $\mathrm{J}_{\mathrm{Ic}}$ as a function of neutron exposure for LWR irradiated austenitic SSs. Dashed lines represent the scatter band for the fast reactor data on SSs irradiated at $350-450^{\circ} \mathrm{C}$ (Refs. $36-$ $40,42-48,56,94,100)$.

All materials consistently show lower fracture toughness in the T-L (transverse-longitudinal) orientation than in the L-T orientation (shown as isosceles triangles with their bases to the left or right, respectively, for T-L and L-T orientations). ${ }^{39}$ The fracture toughness $\mathrm{K}_{\mathrm{Ic}}$ values are lower than the limiting value of $55 \mathrm{MPa} \mathrm{m}{ }^{1 / 2}\left(50 \mathrm{ksi}\right.$ in. ${ }^{1 / 2}$ ) that has been proposed by industry for flaw tolerance evaluations of irradiated austenitic SSs. 38,39 The Type 304 control-rod material irradiated to $7.4-8.4 \mathrm{dpa}$, show poor fracture toughness ( $\mathrm{J}_{\mathrm{Ic}}$ is $40 \mathrm{~kJ} / \mathrm{m}^{2}$ in L-T orientation and $7.5 \mathrm{~kJ} / \mathrm{m}^{2}$ in the T-L orientation). Microstructural characterization ${ }^{39}$ show a fine distribution of the $\gamma^{\prime}$ phase with sizes in a range of $2-10 \mathrm{~nm}$ (average of 4.4 nm ), and the density is $1-3 \times$ $10^{22} \mathrm{~m}^{-3}$. The $\gamma^{\prime}$ phase is not observed in the Type 304 top guide material; it might influence the fracture toughness of these materials. The $\gamma^{\prime}$ phase has been observed at dose levels above 4 dpa in cold worked (CW) Type 316 SS irradiated under the PWR conditions. ${ }^{115}$

The lower fracture toughness along the T-L orientation has been attributed to the presence of stringers consisting of long, narrow particles oriented in the rolling direction. This microstructure results in a long, narrow quasi-cleavage structure parallel to the crack advance, thereby accelerating the crack advance. ${ }^{39}$ The formation of the $\gamma^{\prime}$ phase due to changes in the microchemistry of the material caused by neutron irradiation appears to play an important role in the neutron embrittlement of austenitic SSs. The low $J_{I c}$ of this material might be considered a special case of materials containing a high density of particles aligned in the rolling direction. Nonetheless, these results show that irradiated austenitic SSs, particularly those with material compositions that promote the formation of the $\gamma^{\prime}$ phase, can have very low fracture-toughness values. The contributions that additional precipitate phases, voids, and cavities can make to fracture toughness need to be further investigated.

### 5.1.2 Fracture Toughness J-R Curve

Fracture toughness J-R curve data have been obtained for Types 304, 304L, and 316L SSs, including weld HAZs, and CF-3, CF-8, and CF-8M CASS materials irradiated in LWRs up to about $14 \mathrm{dpa},{ }^{37-47,100}$ and irradiated in fast reactors to much higher dose levels. The change in the fracture toughness J-R curve with the neutron dose for Type 304 SS irradiated under LWR conditions and tested at reactor operating temperatures is shown in Fig. 51. The decrease in fracture toughness is quite rapid up to about 6 dpa, and the toughness continues to decrease moderately at higher dose levels. The effects of various parameters (e.g., material type and heat treatment; test and irradiation temperatures; neutron energy spectrum, flux, dose) are discussed next.

Figure 51. Fracture toughness $\mathrm{J}_{\mathrm{Ic}}$ as a function of neutron exposure for SSs (Refs. 45,100).

### 5.1.2.1 Irradiation Conditions

Fast reactor irradiations were at fluxes and temperatures higher than those typically observed in LWRs and had a different spectrum; the irradiation temperatures were $350-427^{\circ} \mathrm{C}\left(662-801^{\circ} \mathrm{F}\right)$. To accurately determine the effects of the neutron spectrum, flux, and temperature on the fracture properties of these materials, data on the same heat of material irradiated in a fast reactor and in an LWR to a comparable neutron dose are needed, but such data are not available. Although the general data trends appear to be similar for fast reactor irradiations and LWR irradiations, the tensile property data indicate that the tensile strength is higher and the ductility is lower for the BWR-irradiated materials than for the materials irradiated in fast reactors. ${ }^{47,100}$ However, the existing data are inadequate to determine the individual contributions of the irradiation temperature, flux, and energy spectrum to the degradation of fracture properties in irradiated austenitic SSs. Therefore, fast reactor data should be used only for establishing data trends and not for establishing the extent of embrittlement.

### 5.1.2.2 Material Type

Most of the J-R curve data on LWR-irradiated austenitic SSs have been obtained for Type 304 and 304L SSs. Data on Type 316, 316L, 316CW, and 347 SSs are very limited. Similarly, there have been only a few J-R curve tests on LWR-irradiated weld HAZ materials and CASS materials. Some differences in the fracture toughness data trends appear for the various grades of wrought austenitic SSs, but these differences may be artifacts of the limited data. For
example, the heat-to-heat variation for a particular grade may be comparable to the apparent differences between grades in the current data. A few select data from Fig 50 on wrought Types 304, 316, 304L, and 316L SS, Type 304/304L HAZ material, and sensitized Type 304 SS, are plotted in Fig. 52. Note that different symbol colors are used for the low-C (green) and high-C (orange) grades of SSs. The results indicate that the toughness of the high-C grades decreases faster than that of the low-C grades. There is little or no effect of sensitization treatment for high-C Type 304 SS. In addition, for the same irradiation conditions, the fracture toughness of the weld HAZ materials is lower than that of the solution-annealed materials. Example of fracture toughness J-R curves for irradiated, sensitized SS, SS weld HAZ material, and CASS CF-8M material, are shown in Fig. 53. However, these results are based on very limited data.

Figure 52. Change in fracture toughness $J_{\mathrm{Ic}}$ for a select data set as a function of neutron exposure for LWR irradiated austenitic SSs (Refs. 37-40,42,43,45-47,100).

The available data indicate that although the fracture toughness of unirradiated CW steels is lower than that of unirradiated solution-annealed steels, the decrease in the toughness of CW steels with neutron exposure is lower than and the $\mathrm{J}_{\mathrm{IC}}$ at saturation is higher than those values for irradiated solution-annealed steels. ${ }^{47}$ However, the available data for CW steels are from fast reactor irradiations at relatively high temperatures of $400-427^{\circ} \mathrm{C}\left(752-800^{\circ} \mathrm{F}\right)$. The saturation $J_{\text {Ic }}$ for CW SSs is likely to be lower for irradiations at LWR operating temperatures (i.e., $290-320^{\circ} \mathrm{C}\left[554-608^{\circ} \mathrm{F}\right]$ ) and the differences may not be significant.

Unirradiated, thermally aged CASS materials have a lower fracture toughness than do wrought austenitic SSs, and their fracture toughness generally decreases more rapidly with neutron exposure than does that of solution-annealed materials. However, the existing data indicate that the saturation toughness for the CASS materials is not significantly different from that of solution-annealed SSs; the same bounding curve for $J_{\mathrm{Ic}}$ is applicable for both wrought austenitic SSs and CASS materials. Although CF-8 or CF-3 materials are used in the construction of

Figure 53.
Fracture toughness J-R curves for sensitized Type 304 SS, weld HAZ materials of Type 304 and 304L SS, and CF-8M steel in high-purity water at $289^{\circ} \mathrm{C}$ (Ref. 47).

LWR core internals, in the ANL study, initially, the only data for LWR-irradiated CASS were data on CF-8M material. The reason was that significant amounts of experimental data from several heats of CF-3/CF-8 material are needed to accurately establish the lower-bound fracture toughness, whereas a few tests on CF-8M material can provide the worst-case value of fracture toughness for CF-3/CF-8 materials.

### 5.1.2.3 Test Temperature

The fracture toughness of unirradiated austenitic SSs is known to decrease as the test temperature is increased. The change in the $\mathrm{J}_{\mathrm{Ic}}$ of irradiated SSs as a function of test temperature is plotted in Fig. 54 for several grades of SSs and welds irradiated in LWRs and fast reactors. The results indicate that the fracture toughness of austenitic SS welds is lower than that of wrought SSs. For example, the $\mathrm{J}_{\mathrm{Ic}}$ values of a 308 L weld irradiated to 0.7 dpa les then $200 \mathrm{~kJ} / \mathrm{m}^{2}$, and the value is slightly higher at $250^{\circ} \mathrm{C}$ than at RT . The results also indicate that for wrought SSs, the fracture toughness of materials irradiated to relatively low dose ( <5 dpa) decreases with increasing test temperature in most cases. However, for steels

Figure 54.
Fracture toughness $\mathrm{J}_{\mathrm{Ic}}$ of irradiated austenitic SSs and welds as a function of test temperature (Ref. 100).
irradiated to more than 12 dpa , the test temperature has little effect on fracture toughness. Note that at neuron dose of 12 dpa , the toughness value is already low, which makes it difficult to discern definitive trends. The data also indicate differences in the fracture morphology of highly irradiated materials. At temperatures above $230^{\circ} \mathrm{C}\left(446^{\circ} \mathrm{F}\right)$, the failure mode is predominantly channel fracture, characterized by a faceted fracture surface. It is associated with highly localized deformation along a narrow band of slip planes, in which the initial dislocation motion along the narrow band clears away the irradiation-induced defect structure, creating a defectfree channel that offers less resistance to subsequent dislocation motion. The localization of the deformation ultimately leads to channel failure.

### 5.1.2.4 Test Environment

Nearly all of the existing fracture toughness data have been obtained from tests in air and on specimens that were fatigue precracked at relatively low load ratios (typically 0.1-0.2) in RT air. However, in reactor core components, cracks are initiated primarily by SCC and have intergranular morphology, whereas the fatigue precracks in fracture toughness tests are always transgranular). In addition, the corrosion/oxidation reaction could influence fracture toughness. For example, hydrogen generated from the oxidation reaction could diffuse into the material and change the deformation behavior by changing the stacking-fault energy of the material. To investigate potential effects of the reactor coolant environment on the fracture toughness of austenitic SSs and CASS materials, J-R curve tests have been conducted on these materials in a BWR normal water chemistry (NWC) environment ${ }^{100}$ and in low-DO, high-purity water or simulated PWR environments. ${ }^{91}$ The effect of the reactor coolant environment on the fracture toughness of CASS materials was discussed earlier in Section 2.4.3.1.

The results indicate that both NWC BWR and simulated low-DO PWR environment can decrease the fracture toughness of these materials. However, the effect may be insignificant for materials with poor fracture toughness (i.e., $J_{\mathrm{IC}}$ values of $<150 \mathrm{~kJ} / \mathrm{m}^{2}$ ). ${ }^{46,47,91,100}$ For example, the fracture toughness J-R curves for irradiated Type 304L SAW HAZ in air and water environments are essentially identical (Fig. 55). However, for a CF-8M material aged for more than 15 years at $350^{\circ} \mathrm{C}$, the $\mathrm{J}-\mathrm{R}$ curve data for specimens precracked in air at $54^{\circ} \mathrm{C}$ and then tested in an shutdown water chemistry PWR environment at $54^{\circ} \mathrm{C}$ are significantly lower than the data for those specimens tested in air (Fig. 24). The specimens precracked in PWR water

Figure 55.
Fracture toughness J-R curves for irradiated specimens of Type 304L SAW HAZ in air and NWC BWR environment (Ref. 47).
at $315^{\circ} \mathrm{C}$ and tested in PWR water also show reduced fracture toughness, but the effect is less. ${ }^{80}$ The significant decrease in fracture toughness is attributed to the synergism between hydrogen embrittlement and thermal embrittlement. Similarly, J-R curve data for Type 316L gas tungsten arc (GTA) welds indicated that the reactor coolant environment could decrease the fracture toughness by up to $40 \%$ relative to that in air. ${ }^{117}$

The potential contribution of hydrogen-induced embrittlement has also been observed in the thermal embrittlement study at ANL. The J-R curves for the two tests on $1 / 4-$ T CT specimens of thermally aged and irradiated CF-8M steel in NWC BWR water are shown in Fig. 56. Unfortunately, companion tests in air were not conducted on the irradiated material. However, the fracture toughness J-R curve obtained for 1-T CT specimens of unirradiated, thermally aged material are included in the figure. In the two tests in water, large load drops, accompanied by crack extensions of up to 0.5 mm in one specimen and 1.0 mm in the other, were observed at the onset of these crack extension. Such load drops are not typically observed during tests in air. ${ }^{16}$ Thus, although available fracture toughness data in reactor coolant environments are inclusive, the limited data suggest that there could be environmental effects on the fracture toughness of CASS material and austenitic SS welds, at least for materials with moderate or superior fracture toughness. Additional tests on irradiated CASS materials or SS welds in air and water environments are needed to determine the possible effects of LWR coolant environments on their fracture toughness.

Figure 56.
Fracture toughness J-R curves for thermally aged and irradiated CF-8M steel (Ref. 47).

### 5.1.2.5 Irradiation Temperature

The available data are not adequate to establish accurately the effects of the irradiation temperature on the fracture toughness of austenitic SSs. However, tensile data for austenitic SSs indicate that irradiation hardening is highest, and ductility loss is at its maximum at an irradiation temperature of $\sim 300^{\circ} \mathrm{C}\left(\sim 572^{\circ} \mathrm{F}\right) . .^{118}$ Thus, the $\mathrm{J}_{\mathrm{IC}}$ values for all materials irradiated at temperatures above $350^{\circ} \mathrm{C}\left(662^{\circ} \mathrm{F}\right)$ (e.g., fast reactor irradiations), particularly for neutron exposures of more than 20 dpa, should be greater than the $J_{\mathrm{Ic}}$ values for materials irradiated at temperatures of $290-320^{\circ} \mathrm{C}\left(554-608^{\circ} \mathrm{F}\right)$. As mentioned before, to accurately evaluate the potential effects of irradiation temperature on the fracture properties of austenitic SSs and CASS materials, fracture toughness data are needed for a specific heat of material irradiated in LWRs at temperatures of $280-370^{\circ} \mathrm{C}\left(536-798^{\circ} \mathrm{F}\right)$.

### 5.2 Lower-Bound Fracture Toughness Curve

In NUREG/CR-7027, the available fracture toughness data on wrought and cast austenitic SSs and associated welds irradiated in fast reactors or LWRs were reviewed and evaluated to define the lower-bound fracture toughness $\mathrm{J}_{\mathrm{Ic}}$ value or coefficient C of the $\mathrm{J}-\mathrm{R}$ curve as a function of neutron dose (in dpa). ${ }^{46,47}$ The lower-bound curves represent the change in fracture toughness parameters, such as the coefficient C of the power-law J -R curve and the corresponding $\mathrm{J}_{\mathrm{IC}}$ value, as a function of neutron dose. The trend curve considers the following:
(a) The threshold neutron exposure for radiation embrittlement of austenitic SSs and a minimum fracture toughness for these materials irradiated to less than the threshold value,
(b) The saturation neutron exposure and a saturation fracture toughness for materials irradiated to greater than this value, and
(c) A description of the change in fracture toughness between the threshold and saturation neutron exposures.

The change in initiation toughness $J_{\mathrm{Ic}}$ of (a) wrought austenitic SSs and (b) CASS materials and weld metals as a function of neutron exposure (dpa) is shown in Fig. 57. The change in the lower-bound $\mathrm{J}_{\mathrm{Ic}}$ value as a function of the neutron dose (dpa) is given by

$$
\begin{equation*}
J_{\mathrm{Ic}}=7.5+110 \exp \left[-0.35(\mathrm{dpa})^{1.4}\right] . \tag{70}
\end{equation*}
$$

Note that the JAPEIC data on Type 304 SS only is not bounded by the lower bound curve; the data were obtained on short rod specimens and not the standard fracture toughness CT specimens. The lower-bound curve is defined essentially by the austenitic SS weld data. The lower-bound curve represents the following:
(i) Threshold dose of about 0.3 dpa for neutron embrittlement,
(ii) Minimum fracture toughness $\mathrm{J}_{\mathrm{lc}}$ of $\sim 116 \mathrm{~kJ} / \mathrm{m}^{2}$ for neutron doses below 0.1 dpa ,
(iii) Saturation threshold of about 5-7 dpa beyond which the fracture toughness of these materials appears to saturate,
(iv) Saturation fracture toughness $\mathrm{J}_{\mathrm{Ic}}$ of $7.5 \mathrm{~kJ} / \mathrm{m}^{2}$ (or $\mathrm{K}_{\mathrm{lc}}$ or $\mathrm{K}_{\mathrm{Jc}}$ of $38 \mathrm{MPa} \mathrm{m}^{1 / 2}$ ), and
(v) Description of the change in toughness between 0.1 and 10 dpa .

The $J_{\mathrm{lc}}$ value of $\sim 116 \mathrm{~kJ} / \mathrm{m}^{2}$ for neutron doses below the threshold dose is appropriate for thermally aged and unaged CASS materials and SS flux welds. A value that is higher than $116 \mathrm{~kJ} / \mathrm{m}^{2}$ may be considered for the minimum fracture toughness $\mathrm{J}_{\mathrm{Ic}}$ for wrought austenitic SSs irradiated below the threshold dose for neutron embrittlement. However, appropriate justification for using a higher value should be provided. The description of the change in fracture toughness below the threshold value would also change accordingly. The saturation $\mathrm{J}_{\mathrm{Ic}}$ value of $7.5 \mathrm{~kJ} / \mathrm{m}^{2}$ does not change; it is the same for wrought and cast SSs and their welds. The $\mathrm{K}_{\mathrm{Jc}}\left(\mathrm{MPa} \mathrm{m}^{1 / 2}\right)$ values determined from the lower-bound trend curve given by Eq. 70 are comparable to those predicted from the MRP lower-bound model proposed for PWRs ${ }^{42}$ at 0.3

Figure 57. Change in initiation toughness $J_{l c}$ of (a) wrought austenitic SSs and

and 7.0 dpa. The MRP model bounds all the fracture toughness data from fast reactors, BWRs, and PWRs and is given by the expression,

$$
\begin{equation*}
\mathrm{K}_{\mathrm{Jc}}=180-142[1-\exp (-\mathrm{dpa})] . \tag{71}
\end{equation*}
$$

The existing fracture toughness $\mathrm{J}_{\mathrm{IC}}$ data at $290-320^{\circ} \mathrm{C}$ for CASS materials irradiated under LWR conditions are plotted as a function of neutron dose in Fig. 58. ${ }^{37,41,42,80,95,98,100,109,117,119,120}$ Note that the fast-reactor irradiated data for a heat of CF-8 material (slashed square symbols) are included in the figure because they have been used for evaluating neutron embrittlement of CASS CF-8 materials in PWRs. Furthermore, the data were obtained at RT. Therefore, as shown in Fig. 54, the actual fracture toughness of moderate to high toughness materials is expected to be lower at reactor temperatures. The fracture toughness data obtained at ANL on neutron irradiated CASS materials in LWR environments and the data obtained earlier on these

materials in air are listed in Table 7. Note that the recent data obtained at ANL were for CASS materials irradiated to a neutron dose of 0.08 dpa . This irradiation level was selected to help understand the combined effects of thermal and neutron embrittlement on SSs with a duplex structure, consisting of both austenite and ferrite phases. It is well-established that at an irradiation dose of about 0.1 dpa , the neutron embrittlement of the ferrite phase is essentially complete, but the embrittlement of the austenite phase occurs at irradiation levels above a threshold value of 0.3 dpa. In addition, data on materials irradiated to less than 0.1 dpa are needed to accurately evaluate the possible effects of the synergism between thermal and neutron embrittlement of CASS materials and their welds.

Equations. 70 and 71 predict a saturation fracture toughness $\mathrm{K}_{\mathrm{lc}}$ of $38 \mathrm{MPa} \mathrm{m}^{1 / 2}$. For materials irradiated below the threshold dose for irradiation embrittlement, Eq. 70 predicts a minimum $\mathrm{K}_{\mathrm{Jc}}$ of about $151 \mathrm{MPa} \mathrm{m}^{1 / 2}$, but the MRP (Eq. 71) expression predicts fracture toughness values that for some materials, such as SS weld HAZ, may be higher than the minimum toughness of the materials in the unirradiated condition. The existing data for BWR-irradiated austenitic SSs is not bounded by the disposition curve proposed by EPRI for BWRs. For example, at neutron doses of $<0.7 \mathrm{dpa}$, the $\mathrm{J}_{\mathrm{Ic}}$ values based on the EPRI curve are higher than the minimum $\mathrm{J}_{\mathrm{Ic}}$ of some heats of wrought SSs and most thermally aged CASS with $>15 \%$ ferrite. ${ }^{16}$ In addition, the saturation $\mathrm{K}_{\text {Ic }}$ of $55 \mathrm{MPa} \mathrm{m}^{1 / 2}$ at 4.5 dpa for the EPRI curve is also higher than the value of $38 \mathrm{MPa} \mathrm{m}{ }^{1 / 2}$ previously proposed by MRP for PWRs. ${ }^{42}$ The saturation $\mathrm{K}_{\mathrm{Ic}}$ for the EPRI curve was based on data for which the specimen orientation was unknown. As discussed above, recent data indicate that fracture toughness in the transverse orientation is nearly half of that in

${ }^{\text {a }}$ All specimens were irradiated to a neutron dose of 0.08 dpa at $315^{\circ} \mathrm{C}$ and tested in low-DO high-purity water or simulated PWR water at $320^{\circ} \mathrm{C}$, except for the last two specimens (Heat 75), which were irradiated to 2.46 dpa at $297^{\circ} \mathrm{C}$ and tested at $289^{\circ} \mathrm{C}$ in high-purity water with 400 parts per billion (ppb) DO.
${ }^{\mathrm{b}}$ Tested at $289^{\circ} \mathrm{C}$ in high-purity water containing 400 ppb DO.
the longitudinal orientation. ${ }^{39}$ Therefore, the bounding $\mathrm{K}_{\mathrm{Ic}}$ values above 4.5 dpa are likely to be lower than $55 \mathrm{MPa} \mathrm{m}{ }^{1 / 2}$.

A fracture toughness J-R curve may be used to analyze material behavior for loading beyond $J_{\mathrm{Ic}}$. The J-R curve is expressed in terms of the J integral and crack extension ( $\Delta \mathrm{a}$ ) by the power law $\mathrm{J}=\mathrm{C}(\Delta \mathrm{a})^{\mathrm{n}}$. At dose levels below the threshold dose for saturation (i.e., at dose levels less than $\sim 7 \mathrm{dpa}$ ), the effect of neutron irradiation on the fracture toughness of austenitic SSs can be represented by a decrease in the coefficient C of the power-law correlation for the J-R curve with neutron dose. The variation of the fracture toughness coefficient C as a function of neutron dose for the data shown in Fig. 58 is plotted in Fig. 59. One curve in the figure represents the disposition curve proposed by EPRI for BWRs, ${ }^{38}$ and the other represents a trend curve proposed in NUREG/CR-7017 for coefficient C that bounds the existing data. For neutron dose less than 5 dpa , the existing fracture toughness data are bounded by the following expression for C :

$$
\begin{equation*}
\mathrm{C}=25+175 \exp \left[-0.35(\mathrm{dpa})^{1.4}\right] \tag{72}
\end{equation*}
$$

and an exponent $n$ equal to 0.37 (i.e., median value of the experimental data). The exponent n of the power-law curve typically ranges from 0.35 to 0.70 for unirradiated materials and 0.16 to 0.65 for irradiated materials. Unlike the behavior seen for thermally aged cast austenitic SSs (in which exponent $n$ typically decreases with a decrease in fracture toughness), ${ }^{16}$ no obvious trend of $n$ with fluence is evident. Based on the material and irradiation conditions, a conservative value of 0.3 for exponent $n$ may be used to evaluate the neutron embrittlement of these materials. Equation 72 yields a minimum C value of $192 \mathrm{~kJ} / \mathrm{m}^{2}$ (1094 in.-Ib/in. ${ }^{2}$ ) for materials

Figure 59. Coefficient C of the J-R curve as a function of neutron dose for CASS materials. Solid line represents the lower-bound $C$ values proposed in NUREG/CR-7027. The data points plotted at 0.007 dpa are for unirradiated materials.
irradiated to less than 0.1 dpa and a minimum C value of $\sim 31 \mathrm{~kJ} / \mathrm{m}^{2}\left(\sim 177 \mathrm{in}\right.$.-lb/in. $\left.{ }^{2}\right)$ for materials irradiated to 7 dpa .

For the data shown in Figs. 58 and 59, the J-integral values at a crack extension of $2.5 \mathrm{~mm}, \mathrm{~J}_{2.5}$, are plotted as a function of neutron dose in Fig. 60. The solid curve in the figure represents the $J_{2.5}$ values that bound the existing experimental data. The curve was obtained by using the power-law J-R curve relationship, with coefficient C determined from Eq. 72 and the median value of 0.37 for exponent n . The lower-bound curve indicates that for CASS materials irradiated up to 0.5 dpa , the predicted $\mathrm{J}_{2.5}$ values are above the screening value of $255 \mathrm{~kJ} / \mathrm{m}^{2}$ (1456 in.-Ib/in. ${ }^{2}$ ).

Note that most of the J-R curve data for neutron irradiated SSs have been obtained on $1 / 2-\mathrm{T}$ or $1 / 4-$ T CT specimens that were about $6-\mathrm{mm}$ thick. Therefore, the validity of the fracture toughness data using the small CT specimens needs to be assessed. The fracture mechanics approach correlates the behavior of components with that of specimens by using the K parameter. It considers that if the two cracks have the same K, then they have the same strains and stresses in the region near the crack tip. The ASTM specifications for specimen K/size criteria are intended to ensure that the plastic zone is small enough and K is controlling the crack behavior. It has been often argued that since the K/size criterion was developed for materials that show work hardening and it may not be applicable for materials that are irradiated to fluence levels where, on a local level, they do not strain harden and exhibit strain softening. Recent investigations have evaluated the validity of the K/size criterion for irradiated materials by comparing the plastic strain distribution in a $1 / 2-$ T CT specimen estimated from finite element method calculations with experimentally observed plastic deformation area. ${ }^{121,122}$ The plastic

Figure 60. Fracture toughness $\mathrm{J}_{2.5}$ values as a function of neutron dose for CASS materials. Solid line represents the lower-bound $J_{2.5}$ values proposed in NUREG/CR-7027. The data points plotted at 0.007 dpa are for unirradiated materials.
zone size was estimated to be $0.2-0.4 \mathrm{~mm}$ at $\mathrm{K}=30 \mathrm{MPa} \mathrm{m}{ }^{1 / 2 .}{ }^{121}$ The results indicate that for an austenitic SS irradiated to $3 \times 10^{21} \mathrm{n} / \mathrm{cm}^{2}$, the appropriate K range is at least $30 \mathrm{MPa} \mathrm{m}^{1 / 2}$ for a (5.8-mm thick) CT specimen.

Figure 60 shows the results of two tests of CF-8M material thermally aged for $10,000 \mathrm{~h}$ at $400^{\circ} \mathrm{C}$ and then irradiated to well above the threshold dose for neutron embrittlement (shown as closed circles). The resulting $\mathrm{J}_{2.5}$ values for these two tests are bounded by the proposed lower-bound J-R curve. As discussed above, since only CF-3/CF-8 and, in a few cases, CF-3M CASS materials are used for designs of all BWRs and PWRs, the data for CF-8M represent the worstcase values. Actual values for CF-3/CF-8 materials would be higher. However, there is little or no data on LWR-irradiated CF-3 and CF-8 materials to accurately establish the lower-bound J-R curves for these materials during service in LWRs. The only data for CF-8 material is for fast reactor irradiation. The existing data indicate that for the same neutron dose, the embrittlement of LWR irradiated materials is greater than that of materials irradiated in a fast reactor. In addition, the CF-8 data are on materials irradiated at $325^{\circ} \mathrm{C}$; limited data indicate that the extent of embrittlement is greater under BWR service conditions than PWR service conditions.

### 5.3 Methodology for Incorporating Irradiation Effects on CASS Materials including the Combined Effects of Thermal and Neutron Embrittlement

### 5.3.1 Threshold Neutron Dose for Irradiation Effects

To account for the effects of thermal aging and neutron irradiation embrittlement on the fracture toughness of reactor core internal components, the NRC staff has proposed an aging
management program (AMP) for license renewal. ${ }^{123}$ The program does not directly monitor for loss of fracture toughness that is induced by either thermal or neutron irradiation embrittlement. Instead, the impact of a loss of fracture toughness on component integrity is indirectly managed by using visual or volumetric examination techniques to monitor for cracking in the components. If cracking is detected in the components, a flaw tolerance evaluation is performed by using acceptable reduced fracture toughness properties.

The AMP for PWR vessel internals follows the guidance found in EPRI report MRP-227. ${ }^{124}$ The AMP states that a loss of fracture toughness due to thermal and/or neutron embrittlement of CASS materials can occur as a result of exposure to neutron fluence of $>10^{19} \mathrm{n} / \mathrm{cm}^{2}$ ( E of $>1 \mathrm{MeV}$ ) (i.e., 0.015 dpa ) or if CASS material is more susceptible to thermal embrittlement. A fracture toughness value of $255 \mathrm{~kJ} / \mathrm{m}^{2}$ ( $1450 \mathrm{in} .-\mathrm{lb} / \mathrm{in} .{ }^{2}$ ) at a crack extension of $2.5 \mathrm{~mm}(0.1 \mathrm{in}$.) is used to differentiate between CASS materials that are not susceptible and those that might be susceptible to thermal embrittlement. The screening criteria to determine the susceptibility of CASS components to thermal aging embrittlement are outlined in Table 1.51 Based on the review and evaluation of the current fracture toughness data of thermally aged CASS materials, a proposed revision of the screening criteria is presented in Table. 5.

Regarding the neutron dose threshold above which the potential combined effects of thermal and neutron embrittlement are significant and need to be evaluated, the lower-bound curve shown in Fig. 60 indicates that for CASS materials irradiated up to 0.5 dpa, the predicted $\mathrm{J}_{2.5}$ values are above the screening value of $255 \mathrm{~kJ} / \mathrm{m}^{2}$ ( 1456 in . $\mathrm{lb} / \mathrm{in}$. ${ }^{2}$ ). If needed, the lower-bound fracture toughness curves described above can be used to preform a flaw tolerance evaluation. However, note that the fracture toughness of SS weld metals may be significantly lower than this threshold value (see Fig. 57).

### 5.3.2 Potential Effects of Thermal and Neutron Embrittlement

The embrittlement of the ferrite phase because of neutron irradiation occurs at lower dose levels than does embrittlement of the austenite phase. A shift in the nil-ductility transition (NDT) temperature of up to $150^{\circ} \mathrm{C}\left(302^{\circ} \mathrm{F}\right)$ has been observed in pressure vessel steels irradiated to $0.07-0.15 \mathrm{dpa} .{ }^{125}$ Thus, embrittlement of ferrite is expected to occur at $0.05-0.50 \mathrm{dpa}$, whereas any significant neutron embrittlement of the austenite phase occurs only at above $\sim 0.4 \mathrm{dpa}$ (Fig. 58-60). In recent studies at ANL, fracture toughness tests have been conducted in LWR environments on unaged and aged heats of CF-3, CF-8, and CF-8M materials that were either in an unirradiated condition or irradiated to a neutron dose of 0.08 dpa at $315^{\circ} \mathrm{C}$ in the Halden reactor. The results are shown in Fig. 61. The ferrite contents of the CF-3, CF-8, and CF-8M materials, determined from Hull's equivalent factors were, 21.0\%, 14.9\%, and 24.8\%, respectively. The results indicate that only the $J_{\mathrm{lc}}$ values are slightly lower for the aged and irradiated materials than those that were only aged or irradiated. The values of coefficient C and $\mathrm{J}_{2.5}$ show no effect from combined thermal and neutron embrittlement.

Similarly, the fracture toughness data for two other heats of thermally aged and irradiated CF-8 material (Heats 52 and 61, containing $14 \%$ and $13 \%$ ferrite, respectively) yield $\mathrm{J}_{2.5}$ values that are significantly above $255 \mathrm{~kJ} / \mathrm{m}^{2}$. Therefore, the existing data indicate little or no combined effect from thermal and neutron irradiation. Furthermore, the fracture toughness $\left(\mathrm{J}_{2.5}\right)$ values of aged CASS CF-3 and CF-8 materials irradiated to a neutron dose of less than 0.5 dpa are above the screening value of $255 \mathrm{~kJ} / \mathrm{m}^{2}\left(1456 \mathrm{in}\right.$.-Ib/in. ${ }^{2}$ ) proposed by EPRI. ${ }^{93}$

Figure 61.
Comparison of the fracture toughness $\mathbf{J}_{\mathrm{Ic}}$, coefficient, and $\mathbf{J}_{\mathbf{2 . 5}}$ value obtained in air and LWR environment at $290-320^{\circ} \mathrm{C}$ of CF-3, CF-8, and CF-8M materials in the unaged and aged as well as unirradiated and irradiated conditions.

## 6 SUMMARY

The procedure and correlations presented earlier in NUREG/CR-4513, Rev. 1, for predicting the Charpy-impact energy and fracture toughness J-R curve of aged CASS CF-3, CF-3M, CF-8, and CF-8M materials from known material information have been updated by using a much larger database. The applicability of the methodology has been extended to materials with ferrite contents of up to $40 \%$. In addition, for CASS materials used in the reactor core support structure and core internal components, recommendations are provided for evaluating the combined effects of thermal and neutron embrittlement.

As in NUREG/CR-4513 Rev. 1, the fracture toughness and tensile properties of a specific CASS material are estimated from the extent and kinetics of thermal embrittlement. Thermal embrittlement of CASS materials is characterized in terms of RT Charpy-impact energy. Thus, the extent of thermal embrittlement represents the change in Charpy-impact energy. The extent of thermal embrittlement at "saturation" (i.e., the minimum impact energy that can be achieved for the material after long-term aging) is determined from the chemical composition of the steel and its ferrite content. The Charpy-impact energy as a function of the time and temperature of the reactor service is estimated from the kinetics of thermal embrittlement, which are expressed by the activation energy for the degradation of Charpy-impact energy due to thermal aging. The activation energy is also determined from the chemical composition of the material and ferrite content. The initial impact energy of the unaged steel is required for these estimates. The fracture toughness J-R curve for the material (expressed by coefficient $C$ and exponent $n$ ) is then obtained from correlations between the RT Charpy-impact energy and fracture toughness parameters. A common lower-bound J-R curve for CASS materials with an unknown chemical composition is also defined for a given grade of material, range of ferrite contents (e.g., <10\%, $>10-15 \%,>15-20 \%,>20-25 \%,>25-30 \%$, and $>30-40 \%$ ), and temperature. The method for estimating the mechanical properties of CASS materials during reactor service is described.

For CASS materials used in the reactor core support structures and core internal components, the available data are inadequate to definitively establish the effects of thermal and neutron embrittlement of various CASS materials as a function of service time and temperature. The combined effects of thermal and neutron embrittlement are estimated from the lower-bound fracture toughness curves expressed as a function of neutron dose. The fracture toughness is defined in terms of the coefficient C , exponent n , and $\mathrm{J}_{\mathrm{Ic}}$ of the fracture toughness $\mathrm{J}-\mathrm{R}$ curve. However, the existing data are inadequate to definitively determine the combined effects of thermal and neutron embrittlement of CASS materials. Experimental data on aged material irradiated in LWRs to neutron doses $<0.01$ dpa are needed to better define such effects.

The tensile yield and flow stresses and the Ramberg/Osgood parameters for tensile strain hardening are estimated from the flow stress of the unaged material and the kinetics of embrittlement. The fracture toughness $J_{\mathrm{IC}}$ values for aged CASS materials are then determined from the estimated J-R curve and flow stress. Only the chemical composition, initial Charpyimpact energy, and flow stress of the unaged material are needed for the estimates.

The significant differences between NUREG/CR-4513 Rev. 1 and this report are as follows:
(i) Embrittlement-Charpy-impact Energy: Eqs. 18-26 correspond to Eqs. 3.2.4-3.2.12 of Rev. 1; Eqs. 21 and 24 are updated versions of Eqs. 3.2.7 and 3.2.10, all others are the same. For CF-8M materials, the correlation between the RT Charpy-impact energy and material parameter $\phi$ was revised; the effect is significant for CF-8M materials with Ni content of $\geq 10 \%$.
(ii) Embrittlement-Fracture Toughness J-R Curve: Eqs. 27-44 correspond to Eqs. 3.2.133.2.26 of Rev. 1. Eqs. 29 and 35 are new and Eqs. 39-44 are updated versions of $3.2 .15,16,19,22,23$, and 26.

For CF-8M materials, the correlations between the RT Charpy-impact energy and coefficient C of the J-R curve at RT and at $290-320^{\circ} \mathrm{C}$ have been extended to include CASS materials with a ferrite content of up to $40 \%$. The new correlations are applicable to materials with relatively poor RT Charpy-impact energies (i.e., <35-45 J/m²). In addition, the correlations between the RT Charpy-impact energy and exponent $n$ of the $J-R$ curve at RT and at $290-320^{\circ} \mathrm{C}$ have been revised. Estimates of $n$ made from using the updated expressions are slightly lower, particularly for CF-8 materials.
(iii) Minimum Fracture Toughness of Unaged CASS Materials: Eq. 45 is the same as Eq. 3.2.27 of Rev. 1 and Eq. 46 is an updated version of Eq. 3.2.28. The minimum fracture toughness J-R curve for centrifugally cast CASS materials, was revised; the coefficient C of the J-R curve was decreased from 650 to 550.
(iv) New lower-bound curves are presented for correlating the saturation RT Charpy-impact energy and the ferrite content for CF-3, CF-3M, CF-8, and CF-8M materials. These correlations are used to define the lower-bound J-R curves for CASS materials containing ferrite in a specific range (e.g., <10\%, >10-15\%, >15-20\%, >20-25\%, $>25-30 \%$, and $>30-40 \%$ ).
(v) Recommendations are provided for estimating the lower-bound fracture toughness curves for CASS materials used in the reactor core support structures and core internal components.

These updated expressions for estimating fracture toughness of CASS materials during reactor service have the following impact on the criteria proposed by NRC (Table 1) for determining the susceptibility of various categories of CASS components to thermal aging embrittlement. Based on the casting process and whether the materials contains low Mo ( $0.5 \mathrm{wt} . \%$ max.) or high Mo (2.0-3.0 wt.\%), the proposed criteria specify the ferrite content above which the material would be susceptible to thermal embrittlement. The updated criteria are presented in Table 5.

- The criteria for low-Mo CF-3 and CF-8 materials have not changed. All centrifugally cast materials and static cast materials containing $\leq 20 \%$ ferrite are not susceptible to thermal embrittlement. Only static cast materials containing >20\% ferrite are potentially susceptible.
- The criteria for CF-8M materials depend on whether the material contains $\geq 10 \mathrm{wt} . \% \mathrm{Ni}$.
- The criterion for static cast CF-8M materials containing <10\% Ni has not changed. Static cast materials with $\leq 14 \%$ ferrite are not susceptible and with $>14 \%$ ferrite are potentially susceptible.
- The criterion for centrifugally cast CF-8M materials containing $<10 \%$ Ni has been revised. The threshold value of ferrite content has been decreased from $20 \%$ to $19 \%$ ferrite. Centrifugally cast materials with $\leq 19 \%$ ferrite are not susceptible and with $>19 \%$ ferrite are potentially susceptible to thermal embrittlement.
- The criterion for static cast CF-8M materials containing $\geq 10 \%$ Ni has been revised. The threshold value of ferrite content has been decreased from $14 \%$ to $11 \%$ ferrite. Static cast materials with $\leq 11 \%$ ferrite are not susceptible and with $>11 \%$ ferrite are potentially susceptible to thermal embrittlement.
- The criterion for centrifugally cast CF-8M materials containing $\geq 10 \% \mathrm{Ni}$ has been revised. The threshold value of ferrite content has been decreased from $20 \%$ to $13 \%$ ferrite. Centrifugally cast materials with $\leq 13 \%$ ferrite are not susceptible and with $>13 \%$ ferrite are potentially susceptible to thermal embrittlement.

The methodology presented in this report is only applicable to service times that are equivalent to $10,000 \mathrm{~h}$ at $400^{\circ} \mathrm{C}$. This corresponds to

- $\geq 125$ efpy at $290^{\circ} \mathrm{C}$ for CF-8/CF-3 materials, and
- $\geq 30$ efpy at $320^{\circ} \mathrm{C}$ for CF-8/CF-3 and $\geq 15$ efpy for CF-8M materials used within primary pressure boundary components, and
- $\geq 15$ efpy at $350^{\circ} \mathrm{C}$ for CF-8/CF-3 materials used in the reactor core internals.

Additional long-term aging data are needed to estimate fracture properties for longer service times. Furthermore, this methodology may not be applicable for CF-8M materials with more than a trace amount of Nb, particularly for materials containing >15\% ferrite. The methodology also does not consider the potential effect of reactor coolant environment on fracture toughness. Limited data indicate significant effect of environment, particularly at low temperatures (e.g., shutdown water chemistry at $54^{\circ} \mathrm{C}$ ). In addition, the existing fracture toughness data on LWRirradiated CF-8/CF-3 materials is inadequate to accurately establish the lower-bound J-R curves for these materials as a function of neutron dose.

APPENDIX A: MATERIAL INFORMATION
The various grades of CASS materials and their product form, heat designation, chemical composition, and mechanical properties such as Charpy-impact energy, tensile properties, and fracture toughness J-R curves of materials in the as-cast condition or after thermal aging in the laboratory at temperatures between 290 and $400^{\circ} \mathrm{C}$ up to $60,000 \mathrm{~h}$ are presented in the following tables.
Table A1. The chemical composition, product form, and ferrite content of the various CASS materials included in the present study.

## APPENDIX B: J-R CURVE CHARACTERIZATION

The J-R curve tests were performed according to ASTM Specifications E 813-85 (Standard Test Method for $\mathrm{J}_{\mathrm{Ic}}$. a Measure of Fracture Toughness) and E 1152-87 (Standard Test Method for Determining J-R Curve). Compact-tension (CT) specimens, 25.4 mm (1 in.) thick with $10 \%$ side grooves, were used for the tests. The CT specimen design is similar to the specimen of ASTM Specification E 399, the notch region is modified in accordance with E 813 and E 5112 to permit measurement of load-line displacement by axial extensometer. The extensometer was mounted on razor blades that were screwed onto the specimen along the load-line.

Prior to testing, the specimens were fatigue-precracked at room temperature and at load levels within the linear elastic range. The final ratio of the initial crack length to width (a/W) after precracking was about 0.55 . The final 1-mm (0.04-in.) crack extension was carried out at a load range of $13 \mathrm{kN}(2.92 \mathrm{kip})$ to $1.3 \mathrm{kN}(0.292 \mathrm{kip})$, $\mathrm{K}_{\max }$ was $<25 \mathrm{MPa} \cdot \mathrm{m}^{1 / 2}\left(22.6 \mathrm{ksi} \cdot \mathrm{in} .{ }^{1 / 2}\right.$ ). After precracking, all specimens were side-grooved by $20 \%$ of the total specimen thickness (i.e., $10 \%$ per side), to ensure uniform crack growth during testing.

The J-R curve tests were performed on an Instron testing machine with 90 kN (20 kip) maximum load capacity. The load and
load-line displacement data were digitized with digital voltmeters and stored on a disk for post test analysis and correction of the test data. The single-specimen compliance procedure was used to estimate the crack extension. Rotation and modulus corrections were applied to the compliance data. Both deformation theory and modified forms of the J integral were evaluated for each test.

After each test, the specimen was heated to $350^{\circ} \mathrm{C}$ to heat-tint the exposed fracture surface. The specimen was then fractured at liquid nitrogen temperature. The initial (i.e., fatigue precrack) and final (test) crack lengths were measured optically for both halves of the fractured specimen. The crack lengths were determined by the $9 / 8$ averaging technique (i.e., the two near-surface measurements were averaged and the resultant value averaged with the remaining seven measurements).

The fracture toughness $J_{\mathrm{Ic}}$ values were determined in accordance with ASTM Specifications E 813-81 and E 813-85. For the former, $\mathrm{J}_{\mathrm{IC}}$ is defined as the intersection of the blunting line given by $J=2 \sigma_{f} \Delta a$, and the linear fit of the $J-v s .-\Delta a$ test data between the $0.15-\mathrm{mm}$ and $1.5-\mathrm{mm}$ exclusion lines. The flow stress, $\sigma_{\mathrm{f}}$, is the average of the $0.2 \%$ yield strength and the ultimate strength. The ASTM Specification E 813-85 procedure defines $\mathrm{J}_{\mathrm{IC}}$ as the intersection of the $0.2-\mathrm{mm}$ offset line with the power-law fit (of the form $J=C \Delta a^{n}$ ) of the test data between the exclusion lines. J-R curve tests on CASS materials indicate that a slope of four times the flow stress $\left(4 \sigma_{f}\right)$ for the blunting line expresses the J -vs.$\Delta$ a data better than the slope of $2 \sigma_{f}$ that is defined in E 813-81 or E 813-85. The fracture toughness $J_{\mathrm{IC}}$ values were determined with the $4 \sigma_{f}$ slope for the blunting line and the $0.2-\mathrm{mm}$ offset line.

The tearing modulus was also evaluated for each test. The tearing modulus is given by $\mathrm{T}=$ $\mathrm{E}(\mathrm{dJ} / \mathrm{da}) / \sigma_{\mathrm{f}}{ }^{2}$, where E is the Young's modulus and $\sigma_{\mathrm{f}}$ is the flow stress. The ASTM E 813-81 value of tearing modulus is determined from the slope dJ/da of the linear fit to the J -vs.- $\Delta$ a data. For the power law curve fits, an average value of dJ/da was calculated ${ }^{\text {A27 }}$ to obtain average tearing modulus. The fracture toughness results obtained at Argonne on several experimental and commercial heats of CASS materials aged up to $58,000 \mathrm{~h}$ at 290, 320,350,400, and $450^{\circ} \mathrm{C}$, $\left(554,608,662,752\right.$, and $842^{\circ} \mathrm{F}$ ) and for the service-aged materials from the KBR pump
cover plate and the decommissioned Shippingport reactor valve bodies and pump volute and impeller, ${ }^{\mathrm{A} 1-\mathrm{A} 7}$ are given in Table B1. Fracture toughness data from studies at EPRI,A13 EdF,A9-12 Framatome, ${ }^{\mathrm{A} 14,15}$ several institutions in Japan, ${ }^{\text {A18, } 19,21,22}$ Westinghouse, ${ }^{\mathrm{A} 25,26}$ and TWI,A24 are also included. The actual fracture toughness J-R curve data (J vs. $\Delta \mathrm{a}$ ) for various grades and heats of unaged and aged CASS materials are given in Table B2. Note that for a few test specimens, the modified-J values are listed instead of deformation-J. These J-R curves are identified as $J_{m}$ vs. $\Delta$ a in Table B2, and the rest as $J_{d}$ vs. $\Delta$ a. For these tests, the $J_{\mathrm{Ic}}$, coefficient C , and exponent n , corresponding to the deformation-J and modified-J values are listed in Table B3. The tensile test data for thermally aged CASS materials from the Argonne study are presented in NUREG/CR-6142.A6

## Data Analysis Procedure

The compliance method was used to determine the crack length during the tests. The HudakSaxena calibration equation ${ }^{\text {A28 }}$ was used to relate the specimen load-line elastic compliance $\mathrm{C}_{\mathrm{i}}$ on an unloading/loading sequence with the crack length $a_{j}$. The compliance, i.e., slope ( $\Delta \delta / \Delta \mathrm{P}$ ) of the load-line displacement-vs.-load record obtained during the unloading/loading sequence, is given by

$$
\begin{equation*}
\mathrm{U}_{\mathrm{L}}=\frac{1}{\left(\mathrm{~B}_{\mathrm{e}} \mathrm{E}_{\mathrm{e}} \mathrm{c}_{\mathrm{i}}\right)+1} \tag{B-1}
\end{equation*}
$$

and

$$
\begin{align*}
\mathbf{a}_{\mathbf{i}} / \mathbf{W}=1.000196- & 4.06319\left(\mathrm{U}_{\mathrm{LL}}\right)+11.242\left(\mathrm{U}_{\mathrm{LL}}\right)^{2} \\
& -106.043\left(\mathrm{U}_{\mathrm{LL}}\right)^{3}+464.335\left(\mathrm{U}_{\mathrm{LL}}\right)^{4}-650.677\left(\mathrm{U}_{\mathrm{u}}\right)^{5} \tag{B-2}
\end{align*}
$$

where $E_{e}$ is the effective elastic modulus, $B_{e}$ is the effective specimen thickness expressed as $B-\left(B-B_{N}\right)^{2} / B$, and $W$ is specimen width.

Both rotation and modulus corrections are applied to the compliance data. The modulus correction A28 is used to account for the uncertainties in testing, i.e., in the values of initial crack length determined by compliance and measured optically. The effective modulus $\mathrm{E}_{\mathrm{M}}$ is determined from

$$
\begin{equation*}
E_{e}=\frac{1}{C_{o} B_{e}}\left(\frac{W+a_{o}}{W-a_{o}}\right)^{1 / 2} f\left(\frac{a_{o}}{W}\right) \tag{B-3}
\end{equation*}
$$

and

$$
\begin{align*}
f\left(\frac{a_{o}}{W}\right)=2.163+12.219 & \left(\frac{a_{o}}{W}\right)-20.065\left(\frac{a_{o}}{W}\right)^{2} \\
& -0.9925\left(\frac{a_{o}}{W}\right)^{3}+20.609\left(\frac{a_{o}}{W}\right)^{4}-9.9314\left(\frac{a_{o}}{W}\right)^{5} \tag{B-4}
\end{align*}
$$

where $C_{o}$ is initial compliance, $B_{e}$ is effective specimen thickness, and $a_{o}$ is the initial physical crack size measured optically.

To account for crack-opening displacement in CT specimens, the crack size should be corrected for rotation. ${ }^{\text {A2 }}$ The corrected compliance is calculated from

$$
\begin{equation*}
\theta=\operatorname{Sin}^{-1}\left[\left(\frac{d_{m}}{2}+D\right) /\left(D^{2}+R^{2}\right)^{1 / 2}\right]-\tan ^{-1}\left(\frac{D}{R}\right), \tag{B-5}
\end{equation*}
$$

and

$$
\begin{equation*}
C_{c}=C_{m} /\left[\left(\frac{H^{*}}{R} \operatorname{Sin} \theta-\operatorname{Cos} \theta\right)\left(\frac{D}{R} \operatorname{Sin} \theta-\operatorname{Cos} \theta\right)\right], \tag{B-6}
\end{equation*}
$$

where $\mathrm{C}_{\mathrm{c}}$ and $\mathrm{C}_{\mathrm{m}}$ are the corrected and measured elastic compliance at the load line, $\mathrm{H}^{*}$ is the initial half span of load points, $R$ is the radius of rotation of the crack centerline [(W +a)/2)], a is the updated crack length, $D$ is one-half of the initial distance between the displacement points (i.e., half gage length), $\mathrm{d}_{\mathrm{m}}$ is the total measured load-line displacement, and $\theta$ is the angle of rotation of a rigid-body element about the unbroken midsection line.

The $J$ value is calculated at any point on the load-vs.-load-line displacement record by means of the relationship

$$
\begin{equation*}
J=J_{e l}+J_{p l}, \tag{B-7}
\end{equation*}
$$

where $\mathrm{J}_{\mathrm{el}}$ is the elastic component of J and $\mathrm{J}_{\mathrm{pl}}$ is the plastic component of J . For a CT specimen, at a point corresponding to the coordinates $\mathrm{P}_{\mathrm{i}}$ and $\delta_{j}$ on the specimen load-vs.-loadline displacement record, $\mathrm{a}_{\mathrm{i}}$ is $\left(\mathrm{a}_{\mathrm{o}}+\Delta \mathrm{a}_{\mathrm{i}}\right)$, and the deformation J is given by

$$
\begin{equation*}
J_{d(i)}=\frac{\left(K_{i}\right)^{2}\left(1-v^{2}\right)}{E_{e}}+J_{p(i)}, \tag{B-8}
\end{equation*}
$$

where, from ASTM method E 399,

$$
\begin{equation*}
K_{(i)}=\left[\frac{P_{i}}{\left(B B_{N} W_{e}\right)^{1 / 2}}\right] f\left(\frac{a_{i}}{W}\right), \tag{B-9}
\end{equation*}
$$

with

$$
\begin{align*}
f\left(\frac{a_{i}}{W}\right)=\left[2+\left(\frac{a_{i}}{W}\right)\right][0.886 & +4.64\left(\frac{a_{i}}{W}\right)-13.32\left(\frac{a_{i}}{W}\right)^{2} \\
& \left.+14.72\left(\frac{a_{i}}{W}\right)^{3}-5.6\left(\frac{a_{i}}{W}\right)^{4}\right] /\left[1-\left(\frac{a_{i}}{W}\right)\right] \tag{B-10}
\end{align*}
$$

and

$$
\begin{equation*}
J_{p l(i)}=\left[J_{p l(i-1)}+\left(\frac{\eta_{i}}{b_{i}}\right) \frac{A_{p l(i)}-A_{p l(i-1)}}{B_{N}}\right]\left[1-\left(\frac{\gamma_{i}}{b_{i}}\right)\left(a_{i}-a_{i-1}\right)\right], \tag{B-11}
\end{equation*}
$$

where $v$ is Poisson's ratio, $b$ is the uncracked ligament, $A_{p l}$ is the plastic component of the area under the load-vs.-load-line displacement record, and $\eta$ is a factor that accounts for the tensile component of the load as given by

$$
\begin{equation*}
\eta_{i}=2+0.522 b_{\mathbf{i}} / W \tag{B-12}
\end{equation*}
$$

and $\gamma$ a factor that accounts for limited crack growth as given by

$$
\begin{equation*}
\gamma_{\mathrm{i}}=1+0.76 \mathrm{~b}_{\mathrm{i}} / \mathrm{W}, \tag{B-13}
\end{equation*}
$$

The modified J values (i.e., $\mathrm{J}_{\mathrm{M}}$ ) are calculated from the relationship (Ref. A30)

$$
\begin{equation*}
J_{M(i)}=J_{d(i)}+\Delta J_{i}, \tag{B-14}
\end{equation*}
$$

where

$$
\begin{equation*}
\Delta J_{i}=\Delta J_{i-1}+\left(\frac{\gamma_{i}}{b_{i}}\right) J_{p(i)}\left(a_{i}-a_{i-1}\right) \tag{B-15}
\end{equation*}
$$

According to ASTM Specification E 1152-87, the $J_{D}-$ R curves are valid only for crack growth up to $10 \%$ of the initial uncracked ligament. In addition, they show a dependence on specimen size. The $J_{M}-R$ curves have been demonstrated to be independent of specimen size and yield valid results for larger crack growth.

## Data Qualification

The various validity criteria specified in ASTM Specification E 813-85 for $J_{\mathrm{Ic}}$ and in ASTM Specification E 1152-87 for the J-R curve were used to qualify the results from each test. The various criteria include maximum values of crack extension and J-integral; limits for initial uncracked ligament, effective elastic modulus, optically measured physical crack length, and spacing of $\mathrm{J}-\Delta$ a data points. The $\omega$ criterion ${ }^{\mathrm{A} 31}$ was also used to ensure that a region of J dominance exists.

For the present investigation, most of the unaged or short-term-aged specimens yielded invalid $J_{\text {Ic }}$ values because of the relatively high toughness of the material. The reasons for the discrepancies are data point spacing, shape of the final crack front, or size of the uncracked ligament. In general, the size of the uncracked ligament or the specimen thickness was inadequate for the unaged or short-term-aged specimens because of the relatively high toughness of the material. The $\mathrm{J}_{\text {max }}$ limit for the J -vs. $-\Delta$ a data was ignored in most tests to obtain a good power-law fit of the test data.

The shape of the crack front was also very irregular for most CASS materials. This may be attributed to the coarse grain structure of the casting and differences in ferrite morphology.

CASS materials with large columnar grains, in particular, showed significant variation in crack length along the width of a specimen. Furthermore, the crack front always had a leading crack near the edges of the specimen. The near-surface measurements of the final physical crack length were often $> \pm 1.02 \mathrm{~mm}$, the maximum value allowed for data qualification.

The fracture surfaces often showed uncracked ridges or ligaments along the direction of crack extension. The uncracked ligaments add significant error to the estimation of crack length by compliance. Therefore, the difference between the crack extension predicted from elastic compliance and the average measured physical crack extension is more than the maximum value allowed by ASTM E 1152.

All tests showed significant load relaxation during the unloading/reloading cycle for estimating crack length by elastic compliance. All unloadings were $25 \%$ of the load. The load at the end of the unloading/reloading cycle is always lower than it was at the start of the unloading cycle. The difference is appreciable for the room-temperature test. Therefore, the initial $20-30 \%$ of the unloading curve were ignored in estimating crack length.

## APPENDIX C: EXPERIMENTAL AND ESTIMATED CHARPY-IMPACT DATA FOR AGED CASS MATERIALS

The RT Charpy-impact energy of a specific heat of CASS materials as a function of aging time and temperature can be obtained from the estimated saturation RT Charpy-impact energy, $\mathrm{C}_{\text {Vsat }}$, and the kinetics of embrittlement. The value of $\mathrm{C}_{\text {Vsat }}$ is estimated from Eqs. 18-26 described in Section 2.4.1 of the report and the kinetics of embrittlement are estimated from Eqs. 11-17 described in Section 2.3 of the report. Information regarding the initial RT Charpyimpact energy of the unaged material and the aging time and temperature is needed for these estimations. The RT Charpy-impact energy for a specific time and temperature condition is estimated in three steps. First, the aging time and temperature are converted to an equivalent value of Parameter $P$. Next, the tanh function of the term $[(P-\theta) / \alpha]$ is determined; two sets of tanh function values are obtained, one using the experimental value of $\theta$ and the second with an assumed value of 2.9 for $\theta$. The $\mathrm{C}_{\mathrm{V}}$ for the specific time and temperature is then calculated from Eq. 13 from Section 2.3 of the report. A single value of $\theta$ is assumed in this report. However, the existing data suggests that $\theta$ varies with the material composition.

A comparison of the estimated and experimental values of RT Charpy-impact energy for several heats of CF-3, CF-8, and CF-8M CASS materials are shown in Figs. C1 and C2. These figures are an updated version of Figs. 19 and 20 of NUREG/CR-4513 Rev. 1. The solid and dash lines represent the estimated values using, respectively, the experimental value or assumed value of $\theta$.

The results indicate that the estimated values of RT $C_{V \text { sat }}$ are either accurate or slightly conservative for all grades and heats of CASS materials. The two exceptions are the static cast CF-3 Heat 47 and static cast CF-3M Heat FD. For these two heats, the estimated values are significantly higher than the experimental values. The reason for such a large difference for two heats out of more than 130 heats of materials is not known. The results also indicate that the estimates of the change in RT Charpy-impact energy for materials aged at low-temperature (i.e., $290-320^{\circ} \mathrm{C}$ ) are in good agreement with the experimental values for most materials and are conservative for a few. The only exception is static cast CF-8M Heat 75. The estimates for high temperature (i.e., $350-400^{\circ} \mathrm{C}$ ) aged materials show good agreement for most of the materials and are quite conservative for the rest. The exceptions are static cast CF-3 Heat 47 and the EPRI heat, centrifugally cast CF-8 Heat P1 and CF-8M heat P4, and the static cast CF-8M Heat FB. As discussed earlier, the agreement between the estimated and experimental values of RT Charpy-impact energy can be further improved by using a $\theta$ value that varies with the material composition and ferrite content, and activation energy for thermal embrittlement that varies with aging temperature.

Figure C1. RT Charpy-impact energy for 16 ANL heats and 1 EPRI heat, observed experimentally (solid lines) and estimated (dashed lines) from the composition and initial impact energy of the materials aged at $290-400^{\circ} \mathrm{C}$.

| 11. ABSTRACT (200 words or less) Cast austenitic stainless steel (CASS) materials are used extensively in reactor coolant pressure boundary systems as well as core support structure and reactor internals. However, they have a duplex structure consisting of austenite and ferrite phases and are susceptible to thermal aging embrittlement during reactor service. In addition, the prolonged exposure of these materials to neutron irradiation, changes their microstructure and microchemistry, which can degrade their fracture properties even further. This report is a revision of NUREG/CR-4513, Rev. 1, ANL-93/22 (August 1994); it revises the procedure and correlations used for predicting the change in fracture toughness and tensile properties of CASS components due to thermal aging during service in light water reactors at $280-330^{\circ} \mathrm{C}\left(535-625^{\circ} \mathrm{F}\right)$. The updated correlations are based on the current fracture toughness database for CASS materials aged up to $100,000 \mathrm{~h}$ at $290-350^{\circ} \mathrm{C}\left(554-633^{\circ} \mathrm{F}\right)$. The methodology for estimating fracture properties has been extended to cover CASS materials with a ferrite content of up to $40 \%$. The fracture toughness J-R curve, tensile stress, and Charpy-impact energy of aged CASS materials are estimated from material composition. The mechanical properties of a specific CASS material are estimated from the extent and kinetics of thermal embrittlement. Embrittlement is characterized in terms of room-temperature Charpy-impact energy. The extent or degree of thermal embrittlement at "saturation" (i.e., the minimum impact energy that can be achieved for a material after long-term aging) is determined from the chemical composition of the material. A common "predicted lower-bound" J$R$ curve for CASS materials of unknown chemical composition is also defined for a given grade of steel, range of ferrite content, and temperature. |  |

[^0]:    * When the impact energy is expressed in $\mathrm{J} / \mathrm{cm}^{2}$, first multiply by 0.8 to obtain the impact energy of an ASTM standard Charpy V-notch specimen in J.

[^1]:    *The British electricity industry from 1957 to 1990 when it was privatized.

[^2]:    * A higher temperature is used to include gamma-heating effect.

[^3]:    *The CF-3A and CF-8A grades represent materials with a high tensile strength. The chemical composition of these grades is further restricted within the composition limits of CF-3 and CF-8 in order to obtain a ferrite/austenite ratio that results in higher ultimate and yield strengths. In this report, they are considered equivalent to CF-3 and CF-8 grades.

[^4]:    *The first letter represents the direction perpendicular to the plane of the crack, and the second letter represents the direction of crack advance. For plates, $L=$ longitudinal or rolling direction and $T=$ transverse direction (i.e., perpendicular to the rolling direction but not across the plate thickness). For pipes, $\mathrm{L}=$ longitudinal or axial direction, and $\mathrm{C}=$ circumferential direction (across the wall).
